

CIVETTA, TAYLOR, & KIRBY'S MANUAL OF CRITICAL CARE

Andrea Gabrielli, MD, FCCM

Professor of Anesthesiology and Surgery
Division of Critical Care Medicine
Section Head, NeuroCritical Care
University of Florida College of Medicine
Medical Director, Cardiopulmonary Service
and Hyperbaric Medicine
Shands Hospital at the University of Florida
Gainesville, Florida

Mihae Yu, MD, FACS

Professor of Surgery
University of Hawaii John A. Burns School of Medicine
Vice Chair of Education
University of Hawaii Surgical Residency Program
Program Director of Surgical Critical Care Fellowship
Program
Director of Surgical Intensive Care
The Queen's Medical Center
Honolulu, Hawaii

A. Joseph Layon, MD, FACP

Director, Critical Care Medicine
Geisinger Health System
Danville, PA

Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of the information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in the publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

To purchase additional copies of this book, call our customer service department at (800) 638-3030 or fax orders to (301) 223-2320. International customers should call (301) 223-2300.

Visit Lippincott Williams & Wilkins on the Internet: at LWW.com. Lippincott Williams & Wilkins customer service representatives are available from 8:30 am to 6 pm, EST.

DEDICATION

To the memory of my father and mother, Pietro and Giuliana:
They would have been proud to see the results of my efforts
—*Andrea Gabrielli*

To my best friend and partner Susana E. Picado—who makes me better.
To those who, in service to our people, struggle for justice and peace;
Giuliana and Pietro were two.
—*A. Joseph Layon*

To my dad, General Jae Hung Yu, and the Seventh Division for their sacrifices and
changing history for the better.
To my Mom, the late Esang Yoon who was the wind beneath our wings.
To the late Dr. Thomas J. Whelan Jr. who continues to mentor me in the practice of
Surgery and Code of conduct.
To Joe and Judy Civetta who sparked my continuing love for Critical Care and being the
guiding light for all Peepsters.
And to my late daughter Pearl (and CD) who has the Master Key to All...
—*Mihae Yu*

■ CONTRIBUTING AUTHORS

The authors would like to gratefully acknowledge the efforts of the contributors of the original chapters in *Civetta, Taylor, and Kirby's Critical Care*, Fourth Edition.

■ PREFACE

In the Preface to the Fourth Edition of the textbook, we quote Nikos Kazantzakis' *Report to Greco*. Did our attempt succeed? Early reports suggest yes.

However much we have succeeded, the foundation for this was laid by Doctors Civetta, Taylor and Kirby—our teachers and mentors. We truly stand on the shoulders of giants.

We hope you—our readers—will provide us feedback on the quality of this handbook, as you have the textbook. Our desire with the *Manual* was to distill the full textbook into a short, pithy and readable contribution. We are pretty sure the “short” part did not work too well; let us know if we have, however, created something useful for you.

As we noted in the Preface to the textbook, the mistakes of omission or commission found herein are ours and ours alone.

We three editors share a friendship, have given each other guidance and moral support, and will share any failures and successes of our travail.

■ ACKNOWLEDGMENTS

We thank our colleagues at Lippincott—Nicole Dernoski, Tom Gibbons, and Brian Brown—for their assistance. Indu Jawwad from Aptara did superb work.

Our families are part of this handbook, to them, we bow in thanks and respect.

■ CONTENTS

<i>Contributing Authors</i>	<i>v</i>
<i>Preface</i>	<i>xi</i>
<i>Acknowledgments</i>	<i>xiii</i>

SECTION I ■ EMERGENCY SITUATIONS

CHAPTER 1	Fundamentals of Cardiopulmonary Resuscitation	1
CHAPTER 2	Airway Management	9
CHAPTER 3	Temporary Cardiac Pacemakers	21
CHAPTER 4	Altered Consciousness and Coma in the Intensive Care Unit	27
CHAPTER 5	Bioterrorism	33

SECTION II ■ CARDIOVASCULAR MONITORING: INVASIVE AND NONINVASIVE

CHAPTER 6	Invasive Pressure Monitoring: General Principles	48
CHAPTER 7	Hemodynamic Monitoring: Arterial and Pulmonary Artery Catheters	50
CHAPTER 8	Noninvasive Cardiovascular Monitoring	60
CHAPTER 9	Pulse Oximetry and Photoplethysmography	61
CHAPTER 10	Capnography	63
CHAPTER 11	Echocardiography in the ICU	64

SECTION III ■ TECHNIQUES, PROCEDURES, AND TREATMENT

CHAPTER 12	Clean and Aseptic Techniques at the Bedside	65
CHAPTER 13	Vascular Cannulation	66
CHAPTER 14	Feeding Tube Placement	74
CHAPTER 15	Flexible Bronchoscopy	76
CHAPTER 16	Other Important Intensive Care Procedures	83

SECTION IV ■ ESSENTIAL PHYSIOLOGIC CONCERNS**CHAPTER 17** Fluids and Electrolytes 93**CHAPTER 18** Blood Gas Analysis and Acid-Base Disorders 103**SECTION V ■ MODULATING THE RESPONSE TO INJURY****CHAPTER 19** The Host Response to Injury and Critical Illness 114**CHAPTER 20** Multiple Organ Dysfunction Syndrome 117**SECTION VI ■ SHOCK STATES****CHAPTER 21** Shock: General 124**CHAPTER 22** Cardiogenic Shock 125**CHAPTER 23** Sepsis and Septic Shock 129**CHAPTER 24** Hypovolemic and Hemorrhagic Shock 136**CHAPTER 25** Neurogenic Shock 141**CHAPTER 26** Anaphylactic Shock 143**SECTION VII ■ PHARMACOLOGY, NUTRITION, TOXICOLOGY,
AND THE ENVIRONMENT****CHAPTER 27** Sedation and Neuromuscular Blockade 144**CHAPTER 28** Nutritional Issues 151**CHAPTER 29** Practical Aspects of Nutritional Support 154**CHAPTER 30** Toxicology 162**CHAPTER 31** Substance Abuse and Withdrawal: Alcohol, Cocaine,
Opioids, and Other Drugs 185**CHAPTER 32** Envenomation 196**SECTION VIII ■ THE SURGICAL PATIENT: PREOPERATIVE, IMMEDIATE
POSTOPERATIVE EVALUATION AND TRAUMA****CHAPTER 33** Perioperative Pulmonary Function Testing and
Consultation 211**CHAPTER 34** Preoperative Evaluation of the High-Risk Surgical Patient 215**CHAPTER 35** Anesthesia: Physiology and Postanesthesia Problems 227**CHAPTER 36** Initial Management of the Trauma Patient 236**CHAPTER 37** Secondary and Tertiary Triage of the Trauma Patient 239

CHAPTER 38	Surgical and Postsurgical Bleeding	246
CHAPTER 39	Abdominal Trauma: Nonoperative Management and Postoperative Considerations	251
CHAPTER 40	Neurologic Injury: Prevention and Initial Care	255
CHAPTER 41	Orthopedic Trauma	262
CHAPTER 42	Facial Trauma	264
CHAPTER 43	Burn Injury: Thermal and Electrical	268
CHAPTER 44	Temperature-Related Injuries	272
CHAPTER 45	Evaluating the Acute Abdomen	279
CHAPTER 46	The Difficult Postoperative Abdomen	285
CHAPTER 47	Critical Care of Hepatopancreatobiliary Surgery Patients	292
CHAPTER 48	Critical Care of The Thoracic Surgical Patient	300
CHAPTER 49	Postoperative Management of the Adult Cardiovascular Patient	308
CHAPTER 50	Management of the Pediatric Cardiac Surgical Patient	317
CHAPTER 51	Vascular Surgery in the Intensive Care Unit	329
CHAPTER 52	CNS Vascular Disease	334
CHAPTER 53	Urologic Surgery and Trauma	343
SECTION IX ■ ORGAN TRANSPLANTATION		
CHAPTER 54	Critical Care and Transplantation: Overview	351
CHAPTER 55	Heart Transplantation	353
CHAPTER 56	Lung Transplantation	358
CHAPTER 57	Liver Transplantation	363
CHAPTER 58	Pancreatic Transplantation	368
CHAPTER 59	Renal Transplantation	371
CHAPTER 60	Critical Care Aspects of Stem Cell Transplantation	377
SECTION X ■ SPECIAL PATIENT POPULATION		
CHAPTER 61	The Obstetric Patient: General	383
CHAPTER 62	Cardiac Disease and Hypertensive Disorders in Pregnancy	389

CHAPTER 63	Hemorrhagic and Liver Disorders of Pregnancy	400
CHAPTER 64	Acute Abdomen and Trauma During Pregnancy	404
CHAPTER 65	Fetal Monitoring Concerns	411
CHAPTER 66	The Obese Surgical Patient	416
CHAPTER 67	The Geriatric Patient	426
SECTION XI ■ INFECTIOUS DISEASE		
CHAPTER 68	Universal Precautions: Protecting The Practitioner	436
CHAPTER 69	An Approach to the Febrile Intensive Care Unit Patient	444
CHAPTER 70	The Role of Antibiotics in the Management of Serious Hospital-Acquired Infections	453
CHAPTER 71	Surgical Infections	465
CHAPTER 72	Skin Wounds and Musculoskeletal Infection	482
CHAPTER 73	Neurologic Infections	490
CHAPTER 74	Infections of the Head and Neck	511
CHAPTER 75	Catheter-Related Bloodstream Infections (CRBSI)	520
CHAPTER 76	Respiratory Infections in the ICU	526
CHAPTER 77	Adult Gastrointestinal Infections in the ICU	545
CHAPTER 78	Catheter-Associated Urinary Tract Infections in the ICU: Implications for Clinical Practice	551
CHAPTER 79	Fungal and Viral Infections	560
CHAPTER 80	Infections in the Immunocompromised Host	582
CHAPTER 81	Human Immunodeficiency Virus in the ICU	592
CHAPTER 82	Unusual Infections	604
SECTION XII ■ CARDIOVASCULAR DISEASE AND DYSFUNCTION (OTHER CV DISEASE): ACS IN THE ICU		
CHAPTER 83	Non-ST Elevation Acute Coronary Syndrome: Contemporary Management Strategies	615
CHAPTER 84	ST Elevation Myocardial Infarction (STEMI): Contemporary Management Strategies	624
CHAPTER 85	Evaluation and Management of Heart Failure	638

SECTION I ■ EMERGENCY SITUATIONS

CHAPTER 1 ■ FUNDAMENTALS OF CARDIOPULMONARY RESUSCITATION

MAJOR PROBLEMS

- Cardiopulmonary resuscitation (CPR) is a series of assessments and interventions performed during a variety of acute medical and surgical events wherein death is likely without immediate intervention.
- Sudden cardiac arrest (SCA) is a leading cause of adult death in the United States and Canada.
 - Cardiac arrest (CA) is defined as “cessation of cardiac mechanical activity as confirmed by the absence of signs of circulation.”
 - In the prehospital arena, CA is most commonly due to ventricular fibrillation (VF) secondary to ischemic heart disease.
 - Asystole and pulseless electrical activity (PEA) are less common initial rhythms with SCA, although these rhythms may represent the initial identified rhythm in adults who actually experienced an acute VF or ventricular tachycardia (VT) event.
 - Although VF and VT are considered to be the most common out-of-hospital (OOH) arrest rhythms, only 20% to 38% of in-hospital arrest patients have VF or VT as their initial rhythm.
 - Children and young adults require CPR most commonly for respiratory arrest, airway obstruction, or drug toxicity.
 - VF/VT is identified as the initial rhythm in 5% to 15% of OOH arrests in children.
 - Other conditions such as trauma, external or internal hemorrhage, and drowning may call for resuscitation at any age.
- Immediate and effective CPR can save lives.
 - With witnessed VF CA, CPR doubles or triples the rate of survival.
 - Only about 27% of OOH arrest victims receive bystander CPR.
- The primary goal of CPR is to generate sufficient oxygen delivery to the coronary and cerebral circulations to maintain cellular viability while attempting to restore a perfusing cardiac rhythm by defibrillation, pharmacologic intervention, or both.

IMMEDIATE CONCERNS

- Immediately assess the environment for danger and move the patient if necessary. Never assume that an environment is safe.
- Minimize the time from CA recognition to starting effective CPR.
 - For every minute without CPR during witnessed VF CA, survival decreases by 7% to 10%.
 - This is cut in half (3%–4% per minute) when bystander CPR preceded attempted defibrillation.
 - Defibrillate immediately if a defibrillator is rapidly available (less than 3–5 min) in patients with VF.
 - This is the primary treatment focus within the first few minutes of SCA due to VF.
 - For each minute delay in defibrillation, chances of eventual hospital discharge decreased by 8% to 10%.
 - If the time from arrest to emergency medical service (EMS) arrival and initiation of CPR is more than 5 minutes, provision of 2 minutes of CPR before defibrillation is associated with improved outcome.
- “Push hard and fast” during chest compressions and minimize the duration of interruptions to reassess the patient’s rhythm.
 - Interrupt chest compressions only briefly, about every 2 minutes, to assess the rhythm, and switch rescuer if feasible.
- While CPR is in progress, attempt to identify the cause of arrest.
 - Other resuscitation interventions may be indicated based on the cause of CA.
 - If no response to standard CPR interventions, think about delayed recognition and recall the H’s and T’s (Table 1.1).
 - Good teamwork increases the effectiveness of resuscitation when more than one rescuer is available.
- Attention to postresuscitation care is an important element of neurologic outcome.
 - Restore and support adequate cardiac output and tissue perfusion.
 - Monitor and maintain normal blood glucose concentrations.
 - Treat the underlying cause of the arrest.
 - Maintain normothermia.
 - Consider therapeutic hypothermia to maximize survival and cerebral recovery.
- If there is no response to effective CPR, appropriate judgment is needed in determining when to stop resuscitative efforts.

TABLE 1.1**POTENTIAL CORRECTABLE PROBLEMS DURING CARDIAC ARREST: “6 H’S AND 5 T’S”**

Hypovolemia
 Hypoxia
 Hydrogen ion (acidosis)
 Hypo-/hyperkalemia
 Hypoglycemia
 Hypothermia
 Toxins
 Tamponade, cardiac
 Tension pneumothorax
 Thrombosis, coronary or pulmonary
 Trauma

Adapted from 2005 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation*. 2005;112[24]:IV-1–IV-211.

OUT-OF-HOSPITAL CARDIAC ARREST

- Despite improvement in the scientific basis for resuscitation practices and extensive efforts at CPR training of lay and professional rescuers
 - Outcome of most adult victims of out-of-hospital cardiac arrest (OOHCA) remains poor.
 - Median reported survival to hospital discharge is 6.4%.
 - Adults who had a witnessed CA were more likely to arrive to the hospital alive (39% vs. 31%, $p = 0.049$) and were more likely to have a good neurologic outcome after 6 months (35% vs. 25%, $p = 0.023$) as compared with patients who had a CA in a nonpublic location.
- In children, epidemiology and physiology of OOHCA are different.
 - Recent systematic review of 41 OOHCA studies, including trauma, revealed a restoration of spontaneous circulation (ROSC) of 30%, with survival to admission of 24% but survival to discharge of 12% and neurologically intact survival of only 4%.
 - Initial cardiac rhythms observed in these children were as follows:
 - Asystole, 78%
 - PEA, 12.8%
 - VF/pulseless VT, 8.1%
 - Bradycardia with a pulse, 1%

IN-HOSPITAL CARDIAC ARREST

- Objective survival rates over the years have hardly changed.
 - Current adult in-hospital cardiac arrest (IHCA) has overall survival of about 18%.
 - Analysis of data from the national CPR registry found
 - Prevalence of VF or pulseless VT as the first documented pulseless rhythm during IHCA was only 23% in adults and 14% in children.
 - Prevalence of asystole as the initial rhythm was 35% in adults and 40% in children.
 - Prevalence of PEA was 32% versus 24% in adults and children, respectively.
- Survival rate to hospital discharge after pulseless CA

- Higher in children than adults (27% vs. 18%, respectively)
- Of these survivors, 65% of children and 73% of adults had good neurologic outcome.
- After adjusting for known predictors, such as arrest location and monitoring at time of arrest, outcome was surprisingly worse when the rhythm was VF/VT in children compared with asystole and PEA.
 - Further analysis of these data showed that VF/VT occurred during CPR in children more commonly than it occurred as the initial rhythm.
 - Survival to discharge is highest (35%) when VF/VT is the initial rhythm compared with survival of 11% if this rhythm develops during resuscitation.

NEUROLOGIC OUTCOME

- Determined by the following:
 - The cause of arrest (e.g., degree of shock or hypoxemia prior to arrest)
 - The duration of no flow, adequacy of flow during CPR
 - Restoration of adequate flow after ROSC
 - Subsequent injury secondary to postarrest management such as the occurrence of hyperthermia or hypoglycemia
- Survivors who ultimately have a good outcome
 - Generally awaken within 3 days after CA
 - Most patients who remain neurologically unresponsive due to anoxic-ischemic encephalopathy for more than 7 days will fail to survive.
 - Those who do survive often have poor neurologic recovery.
 - Neurocognitive impairment ranges from dependency on others for care to remaining in a minimally conscious or vegetative state.
- Achieving good functional outcome is the ultimate goal for successful CPR.
 - The financial implications of caring for patients with disordered consciousness are substantial.
 - Most studies reporting outcome data have used crude methods to describe neurologic outcome, such as the composite scores from the Glasgow Outcome Scale and Cerebral Performance Category.
 - An important limitation of these scales is the possibility of wide variation of neurologic function for the same score.
 - In children, the Pediatric Cerebral Performance Category and Pediatric Overall Performance Category have been used.
- 11% to 48% of CA patients admitted to the hospital will be discharged with good neurologic outcome.
 - Recent data from the National Registry for Cardiopulmonary Resuscitation (NRCPR) show that neurologic outcome in discharged adult survivors is generally good, with 73% of patients with Cerebral Performance Category 1.

INITIAL CONSIDERATIONS

- CPR is primarily based on two principles.
 - Providing artificial ventilation and oxygenation through an unobstructed airway
 - Cardiac output is limited; avoid ventilation in excess of that required for adequate ventilation/perfusion matching.

- Delivering chest compressions to maintain threshold blood flow
 - Especially to the heart and brain, while minimizing interruption of compressions

Basic Life Support

- Basic life support (BLS) is the initial “ABCs” phase of CPR.
 - A: airway
 - B: breathing
 - C: circulation
- Effective BLS can provide almost 30% of normal cardiac output with adequate arterial oxygen content.
 - Sufficient to protect the brain for minutes until effective defibrillation or other definitive therapeutic maneuvers are provided Table 1.2.

Advanced Life Support

- Advanced life support (ALS) entails the following:
 - Advanced airway management including use of ancillary equipment to support ventilation and oxygenation

- Prompt recognition and, when appropriate, treatment of life-threatening arrhythmias using electrical therapy including defibrillation, cardioversion, pacemaker insertion, and pharmacologic therapy
- Inclusion of the use of pharmacologic therapy and advanced procedures extending into the postarrest setting such as the use of therapeutic hypothermia

Advanced Airway Management

- Tracheal intubation
 - Endotracheal intubation (ETI) is indicated if unable to adequately ventilate or oxygenate the arrested or unconscious patient with bag-mask ventilation or if prolonged ventilation is required and airway protective reflexes are absent in the patient with a perfusing rhythm
 - A properly placed endotracheal tube (ET) is the gold standard method for securing the airway.
 - Attempted ETI by less skilled rescuers results in a 6% to 14% incidence of misplaced or displaced ETs.
- Confirmation of correct ET placement
 - Clinical signs used to confirm correct ET placement
 - Visualization of bilateral chest rise

TABLE 1.2

SUMMARY OF BASIC LIFE SUPPORT ABCD MANEUVERS FOR INFANTS, CHILDREN, AND ADULTS FOR LAY RESCUERS AND HEALTH CARE PROVIDERS (NEWBORN INFORMATION NOT INCLUDED)

Maneuver	Adult lay rescuer: ≥ 8 y HCPs: Adolescent and older	Child lay rescuers: 1–8 y HCPs: 1 y to adolescent	Infant ≤ 1 y of age
Airway	Head tilt–chin lift (HCPs: Suspected trauma, use jaw thrust)		
Breathing: Initial	Two breaths at 1 sec/breath	Two breaths at 1 sec/breath	
HCPs: Rescue breathing without chest compressions	10–12 breaths/min (approximate)	12–20 breaths/min (approximate)	
HCPs: Rescue breaths for CPR with advanced airway	8–10 breaths/min (approximately)		
Foreign-body airway obstruction	Abdominal thrusts	Back slaps and chest thrust	
Circulation	Carotid	Brachial or femoral	
HCPs: Pulse check (≤ 10 s)			
Compression landmarks	Lower half of sternum, between nipples	Just below nipple line (lower half of sternum)	
Compression method	Heel of one hand, other hand on top	Heel of one hand or as for adults	Two or three fingers HCPs (two rescuers): Two thumb– encircling hands
• Push hard and fast			
• Allow complete recoil			
Compression depth	1½–2 inches	Approximately one-third to one-half the depth of the chest	
Compression rate	Approximately 100/min		
Compression:ventilation ratio	30:2 (one or two rescuers)	30:2 (single rescuer) HCPs: 15:2 (two rescuers)	
Defibrillation AED	Use adult pads Do not use child pads	Use AED after five cycles of CPR (out of hospital) Use pediatric system for child 1–8 y if available HCPs: For sudden collapse (out of hospital) or in-hospital arrest use AED as soon as available	No recommendation for infants <1 y of age

AED, automated external defibrillator; CPR, cardiopulmonary resuscitation.

Note: Maneuvers used by only health care providers are indicated by HCPs. AED, automated external defibrillator; CPR, cardiopulmonary resuscitation. Adapted from 2005 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation*. 2005;112[24]:SIV-1–IV-211.

- Bilateral breath sounds over the lateral lung fields
- Absent breath sounds over the epigastrium
- Presence of water vapor/mist in the tube
- None of these signs is confirmatory, and an ETCO_2 detector or esophageal detector is indicated to confirm correct tube placement.
 - *ETCO₂ detector device* is a disposable colorimetric device that detects ETCO_2 has been investigated as a guide to correct ET placement.
 - The device fits on the end of the ET and is normally purple; exhaled CO_2 turns the color to bright yellow, indicating that the ET is in the trachea.
 - The positive predictive value of this device for correct tube placement is close to 100%, but the negative predictive value ranges from 20% to 100% depending on whether the patient has a perfusing rhythm.
 - False-negative results are seen if there is no or very low pulmonary blood flow, such as during CA or with a large pulmonary embolus.
 - False-positive (i.e., the detector remains yellow) results are seen when it is contaminated with an acidic drug (e.g., epinephrine) or gastric contents.
 - *Esophageal detector device* comes in two versions: the bulb and the syringe esophageal detector devices (EDD).
 - Bulb EDD consists of a bulb that is compressed and attached to the ET. When released, if the tube is in the esophagus, the suction collapses the lumen of the esophagus or pulls the esophageal tissue against the tip of the tube, and the bulb will not re-expand (positive result for esophageal placement).
 - Syringe EDD consists of a syringe attached to the ET; the rescuer attempts to pull the plunger of the syringe. If the tube is in the esophagus, it will not be possible to pull out the plunger (i.e., aspirate air) with the syringe.
 - This device has high sensitivity for esophageal placement of ETs in both CA and patients with a perfusing rhythm but poor specificity for tracheal placement.

Electrical Therapy

- One of the mainstays of ALS, especially in adults
- Electrical energy is used to treat life-threatening cardiac dysrhythmias.
 - Constitute 16% to 85% of OOH and 14% to 56% of in-hospital CAs
 - Recent data suggest that VF and VT are decreasing, with only 24% of the initial rhythms in more than 36,000 adult arrests being VF- or VT-based in a recent analysis from the NRCPR.
 - In hospitalized children with CA, VF is the initial rhythm in approximately 10% of cases and subsequently occurs during 15% of the cases.
- Defibrillation
 - Defined as delivery of electrical energy resulting in termination of VF for at least 5 seconds after the shock
 - The goal is to quickly depolarize the entire myocardium, terminating the rhythm and hoping that a sinus rhythm will start.
 - *Defibrillator device*
 - Manual defibrillator devices require the rescuer to analyze the rhythm and then manually set and determine the electrical energy dose.
 - Automatic defibrillator devices analyze the rhythm, determine whether a shock is required, and deliver the shock if needed automatically.
 - Two types of automatic defibrillators: internal implantable cardioverter defibrillator and automated external defibrillator (AED)
 - Defibrillators are also characterized by the mode and waveform of electrical current delivered into monophasic and biphasic defibrillators.
 - Animal and human data show that biphasic defibrillators have a higher first-shock success in terminating VF compared with monophasic devices.
 - *Defibrillation dose*
 - Optimal initial energy dose for the first shock \ required for effective defibrillation remains unknown despite multiple studies.
 - Reasonable to use selected energies of 150 J to 200 J with a biphasic truncated exponential waveform or 120 J with a rectilinear biphasic waveform for the initial shock
 - For second and subsequent biphasic shocks, the same or higher energy can be given.
 - Most manual defibrillators are set to an initial default of 200 J of energy.
 - If only a monophasic defibrillator is available, an energy dose of 360 J is recommended for all shocks.
 - The optimal dose for effective defibrillation in infants and children
 - Not known
 - Upper limit for safe defibrillation also not known
 - Doses more than 4 J/kg (as high as 9 J/kg) have effectively defibrillated children.
 - Recommended manual defibrillation (monophasic or biphasic) doses for children are 2 J/kg for the first attempt and 4 J/kg for subsequent attempts.
 - *Electrode position*
 - Either handheld paddles or self-adhesive pads are used for shocks.
 - Electrodes are applied to the bare chest in the conventional sternal-apical (anterolateral) position.
 - The right (sternal) chest pad is placed on the victim's right superior-anterior (infraclavicular) chest, and the apical (left) pad is placed on the victim's inferior-lateral left chest, lateral to the left breast.
 - *Electrode size*
 - The largest pad or paddle that can be placed on the chest while avoiding contact between the pads or paddles should be used. There should be at least 1 inch between the pads.
 - Paddles that are too small increase the risk of skin burn injury.
- Electrical cardioversion
 - Used for some life-threatening arrhythmias causing rapid cardiovascular deterioration
 - Including VT and supraventricular tachycardias (SVTs) such as paroxysmal atrial tachycardia, atrial flutter, or atrial fibrillation with a rapid ventricular response
 - The technique, unlike defibrillation, must be synchronized with the patient's electrocardiogram.
 - Delivery of the energy during the T wave of the QRS may result in VF.
 - *Energy level*
 - The amount of energy recommended for emergency cardioversion varies with the rhythm.

- 100 J is recommended for atrial fibrillation and 50 J for atrial flutter.
- Monomorphic VT responds well to cardioversion, and 100 J should be attempted first.
- Pulseless VT behaves like VF, and 200 J should be used initially.
- In conscious patients, sedation with intravenous diazepam, midazolam, or methohexital is indicated, and the cardioversion is accomplished with the lowest energy possible (50–200 J).
- In children, the recommended initial cardioversion dose is 0.5 to 1 J/kg.
- External cardiac pacing
 - External (transcutaneous) pacing is not recommended for patients in asystolic CA, but it should be always considered in the ICU or other critical care areas of the hospital where the device and adequate skill are promptly available.
 - Pacing can be considered in patients with symptomatic bradycardia when a pulse is present.

Pharmacologic Therapy

- Used in CA to increase the rate of ROSC and terminate or limit the risk of recurrent arrhythmias
- Route of administration for resuscitation medications
 - A central venous line may not be available at the time of the arrest and immediate placement is not necessary to ensure survival.
 - Peripheral IV access can be used effectively with the advantage of not interrupting CPR.
 - Rapidly follow the medication bolus with a 10- to 20-mL fluid bolus to ensure central delivery.
 - Intraosseous cannulation is an effective alternate for drug delivery.
 - Instillation can be made through an ET, if available. Lipid-soluble medications that can be delivered via ET are lidocaine, epinephrine, atropine, naloxone, and vasopressin.
 - Recommended to administer at least 2 to 2½ times the IV recommended doses.
- *Epinephrine*
 - The most commonly used medication during CPR
 - Primary action in CA is to increase the coronary perfusion pressure through systemic vasoconstriction mediated by its α -adrenergic effects. The β -adrenergic effects are relatively unimportant.
 - Epinephrine is used primarily during CA due to asystole and PEA.
 - A second-line agent used for shock-refractory VF or pulseless VT
 - Little pharmacologic data supporting the currently recommended dose of 1 mg of epinephrine in adult CA and 0.01 mg/kg in children
- *Vasopressin*
 - An endogenous antidiuretic hormone that, when given at high doses, causes vasoconstriction by directly stimulating vascular smooth-muscle V1 receptors.
 - Improves coronary perfusion pressure but, unlike epinephrine, offers theoretical advantages of cerebral vasodilation, possibly improving cerebral perfusion.
 - Lack of β_1 -adrenergic activity potentially avoids unnecessary increases of myocardial oxygen consumption, resulting in postresuscitation arrhythmias.
- Half-life of 10 to 20 minutes compared to the 3 to 5 minutes observed with epinephrine
- *Sodium bicarbonate*
 - Metabolic and respiratory acidosis develops during CA resulting from anaerobic metabolism, leading to lactic acid generation and inadequate ventilation along with reduced blood flow during CPR, which leads to inadequate pulmonary delivery of carbon dioxide for elimination.
 - Untreated acidosis suppresses spontaneous cardiac activity, decreases the electrical threshold required for the onset of VF, decreases ventricular contractile force, and decreases cardiac responsiveness to catecholamine such as epinephrine.
 - Elevated PCO₂ tension probably is more detrimental to myocardial function and catecholamine responsiveness than metabolic acidosis.
 - If arterial blood gas and pH measurements not available:
 - Recommended initial dose of sodium bicarbonate is 1 mEq/kg intravenously.
 - Half of this dose may be repeated at 10-minute intervals.
 - In pediatric patients, the 1 mEq/kg dose should be diluted 1:1 with sterile water to reduce the osmolality.
- *Atropine*
 - Used in sinus bradycardia when accompanied by hypotension or frequent premature ventricular contractions (PVCs) secondary to unsuppressed ectopic electrical activity arising in the area of injured tissue during the prolonged period after repolarization
 - Sinus bradycardia after myocardial infarction may predispose the heart to the onset of VF.
 - When profound bradycardia is present, acceleration of the heart rate above 60 bpm may improve cardiac output and reduce the incidence of VF.
 - Dosage of atropine for severe symptomatic bradycardia is 0.5 to 1.0 mg intravenously repeated every 3 to 5 minutes until the desired pulse rate is obtained or a maximum of 0.04 mg/kg has been given.
 - A larger dose has little therapeutic value, and a smaller dose may actually slow the heart rate.
 - Endotracheal dose is 2 to 2.5 mg.
- *Lidocaine*
 - Decreases ectopic electrical myocardial activity by raising the electrical stimulation threshold of the ventricle during diastole
 - In ischemic myocardial tissue after infarction, it may suppress re-entrant arrhythmias such as VT or VF.
 - The 2005 guidelines recommend lidocaine only when amiodarone is not available.
 - Lidocaine may be used in stable monomorphic VT and polymorphic VT with normal or prolonged QT interval if ventricular function is not decreased.
 - Loading dose of lidocaine is approximately 1 to 1.5 mg/kg given as an IV bolus.
 - If needed, repeat 0.5 to 0.75 mg/kg every 5 to 10 minutes, up to a total of 3 mg/kg.
 - Followed by a continuous infusion of 30 to 50 μ g/kg/minute (1–4 mg/min in a 70-kg patient)
 - Toxicity may occur in oliguric or anuric patients because renally excreted lidocaine degradation products also have pharmacologic effects and toxic potential.
 - Early signs of lidocaine toxicity are due to central nervous system effects and include anxiety, loquacity, tremors, metallic taste, and tinnitus.

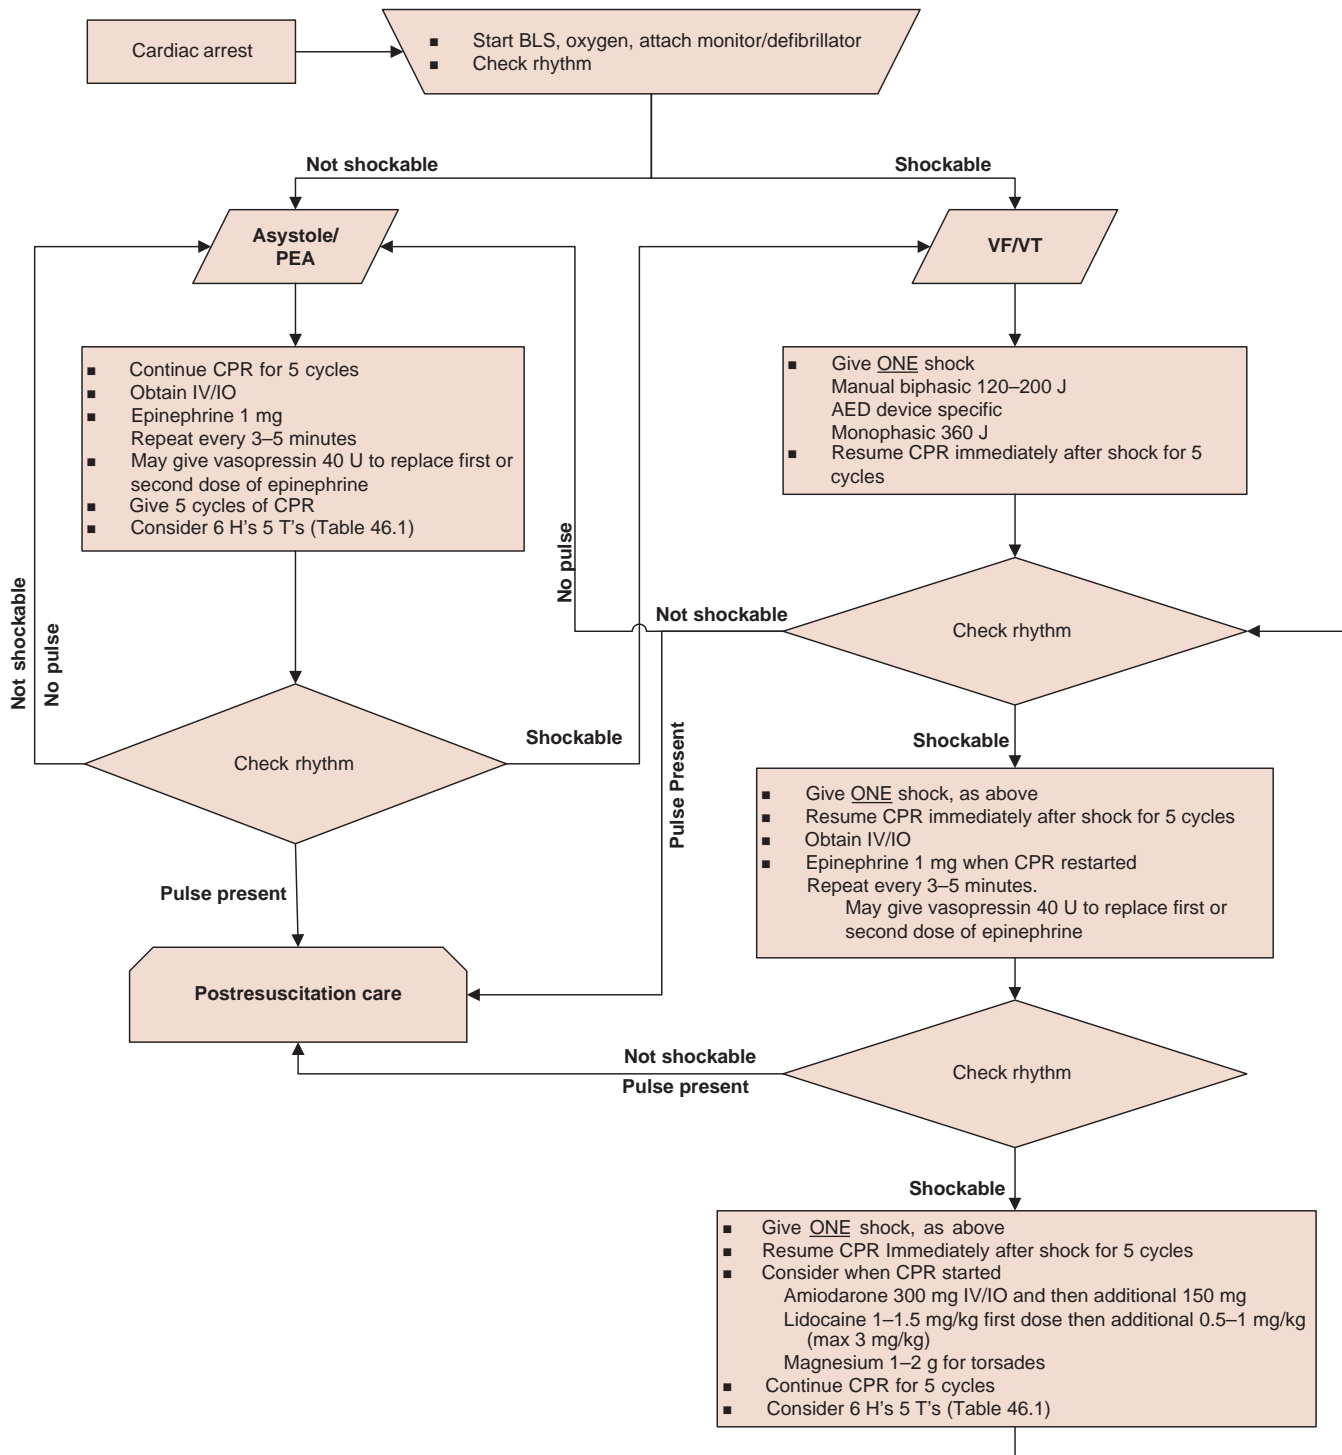

FIGURE 1.1. Suggested treatment algorithm for pulseless cardiac arrest. It is important that resuscitation drugs should be given during the cardiopulmonary resuscitation (CPR) cycles to minimize “no CPR” time. BLS, basic life support; PEA, pulseless electrical activity; VF, ventricular fibrillation; VT, ventricular tachycardia; AED, automated external defibrillator; IO, intraosseous. (Adapted and modified from 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation*. 2010;122:S729–S767).

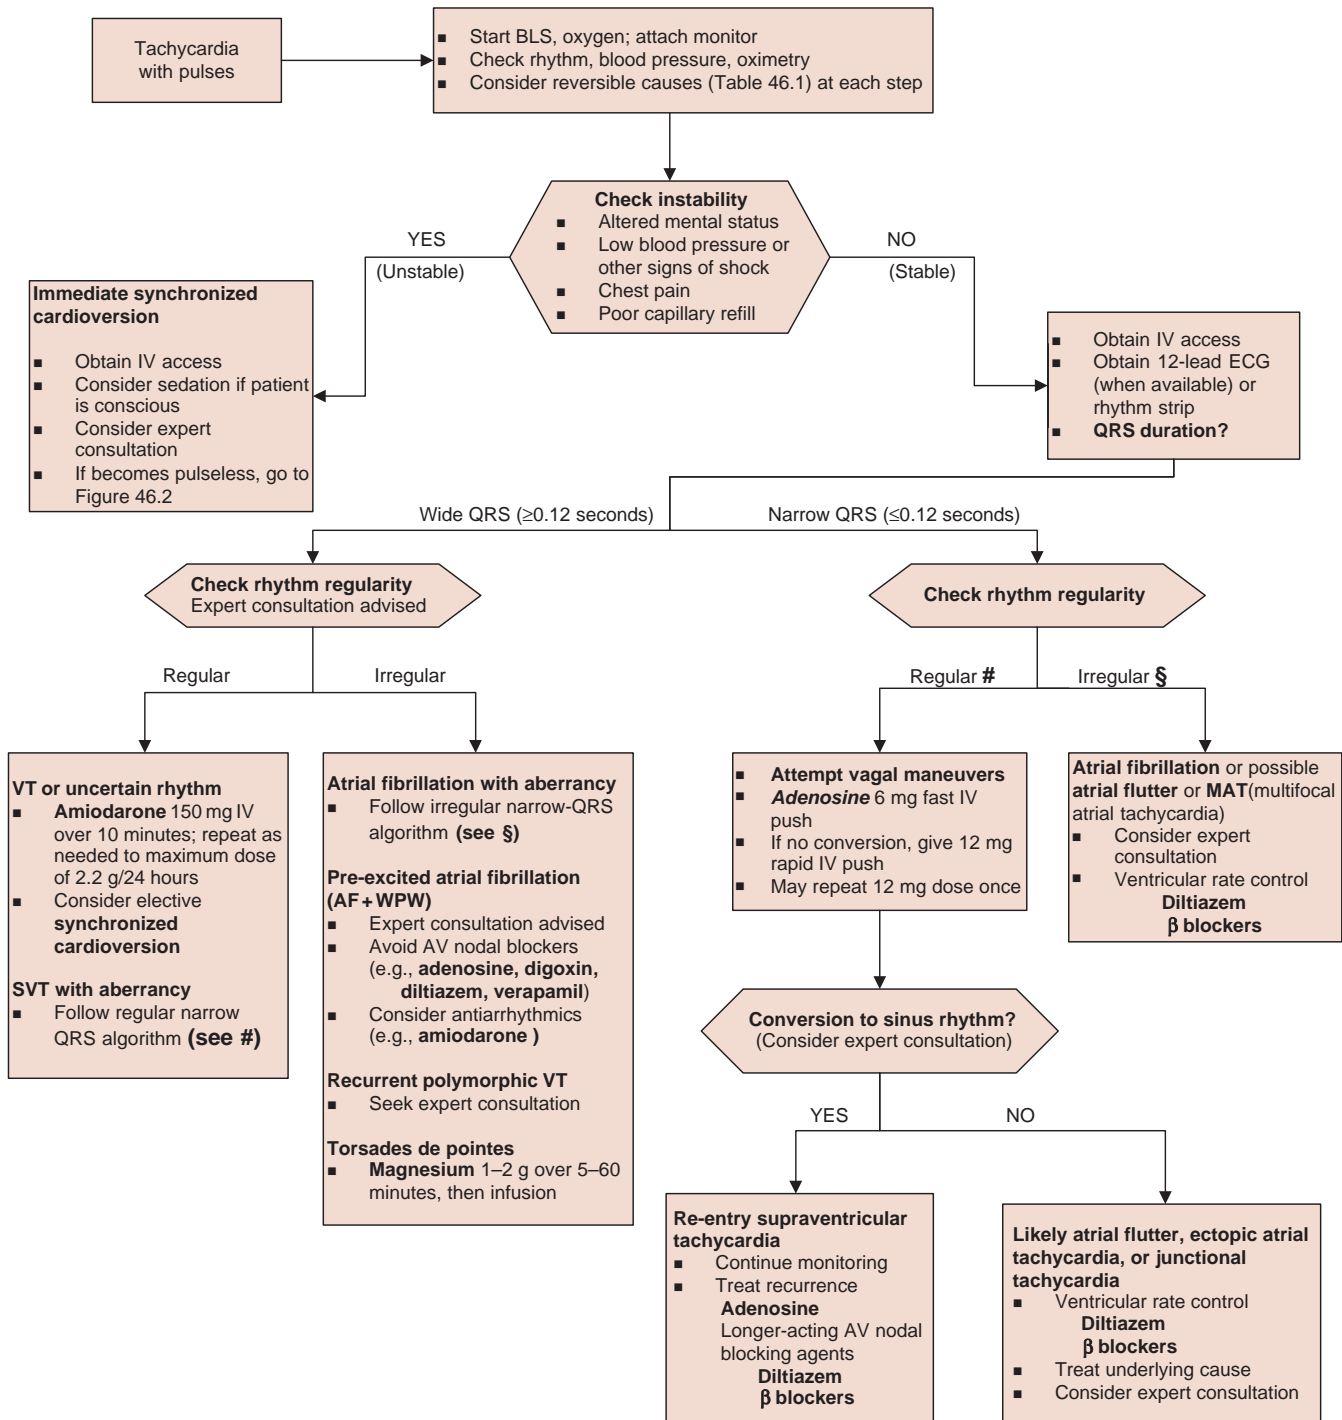

FIGURE 1.2. Suggested treatment algorithm for tachycardia with pulse. BLS, basic life support; ECG, electrocardiogram; VT, ventricular tachycardia; SVT, supraventricular tachycardia; WPW, Wolff-Parkinson-White syndrome. (Adapted and modified from 2005 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation*. 2005;112[24]SIV-1–IV-211.

- May be followed by somnolence, respiratory depression, apnea and, in severe cases, cardiovascular collapse.
- **Procainamide**
- Suppresses both atrial and ventricular arrhythmias with mechanisms of action similar to those of lidocaine

- Is used in the management of PVCs, VT, and persistent VF, but amiodarone is usually preferred
- Incremental bolus injections are slowly infused at 20 mg/minute until
 - The arrhythmia is controlled.

- Hypotension occurs.
- The QRS complex is widened 50% from baseline.
- A total dose of 17 mg/kg (1.2 g in a 70-kg adult) is given, followed by a continuous infusion of 1 to 4 mg/minute to prevent recurrent arrhythmias.
 - Therapeutic plasma level of 4 to 8 $\mu\text{g/mL}$.
- **Amiodarone**
 - A complex drug with effects on sodium, potassium, and calcium channels on myocardial cells and α - and β -adrenergic blocking properties
 - The 2005 guidelines denote it the preferred agent for both atrial and ventricular arrhythmias, especially in the presence of impaired cardiac function.
 - Amiodarone is recommended for narrow-complex tachycardias that originate from a re-entry mechanism (re-entry SVT); ectopic atrial focus; control of hemodynamically stable VT, polymorphic VT with a normal QT interval, or wide-complex tachycardia of uncertain origin, and control of rapid ventricular rate due to accessory pathway conduction in pre-excited atrial arrhythmias with AV nodal blockade in patients with preserved or impaired ventricular function
 - In treatment of arrhythmias with a pulse, 150 mg amiodarone is given IV over 10 minutes, followed by a 1 mg/minute infusion for 6 hours and then a 0.5 mg/minute maintenance infusion over 18 hours.
 - Supplementary infusions of 150 mg can be repeated every 10 minutes as necessary for recurrent or resistant arrhythmias to a maximum manufacturer-recommended total daily IV dose of 2.2 g.
 - When used in the treatment of VF or pulseless VT, a bolus dose of 300 mg is recommended diluted in 20 to 30 mL of D5W.
 - A single second dose may be given (150 mg) in 3 to 5 minutes for shock-refractory VF or VT.
 - In children, 5 mg/kg is given as a rapid bolus and may be repeated up to 15 mg/kg.
 - Major adverse effects of amiodarone are hypotension and bradycardia.
 - Can be prevented by slowing the rate of drug infusion
 - Amiodarone can increase the QT interval; therefore, its use should be carefully considered when other drugs that can prolong the QT interval are administered.
- **Calcium**
 - Plays a critical role in myocardial contractility and action potential generation, but studies have shown no benefit of calcium in CA
 - When indicated, the recommended dose is 5 to 10 mL of a 10% solution of calcium chloride (8–16 mg/kg).
 - Calcium gluconate is given in a dose of 6 to 8 mL if peripheral IV access is available. Undiluted calcium chloride given through a peripheral vein may cause sclerosis and tissue injury; therefore, if a central site is not available and the patient is not in CA, it either should be diluted or calcium administered in a less irritating form (e.g., calcium gluconate).
 - In children, a dose of 10 to 20 mg/kg of calcium chloride is recommended.
- **Magnesium**
 - Recommended for the treatment of torsades de pointes VT with or without CA

- Given at a dose of 1 to 2 g diluted in D5W over 10 to 60 minutes
- In children, a dose of 25 to 50 mg/kg is used.

Algorithms for Advanced Life Support

- The treatment algorithms of pulseless CA and tachycardia with pulse are summarized in Figures 1.1 and 1.2, respectively

ETHICAL CONSIDERATIONS

Termination of Cardiopulmonary Resuscitation Efforts

- CPR is inappropriate when survival is not expected.
- There are few criteria that can reliably predict the futility of CPR.
- Recommended that all patients with cardiopulmonary arrest receive CPR with the following exceptions:
 - There is a valid Do Not Attempt Resuscitation order, which can be verified
 - Signs of irreversible death are already present (e.g., rigor mortis, decapitation, decomposition, dependent lividity).
 - No physiologic benefit can be expected with further CPR.
 - In newborns, gestational age or congenital abnormality is related to almost certain early death.
- In the ICU, CPR is started without a physician's order, which is based on implied consent for emergency treatment.
 - The decision to stop CPR should be made by a physician treating the patient, ideally familiar with the patient's pre-existing conditions.
 - Rarely good outcome with prolonged CPR has been reported.
 - Acceptable to prolong resuscitative efforts in children with recurrent VF or VT, drug toxicity, or a primary hypothermic insult.

Family Presence during Cardiopulmonary Resuscitation

- Has been a common practice to exclude family of the arrest victim during CPR efforts
- Helping the family of a dying patient is an important part of CPR and should be done in a compassionate manner considering the family's cultural and religious beliefs and practices.
 - Concern that allowing family presence may become disruptive, interfere with resuscitation, cause them to experience syncope, and increase the risk of legal liability were not substantiated by good evidence.
 - Family surveys after CPR suggested that the majority of family members want to be present during CPR.
 - In pediatric arrest, most parents surveyed wanted an option to be present during CPR.
 - The resuscitation team should be sensitive to the family's presence, and a team member should be assigned to comfort the family, answer questions, and clarify the procedures.

CHAPTER 2 ■ AIRWAY MANAGEMENT

GENERAL PRINCIPLES

- You may *not* neglect the “A” of the ABCs and wait for airway management to turn into an emergency.
- Bag-valve-mask should be attempted by application of a mask and initiation of bag ventilation with an increased FiO_2 while equipment for intubation is prepared.
- An appropriate mask provides a tight seal around the nose and mouth, and the colorless plastic with soft and pliable edges allows visualization of the mouth and secretions.
- The mask is attached to the resuscitation (self-inflating or collapsible) bag with a high-flow oxygen source.
- Proper inflation requires two hands
 - One to hold the mask firmly in place against the patient’s face
 - The other to compress the bag
 - The mandible must be lifted to create a seal without airway occlusion.
 - An oropharyngeal or nasal airway facilitates oxygen delivery by bypassing or retracting the tongue.
 - Forceful bag compression should be avoided to prevent gastric distention and possible pulmonary aspiration.
 - Gentle insufflation allows assessment of lung compliance and minimizes complications.
- Contraindications to bag-valve-mask ventilation include:
 - Airway obstruction
 - Pooling of blood or secretions in the pharynx
 - Severe facial trauma
- Critically ill patients require tracheal intubation for the reasons listed in Table 2.1.
- Relative or absolute contraindications to **conventional** tracheal intubation
 - Traumatic or severe degenerative disorders of the cervical spine
 - Acute infectious processes such as acute supraglottitis or intrapharyngeal abscess
 - Extensive facial injury and basal skull fracture
- Blind nasal intubation may be contraindicated in the following situation:
 - Upper-airway foreign-body obstruction, because the tube may push the foreign body distally and exacerbate airway compromise

ANATOMIC CONSIDERATIONS

Adult

- Neck flexion aligns the pharyngeal and tracheal axes, whereas head extension on the neck and opening of the mouth align the oral passage with the pharyngeal and tracheal axes.

- This maneuver places the patient in a “sniffing position” (Fig. 2.1).
 - Flexion/extension of the head decreases 20% by 75 years of age.
 - Degenerative arthritis limits cervical spine motion, more with extension than flexion.
 - Spine movement is contraindicated in the presence of potential cervical spine injury.
 - Hence, patient is maintained in a neutral position with in-line stabilization.
 - Barring the edentulous patient, the front component of the hard cervical collar is commonly removed to allow full mandibular movement/optimize mouth opening.
- Knowledge of anatomic landmarks may help during direct laryngoscopy (Fig. 2.2).
 - The cricoid, a circle of cartilage above the first tracheal ring, can be compressed to occlude the esophagus (Sellick maneuver) to prevent passive gastric regurgitation into the trachea.
 - The epiglottis lies in the anterior pharynx.
 - The vallecula, a furrow between the epiglottis and base of the tongue is placement site for the tip of a curved laryngoscope blade.
 - The larynx is located anterior and superior to the trachea and contains the vocal cords.

Pediatric

- Differences exist between the adult and the pediatric airways.
 - Pediatric patients have a relatively large head and flexible neck.

TABLE 2.1

INDICATIONS FOR TRACHEAL INTUBATION

Open an obstructed airway
Provide airway pressure support to treat hypoxemia
 $\text{PaO}_2 < 60$ mm Hg with an $\text{FiO}_2 > 0.5$
Alveolar-to-arterial oxygen gradient 300 mm Hg
Intrapulmonary shunt $> 15\%$ – 20%
Provide mechanical ventilation
Respiratory acidosis
Inadequate respiratory mechanics
Respiratory rate > 30 breaths/min
 $\text{FVC} < 10$ mL/kg
 $\text{NIF} > -20$ cm H_2O
 $\text{V}_\text{D}/\text{V}_\text{T} > 0.6$
Facilitate suctioning, instillation of medications, and bronchoscopy
Prevent aspiration
Gag and swallow reflexes absent

FiO_2 , fraction of inspired oxygen; FVC, forced vital capacity; NIF, negative inspiratory force; $\text{V}_\text{D}/\text{V}_\text{T}$, dead space/tidal volume ratio.

FIGURE 2.1. Demonstration of the “sniffing position” for optimal visualization of the glottic opening.

- The air passages are small.
- The tongue, adenoids, and tonsils are larger than those in adults.
- The epiglottis is floppy.
- The glottis is typically slanted at a 40-degree to 50-degree angle, making intubation more difficult.
- Mucous membranes are softer, looser, and more fragile and readily become edematous when an oversized endotracheal tube is used.
- The epiglottis and larynx of infants lie more cephalad and anterior.

- The cricoid cartilage ring is narrowest portion of the upper airway in children.
- In the adult, the glottic opening is narrowest.
- The pediatric vocal cords have a shorter distance from the carina.
- The mainstem bronchus angulates symmetrically at the level of the carina at about 55 degrees.
 - In adults, the right mainstem angulates at about 25 degrees and the left at about 45 degrees.
- The cupulae of the lungs are higher in the infant’s neck, increasing the risk of lung trauma.

Intubation

- All anticipated equipment/drugs must be available for the planned intubation technique (Table 2.2).
- A difficult-airway cart or bag with a variety of airway rescue devices—and a bronchoscope and/or fiberoptic laryngoscope—should be readily available.

MEDICATIONS

- Local anesthetics
 - Aerosolized or nebulized 1% to 4% lidocaine can readily achieve nasopharyngeal and oropharyngeal anesthesia if the patient is cooperative and capable of deep inhalation, thus limiting its usefulness in the ICU.
 - Transtracheal (cricothyroid membrane) instillation of 2 to 4 mL of 1% to 4% lidocaine with a 22- to 25-gauge needle causes sufficient coughing-induced reflex to afford ample

FIGURE 2.2. Laryngoscopic landmarks. Panel shows the cricoid cartilage.

TABLE 2.2**STANDARD EQUIPMENT AND DRUGS FOR TRANSLARYNGEAL INTUBATION**

Bag-valve-mask resuscitation bag
 LMA-type device
 Oxygen source
 Suction apparatus
 Selection of oral and nasal airways
 Magill forceps
 Assortment of laryngoscope blades and endotracheal tubes
 Tape, stylet, lubricant, syringes, and tongue depressors
 Monitors (ECG, blood pressure monitor, pulse oximeter, capnography, or similar device) and defibrillator^a
 Fiberoptic bronchoscope,^a rigid fiberscope,^a and specialty blades^a
 A drug tray or cart with vasoconstrictors, topical anesthetics, induction agents, muscle relaxants, and emergency medications
 14-Gauge IV, scalpel, assortment of supraglottic airways,^a bougie,^a Combitube,^a ET exchanger,^a and Melker-type cricthyrotomy kit

^aImmediately available.

LMA, laryngeal mask airway; ECG, electrocardiograph; ET, endotracheal tube.

distribution to anesthetize the subglottic and supraglottic regions plus the posterior pharynx in 90% of patients.

- Cocaine provides excellent conditions for facilitating intubation through the nasopharynx due to its outstanding topical anesthetic and mucosal and vascular shrinkage capabilities. In-hospital availability may limit its use in favor of phenylephrine or oxymetazoline combined with readily available local anesthetics.
- Lidocaine ointment applied to the base of the tongue with a tongue blade or similar device allows performance of direct laryngoscopy in many patients.
 - If time permits, nasal spraying with a vasoconstrictor followed by passing a progressively larger nasal airway trumpet from 24 French to 32 French that is coated/lubricated with lidocaine gel/ointment provides exceptional coverage of the nasocavity in preparing for a nasal intubation.
- Barbiturates
 - Sodium thiopental, an ultra-short-acting barbiturate, decreases the level of consciousness and provides amnesia without analgesia.
 - Intubation dose in the operating room (OR) of 4 to 7 mg/kg ideal body weight (IBW) (1 to 2 mg/kg in the ICU) dose over 20 to 50 seconds (more rapidly via central venous line (CVL))
 - Duration of action 5 to 10 minutes
 - Lowers cerebral metabolic rate while maintaining cerebral blood flow as long as systemic blood pressure is maintained within an adequate range
 - Thiopental may lead to hypotension in critically ill patients due to its vasodilatation properties, especially with hypovolemia.
- Narcotics
 - Morphine, hydromorphone, fentanyl, and remifentanyl reduce pain perception and allay anxiety, making intubation less stressful.

- Fentanyl and the ultra-short-acting remifentanyl have a more rapid onset (seconds) and shorter duration of action (about 20 minutes and 5 minutes, respectively) than the conventional narcotics used in the ICU.
- Morphine may lead to histamine release and its potential sequelae.
- Though all narcotics cause respiratory depression, the newer synthetic narcotics may lead to glottic spasm that may hamper ventilation.
- Benzodiazepines
 - Lorazepam and midazolam have excellent amnestic and sedative properties.
 - May be combined with an analgesic agent during intubation
 - Lorazepam use for intubation is possible, but it is hampered by a slower pharmacodynamic onset (2–6 minutes) as compared to midazolam.
 - Hypotension may occur with hypovolemia.
- Neuromuscular blocking agents
 - Administration of a sedative-hypnotic agent with a rapid-acting muscle relaxant, typically succinylcholine, is cited as improving intubation conditions and leading to fewer complications.
 - If one does not fully contemplate the patient's risk for airway management difficulties and does not have access or a good working knowledge of airway rescue devices if conventional laryngoscopy techniques fail, disaster may ensue. Any clinician who administers drugs such as induction agents, including paralytics, must have developed a rescue strategy coupled with the equipment to deploy such a strategy.
 - Indications: include agitation or lack of cooperation not related to inadequate or no sedation
 - Neuromuscular blocking agents may cause depolarization of the motor end-plate (succinylcholine, a depolarizing agent) or prevent depolarization (nondepolarizer: pancuronium, vecuronium, rocuronium).
 - Succinylcholine has a rapid onset and short duration of effect
 - It may raise serum potassium levels by 0.5 to 1.0 mEq/L.
 - It is contraindicated in bedridden patients and in those with pre-existing hyperkalemia, burns, or recent or long-term neurologic deficits.
 - Other side effects are elevation of intragastric and intraocular pressures, muscle fasciculation, myalgia, malignant hyperthermia, cardiac bradyarrhythmias, and myoglobinuria.
 - At a dose of 0.25 mg/kg IBW - the ED95 - succinylcholine has a duration of about 3 minutes. This is our recommendation, despite the commonly-used dose recommended in the literature of 1.0 to 1.5 mg/kg IBW.
 - Nondepolarizing muscle relaxants have a longer time to onset and duration of action as compared to succinylcholine.
 - Rocuronium (typical OR dose, 0.6 mg/kg) can approach succinylcholine in rapid time of onset if dosed at 1.2 mg/kg).
- Ketamine
 - A phencyclidine derivative that provides profound analgesia, amnesia, and dissociative anesthesia
 - Airway reflexes often, but not always, preserved.

- Has a rapid onset and relatively short duration of action
- Its myocardial depressant action is often countered by its sympathomimetic properties, leading to hypertension and tachycardia.
 - Use in the critically ill patient with ongoing activation of his or her sympathetic outflow could lead to profound hemodynamic instability, as the underlying myocardial depression may not be successfully countered.
- Has significant bronchodilatory properties but promotes bronchorrhea, salivation, and a high incidence of dreams, hallucinations, and emergence delirium (at doses well above those noted)
- Dose at 0.5 to 1 mg/kg leads to anesthesia for about 20 minutes and analgesia for about 60 minutes.
- Propofol
 - IV administration of 1 to 3 mg/kg IBW results in unconsciousness within 30 to 60 seconds.
 - Awakening is observed in 4 to 6 minutes.
- Hypotension, cardiovascular collapse, and, rarely, bradycardia may complicate its use.
- Etomidate
 - Considered the preferred induction agent in the critically ill patient due to its favorable hemodynamic profile
 - Role as a single-dose induction agent is in question due to its transient depression of the adrenal axis, and this adrenal suppression may be influential in the outcome of the critically ill.

EQUIPMENT FOR ACCESSING THE AIRWAY

- Esophageal Tracheal Combitube
 - The esophageal tracheal Combitube (ETC) is recommended by the American Heart Association Advanced Cardiovascular Life Support course and other national guidelines as an advanced variant of the older esophageal obturator airway and the pharyngeal tracheal lumen airway.
 - The double lumens with proximal and distal cuffs allow ventilation and oxygenation in a majority of nonawake patients whether placed in the esophagus (95% of all insertions) or the trachea.
 - The proximal cuff is placed between the base of the tongue and the hard palate and the distal cuff within the trachea or upper esophagus.
 - The ETC is inserted blindly, assisted by a jaw thrust or laryngoscopic assistance.
- Laryngoscopes
 - Fiberoptic versus conventional is used to expose the glottis to facilitate passage of the tracheal tube.
 - The utility of the laryngoscope under elective circumstances, with otherwise healthy surgical patients, is essentially limited to individuals with a grade I or II view that can be easily intubated.
 - Difficult view (grade III or IV) has been documented in 14% of patients despite optimizing maneuvers such as the optimal external laryngeal manipulation (OELM) and the backward upward right pressure (BURP) technique (Fig. 2.3).
 - Up to 33% of critically ill patients have a limited view with laryngoscopy (epiglottis only or no view at all).

Determining Optimal External Laryngeal Manipulation with Free (right) Hand

FIGURE 2.3. Diagrammatic representation of the optimal external laryngeal movement (OELM) and backward upward rightward pressure (BURP) maneuvers for optimal visualization of the glottis.

- Hence, critical care practitioners responsible for airway management must be prepared to embark on a plan B or plan C immediately if conventional direct laryngoscopy fails.

- Blades
 - Laryngoscope blades are of two principal kinds, curved and straight, varying in size for use in infants, children, or adults (Fig. 2.4)
- Endotracheal tubes
 - The tube size used depends on the size of the patient (Table 2.3).
- Malleable stylet
 - A well-lubricated malleable stylet is preferred by many to pre-form the endotracheal tube (ET) into a shape that may expedite passing through the glottis.

FIGURE 2.4. Various types of laryngoscope blades in common use.

TABLE 2.3
RECOMMENDED SIZES FOR ENDOTRACHEAL TUBES

Patient age	Internal diameter of tube (mm) ^a
Newborn	3.0
6 mo	3.5
18 mo	4.0
3 y	4.5
5 y	5.0
6 y	5.5
8 y	6.0
12 y	6.5
16 y	7.0
Adult female	7.0–7.5
Adult male	8.0–9.0

^aOne size larger and one size smaller should be allowed for individual intra-age variations and shorter-stature individuals. Where possible, the subglottic suction endotracheal tube should be used.

- The stylet is a guide, not a “spear,” and its tip should be safely inside the ET, never distal to the ET tip.
- Ideally, the styleted ET tip should be placed at the entrance of the glottis, and then, with stylet removal, the ET will advance into the trachea less traumatically.

HOW MIGHT THE AIRWAY BE ACCESSED?

General Indications and Contraindications

- The oral approach is the standard method for tracheal intubation today unless there is limited access to the oral cavity due to trauma, edema, or anatomic difficulties.
- If the nasal approach is not feasible, a surgical approach via the cricothyroid membrane or a formal tracheostomy would be clinically indicated.

Orotracheal Intubation

- Expediently prepare both the patient and the equipment for the airway management procedure.
- While bag ventilation (preoxygenation) is being provided, obtain appropriate towels for optimizing head and neck position or blankets for ramping the obese patient and adjusting the bed height and angulation (Fig. 2.5).
 - Assemble the necessary equipment, such as the ET, syringes, suction equipment, lubricant, CO₂ detector, and a stylet, if desired.
 - Obtain a rapid medical–surgical history.
 - Review previous intubation procedures sought.
 - Complete an airway examination.
 - Ensure IV access and develop a primary plan for induction.
 - Place airway rescue devices at the bedside.
 - Insist on clear communication among team members.
- Awake intubation
 - Awake intubation techniques comprise both nasal and oral routes and, most often, involve topically applied local anesthetics or local nerve blocks.
 - Practitioners may prefer to maintain spontaneous ventilation during emergency airway management by avoiding excessive sedative–hypnotic agents and/or muscle relaxants.
 - Light sedation and analgesics, however, are typically administered despite the label of being “awake.”
 - After proper preparation, unless the patient is unconscious or has markedly depressed mental status, the “awake look” technique incorporates conventional laryngoscopy to evaluate the patient’s airway to gauge the feasibility and ease of intubation.
 - If viewing the airway structures during an “awake look” proves fruitful, intubation should be performed during the same laryngoscopic attempt either directly—grade I or II view—or by bougie assistance—grade I, II, or III—or by other means.
- Rapid sequence intubation (RSI)
 - RSI refers to the administration of an induction agent followed by a neuromuscular blocking agent, with the goal

FIGURE 2.5. Ramping of an obese patient’s torso to improve glottic visualization is noted on the left panel. The right panel shows the patient position *without* proper ramping.

of hastening the time needed to induce unconsciousness and muscle paralysis and minimizing the time the airway is unprotected with less risk of aspiration.

- Preoxygenation is paramount via a bag-mask.
- Cricoid pressure is applied to reduce the risk of passive regurgitation of any stomach contents.
 - Cricoid pressure may sometimes worsen the laryngoscopic view, plus impede mask ventilation; hence, adjustment or release of cricoid pressure should be considered in these circumstances.
- RSI is said to be associated with a lower incidence of complications and higher first-pass intubation success rate as compared to the “sedation only” method.
- A predetermined induction regimen, such as etomidate and succinylcholine—0.25 mg/kg IBW etomidate and 0.25 mg/kg IBW of succinylcholine—generally works well for most critically ill patients.

Positioning the Patient

- One of the most important factors in improving the success rate of orotracheal intubation is positioning the patient properly (see Fig. 2.1).
- Classically, the sniffing position, namely cervical flexion combined with atlanto-occipital extension, will assist in improving the “line of sight” of the intubator.
- Bringing the three axes into alignment (oral, pharyngeal, and laryngeal) is commonly optimized by placing a firm towel or pillow beneath the head (providing mild cervical flexion) combined with physical backward movement of the head at the atlanto-occipital joint via manual extension.
- This, when combined with oral laryngoscopy, will improve the “line of sight” for the intubator to better visualize the laryngeal structures in most patients.
- Optimizing the position of the obese patient (see Fig. 2.5, left panel) is an absolute requirement to assist with the following:
 - Spontaneous ventilation and mask ventilation
 - Opening the mouth
 - Gaining access to the neck for cricoid application, manipulation of laryngeal structures, or invasive procedures
 - Improving the “line of sight” with laryngoscopy
 - Prolonging oxygen saturation after induction

Blade Use

- Curved blade
 - After opening of the mouth either by the extraoral technique (finger pressing downward on chin) or the intraoral method (the finger scissor technique to spread the dentition), the laryngoscope blade is introduced at the right side of the mouth and advanced to the midline, displacing the tongue to the left.
 - The epiglottis is seen at the base of the tongue and the tip of the blade inserted into the vallecula.
- The laryngoscope blade should be lifted toward an imaginary point in the corner of the wall opposite the patient to avoid using the upper teeth as a fulcrum for the laryngoscope blade.
 - A forward and upward lift of the laryngoscope and blade stretches the hyoepiglottic ligament, thus folding the epiglottis upward and further exposing the glottis.
- With visualization of the glottic structures, the ET is passed to the right of the laryngoscope through the glottis into the

trachea until the cuff passes 2 to 3 cm beyond the vocal cords.

- A blind guide underneath the epiglottis (tracheal tube introducer, bougie) or a rigid fiberoptic stylet may be incorporated to improve the insertion success rate.
- Straight blade
 - Intubation with a straight blade involves the same maneuvers but with one major difference.
 - The blade is slipped *beneath* the epiglottis, and exposure of the larynx is accomplished by an upward and forward lift at a 45-degree angle toward the corner of the wall opposite the patient.
 - Leverage must not be applied against the upper teeth.
- Repetitive laryngoscopies are not in the best interest of patient care and may place the patient at extreme risk for potentially life-threatening airway-related complications.
- Conventional laryngoscopy should be abandoned in favor of incorporating an airway adjunct to assist the clinician.

Nasotracheal Intubation

- Nasotracheal intubation is still commonly used in oral and maxillofacial operative interventions but less commonly in emergency situations outside the OR.
- The presence of midfacial or posterior fossa trauma and coagulopathy are absolute contraindications to this technique. It is also contraindicated in the presence of acute sinusitis or mastoiditis and best avoided in patients with a basilar skull fracture, a fractured nose, or nasal obstruction.
- As the nasal portal dictates a smaller-diameter tracheal tube, the length of the tracheal tube will be shortened; hence, the length must be considered when placing a small-caliber tube (e.g., a 6.0-mm diameter in an individual taller than about 69 inches), as the nasal tracheal tube may end up as an elongated nasal trumpet, without entrance into the trachea.
- The method of intubation via the nasal approach is variable.
 - It may be placed blindly during spontaneous ventilation, combined with oral laryngoscopic assistance to aid with ET advancement utilizing Magill forceps; utilize indirect visualization through the nares via an optical stylet or a flexible or rigid fiberscope; or incorporate a lighted stylet for transillumination of the laryngeal structures.
- Technique
 - The patient is prepared for the nasal approach by pretreatment of the mucosa of both nostrils with a solution of 0.1% phenylephrine and a decongestant spray such as oxymetazoline for 3 to 10 minutes.
 - This is followed by progressive dilation, starting with either a 26 French or 28 French nasal trumpet, and progressing to a No. 30 French to No. 32 French trumpet lubricated with 2% lidocaine jelly. Conversely, placement of cotton pledgets soaked in a mixture of vasoconstrictor agent and local anesthetic is equally effective.
 - Supplemental oxygen may be provided by nasal cannulae placed between the lips or via a face mask.
 - The patient is best intubated with spontaneous ventilation maintained.
 - Incremental sedation/analgesia may be provided. Sitting upright has the advantage of maximizing the oropharyngeal diameter.

- Orientation of the tracheal tube bevel is important for patient comfort and to reduce the risk of epistaxis and tearing or dislocation of the nasal turbinates. On either side of the nose, the bevel should face the turbinate (away from the septum).
- Tube advancement should be slow and gentle, with rotation.
- If advancement is met with resistance from glottic/anterior tissues, helpful maneuvers include sitting the patient upright, flexing the head forward on the neck, and manually pulling the larynx anteriorly.
- Conversely, if advancement is met with posterior displacement into the esophagus, sitting the patient upright, extending the head on the neck, and applying posterior-directed pressure on the thyrocricoid complex may assist in intubation.
 - Rotation of the tube and manual depression or elevation of the larynx may be required to succeed.
 - Voluntary or hypercapnic-induced hyperpnea helps if the patient is awake because maximal abduction of the cords is present during inspiration.
- Entry into the trachea is signified by consistent breath sounds transmitted by the tube and inability to speak, if the patient is breathing, and by lack of resistance, often accompanied by cough. Confirmation with end-tidal CO₂ measurement or fiberoptic viewing is imperative.
- Nasotracheal intubation may also be accomplished with *fiberoptic assistance*.
 - Advancement of the ET into the glottis may be impeded by hang-up on the laryngeal structures: the vocal cord, the posterior glottis or, typically, the right arytenoid.
 - When resistance is met, a helpful tip is as follows: Withdrawing the tube 1 to 2 cm, rotate the tube counterclockwise 90 degrees, and then readvance with the bevel facing posteriorly.
 - Matching the tracheal tube to the fiberscope to minimize the gap between the internal diameter of the tube and the scope may also improve advancement.
 - Tracheal confirmation and tip positioning are added advantages to fiberoptic-assisted intubation.
 - The nasal approach has decreased in popularity due to
 - A restriction of tube size
 - The potential to add epistaxis to an already tenuous airway situation
 - The potential for sinus obstruction and infection beyond 48 hours

CONFIRMATION OF TRACHEAL INTUBATION

Physical Examination

- Confirmation of ET location after intubation is imperative and consists of the following:
 - Observation of the ET passing through the vocal cords
 - Absence of gurgling over the stomach with bag-valve ventilation
 - Chest rise with bag-valve ventilation
 - Presence of condensation upon exhalation
 - Presence of breath sounds over the **lateral** midhemithoraces
 - Presence of CO₂

Capnography

- Identification of exhaled CO₂ measured *via* disposable colorimetric devices or capnography is a standard of practice.
- Capnography may fail due to
 - Low-flow or no-flow cardiac states (no pulmonary blood flow as a source of exhaled carbon dioxide)
 - Soilage from secretions, pulmonary edema fluid, or blood, temperature alterations (outside helicopter rescue), age, lack of maintenance

Other Devices

- Esophageal detector devices
 - Syringe or the self-inflating bulb models (Fig. 2.6) assist in the detection of ET location based on the anatomic difference between the trachea (an air-filled column) and the esophagus (a closed and collapsible column).
 - Applying a 60-mL syringe to the ET and withdrawing air should collapse the esophagus, while the trachea should remain patent.
 - False-negative results may still be seen (no reinflation even though the ET is in the trachea) in less than 4% of cases.
 - Technique failures include ET soilage, carinal or bronchial intubation in the obese, and those with severe pulmonary disease (chronic obstructive pulmonary disease, bronchospasm, thick secretions, or aspiration), and gastric insufflation.
- Two infallible or fail-safe techniques when used under optimal conditions
 - Visualizing the ET within the glottis
 - Fiberoptic visualization of tracheal/carinal anatomy

FIGURE 2.6. Esophageal detector devices, either the syringe or the self-inflating bulbs, assist in the detection of endotracheal tube location based on the anatomic difference between the trachea (an air-filled column) and the esophagus (a closed and collapsible column). Note that a 15-mm adaptor inserts onto the tip of the bulb syringe so that the connection may be made.

Cheney Test

- Clinically useful adjunct for assisting in the verification of the ET location
- Hang-up test
 - Passing a bougie or similar catheter-like device for the purpose of detecting tip impingement on the carinal or bronchial lumen
 - Gently advancing a bougie to 27 to 35 cm depth may allow the practitioner to appreciate hang-up on distal structures.
 - Compared to unrestricted advancement if ET is in esophagus
 - Care must be taken not to perforate the trachea

DEPTH OF ENDOTRACHEAL TUBE INSERTION

- Classic depth of insertion is height and gender based.
- Also affected by the route of ET placement (i.e., oral vs. nasal)
- Final tip position is best at about 2 to 4 cm above the carina to limit irritation with head movement and patient repositioning.
 - ET depth in the adult patient less than or equal to 62 inches (157 cm) in height should be approximately 18 to 20 cm.
 - Otherwise, 22 to 26 cm may be the appropriate depth.
 - Chest radiography only determines the tip depth at the time of film exposure.

AMERICAN SOCIETY OF ANESTHESIOLOGISTS PRACTICE GUIDELINES

- Airway management procedures should be accompanied by capnography or similar technology to reduce the incidence of unrecognized esophageal intubation.
- Preintubation evaluation to recognize the potential difficult airway is paramount (Table 2.4)
 - Is there a reasonable expectation for successful mask ventilation?
 - Is intubation of the trachea expected to be problematic?
 - Should the airway approach be nonsurgical or surgical?
 - Should an awake or a sedated/unconsciousness approach be pursued?
 - Should spontaneous ventilation be maintained?
 - Should paralysis be pursued?

Awake Pathway

- If difficulty is recognized, an awake approach may be appropriate.
 - Patient preparation with an antisialagogue, assembling equipment and personnel, discussion with the patient, and optimal positioning should be pursued unless emergent.
 - The awake choices, following optimal preparation,
 - May allow an “awake look” with conventional laryngoscopy
 - May allow bougie-assisted intubation

- May allow laryngeal mask airway (LMA) insertion
- May allow indirect fiberoptic techniques (rigid and flexible) or proceeding with a surgical airway
- Access to the airway via cricothyroid membrane puncture via large-bore catheter insertion with either modified tubing or a jet device to ventilate, or via Melker cricothyrotomy kit, is an option prior to other awake or asleep methods.

Asleep Pathway

- After induction in the patient with a known or suspected difficult airway or in the unrecognized difficult airway (Table 2.5)
- Ability to adequately mask ventilate will determine direction of management
 - Mask ventilation adequate but conventional intubation is difficult
 - The nonemergency pathway is appropriate, utilizing the bougie, specialty blades, supraglottic airway, flexible or rigid fiberoptic technique, or surgical airway.
 - Mask ventilation is suboptimal or impossible, intubation of the trachea may be attempted, but immediate placement of a supraglottic airway such as the LMA is the treatment of choice.
 - If the supraglottic device fails, an extraglottic device such as the Combitube or similar device can be placed.
 - Otherwise, transtracheal jet ventilation may be used or a surgical airway placed.

COMPLICATIONS RELATED TO ACCESSING THE AIRWAY

- Complications occur in four time periods (Tables 2.6 – 2.9):
 - During intubation
 - After placement
 - During extubation
 - After extubation
- Cuffed tube usage for prolonged intubation and artificial ventilation increases rate of tracheal and laryngeal injury.
 - Cuff pressures above 25 to 35 mm Hg further add to risk by compressing tracheal capillaries.
- Other factors include the duration of intubation, reintubation, and route of intubation. More complications occur from: nasal intubation versus oral, patient-initiated self-extubation, excessive tracheal tube movement, trauma during procedures, poor tube care.

Failed Intubation

- In the clinical situation of can't ventilate, can't intubate, the practitioner will need to rapidly deploy the rescue plan.
 - After *failure* of conventional mask ventilation (no ventilation or oxygen delivery) or when mask ventilation is *failing* (*inadequate gas exchange, SpO₂ less than 90%, or a falling SpO₂*).
 - Supraglottic airway (LMA) should be placed.
 - If unsuccessful, placement of the LMA, the Combitube may serve as a backup for LMA failure.

TABLE 2.4

AMERICAN SOCIETY OF ANESTHESIOLOGISTS DIFFICULT-AIRWAY ALGORITHM

DIFFICULT AIRWAY ALGORITHM

1. Assess the likelihood and clinical impact of basic management problems:

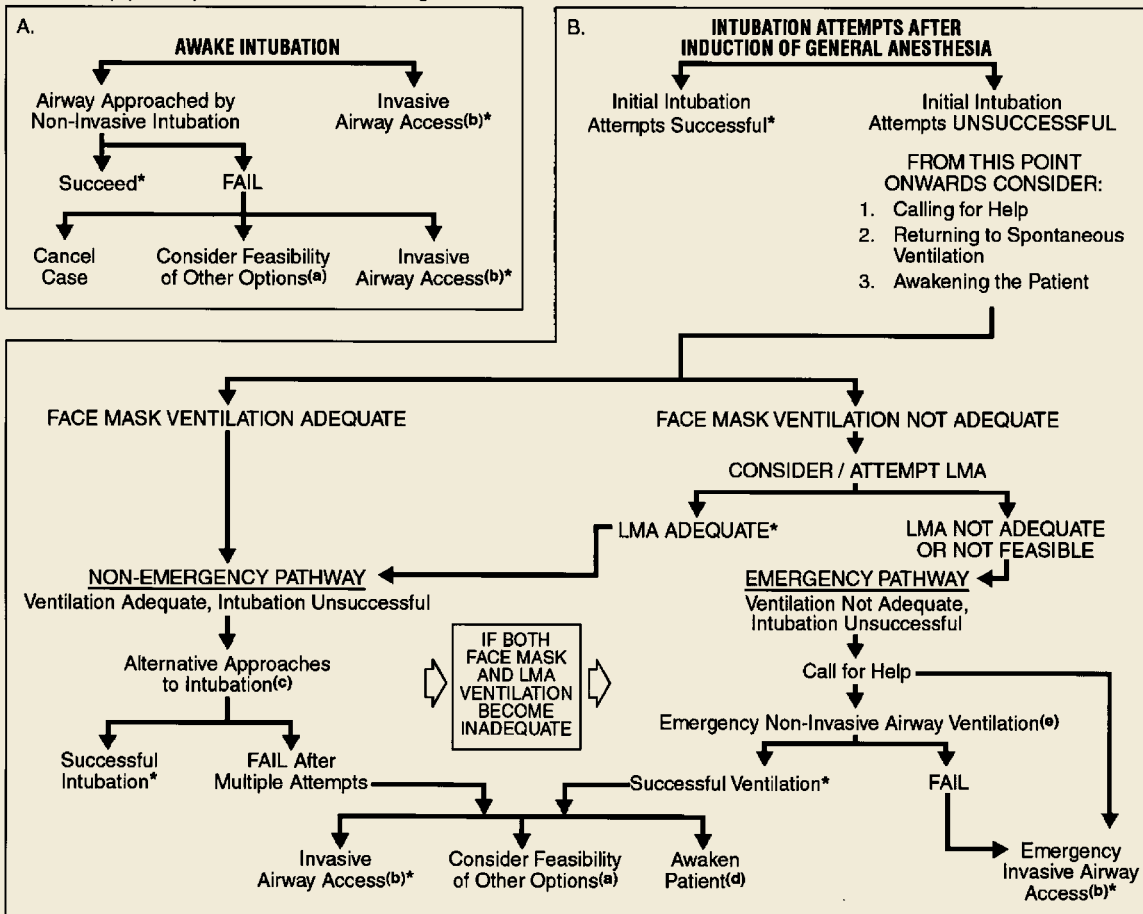

- A. Difficult Ventilation
- B. Difficult Intubation
- C. Difficulty with Patient Cooperation or Consent
- D. Difficult Tracheostomy

2. Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management

3. Consider the relative merits and feasibility of basic management choices:

- A. Awake Intubation vs. Intubation Attempts After Induction of General Anesthesia
- B. Non-Invasive Technique for Initial Approach to Intubation vs. Invasive Technique for Initial Approach to Intubation
- C. Preservation of Spontaneous Ventilation vs. Ablation of Spontaneous Ventilation

4. Develop primary and alternative strategies:

* Confirm ventilation, tracheal intubation, or LMA placement with exhaled CO₂

a. Other options include (but are not limited to): surgery utilizing face mask or LMA anesthesia, local anesthesia infiltration or regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has been reached via the Emergency Pathway.

b. Invasive airway access includes surgical or percutaneous tracheostomy or cricothyrotomy.

c. Alternative non-invasive approaches to difficult intubation include (but are not limited to): use of different laryngoscope blades, LMA as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, retrograde intubation, and blind oral or nasal intubation.

d. Consider re-preparation of the patient for awake intubation or canceling surgery.

e. Options for emergency non-invasive airway ventilation include (but are not limited to): rigid bronchoscope, esophageal-tracheal combitube ventilation, or transtracheal jet ventilation.

TABLE 2.5**STRATEGY FOR EMERGENCY AIRWAY MANAGEMENT OF THE CRITICALLY ILL PATIENT**

1. Conventional intubation—grade I or II view
2. Bougie—grade III view
 - a. May use for grade I and II if needed
3. LMA/supraglottic device—grade III or IV view
 - a. LMA/supraglottic rescue for bougie failure
 - b. Or use the LMA/supraglottic device as a primary device (i.e., known difficult airway, cervical spine limitations, Halo-vest)
4. Combitube—rescue device for any failure or as a primary device if clinically appropriate
5. Fiberscope (optical/video-assisted rigid or flexible models)—primary mode of intubation, an adjunct for intubation via the LMA

LMA, laryngeal mask airway.

- Both devices have a high rate of success for ventilation, are placed rapidly and blindly, and require a relatively simple skill set.
- Limiting intubation attempts is a key to successful management.
 - Repeated attempts are probably futile (e.g., a grade IV view with conventional methods) and markedly increase the risk of hypoxemia and other potentially devastating complications.
- Conventional intubation failure should be supplemented by an airway adjunct.
 - Bougie, specialty blades, or fiberscopes if immediately available
 - Key point: Use them early and use them often.
 - More invasively, transtracheal jet ventilation via a large-gauge (12- or 14-gauge) IV catheter through the cricothyroid membrane may be an appropriate alternative.

- However, advanced planning with ready access to the proper equipment and a sound understanding of “jetting” principles (lowest PSI setting to maintain SpO₂ in the 80%–90% range, prolonged inspiration-to-expiration ratio [i.e., 1:5], 6–12 quick breaths per minute, allowing a path for exhalation, constant catheter stabilization, and barotrauma vigilance) must be followed; otherwise, the consequences may be very serious.

EXTUBATION OF THE DIFFICULT AIRWAY IN THE INTENSIVE CARE UNIT

- Airway management also constitutes maintaining control of the airway into the postextubation period.
- The known or suspected difficult-airway patient should be evaluated in regard to factors that may contribute to his or her inability to tolerate extubation (Tables 2.10 and 2.11).
 - “Difficult extubation” is defined as the clinical situation when a patient presents with known or presumed risk factors that may contribute to difficulty re-establishing access to the airway.
- Reintubation, immediately or within 24 hours, may be required in up to 25% of intensive care unit patients.
 - Measures to avert reintubation such as noninvasive ventilation may reduce mortality rate if done so upon extubation.

PARAMETERS OF AIRWAY EVALUATION FOR EXTUBATION

NPO Status

- Although not thoroughly studied, it makes clinical sense to consider 2 to 4 hours off of distal enteral feeds prior to

TABLE 2.6**RISKS OF TRACHEAL INTUBATION**

Time	Tissue injury	Mechanical problems	Other
Tube placement	Corneal abrasion; nasal polyp dislodgement; bruise/laceration of lips/tongue; tooth extraction; retropharyngeal perforation; vocal cord tear; cervical spine subluxation or fracture; hemorrhage; turbinate bone avulsion	Esophageal/endobronchial intubation; delay in cardiopulmonary resuscitation; ET obstruction; accidental extubation	Dysrhythmia; pulmonary aspiration; hypertension; hypotension; cardiac arrest
Tube in place	Tear/abrasion of larynx, trachea, bronchi	Airway obstruction; proximal or distal migration of ET; complete or partial extubation; cuff leak	Bacterial infection (secondary); gastric aspiration; paranasal sinusitis; problems related to mechanical ventilation (e.g., pulmonary barotrauma)
Extubation	Tear/abrasion of larynx, trachea, bronchi	Difficult extubation; airway obstruction from blood, foreign bodies, dentures, or throat packs	Pulmonary aspiration; laryngeal edema; laryngospasm; tracheomalacia; intolerance of extubated state

ET, endotracheal tube.

TABLE 2.7**AIRWAY COMPLICATIONS CONTRIBUTING TO HYPOXEMIA**

Esophageal intubation	Regurgitation/aspiration
Mainstem bronchial intubation	Multiple attempts
Inadequate or no preoxygenation	Duration of laryngoscopy attempt
Failure to “reoxygenate” between attempts	Airway obstruction, unable to ventilate
Tracheal tube occlusion: Biting, angulation	Accidental extubation after intubation
Tracheal tube obstruction after intubation	Bronchospasm, coughing, bucking
Due to:	
Particulate matter	
Blood clots	
Thick, tenacious secretions	

extubation and maintaining the NPO status after extubation until the patient appears at low risk for failing the extubation “trial.”

Cuff Leak

- Hypopharyngeal narrowing from edema or redundant tissues, supraglottic edema, vocal cord swelling, and narrowing in the subglottic region of any etiology may contribute to the lack of a cuff leak.
- Too large a tracheal tube in a small airway should be considered.
- If airway edema is the culprit
 - Steps to decrease airway edema include elevation of the head, diuresis, steroid administration, minimizing further airway manipulation, and “time.”
- The performance of a cuff leak test varies by institution and protocol.
- A relatively crude yet effective method of cuff leak test involves auscultation for cuff leak with or without a stethoscope.

TABLE 2.8**FACTORS CONTRIBUTING TO POSTINTUBATION HEMODYNAMIC INSTABILITY**

Anesthetic medications
Sympathetic surge, vasovagal response
Excessive parasympathetic tone
Loss of spontaneous respirations
Positive pressure ventilation
Positive end-expiratory pressure (PEEP)
Auto- or intrinsic PEEP
Hyperventilation with pre-existing hypercarbia
Decrease in patient work
Underlying disease process (i.e., myocardial insufficiency)
Volume imbalances (sepsis, diuretics, hypovolemia, hemorrhage)
Preload dependent physiology
Valvular heart disease, congestive heart failure, pulmonary embolus, right ventricular failure, restrictive pericarditis, cardiac tamponade
Hypoxia-related hemodynamic deterioration
Hyperkalemia-induced deterioration (succinylcholine)

- Cuff leak volume (CLV) may be measured as the difference of tidal volume delivered with and without cuff deflation and stated as a percentage of leak or as an absolute volume. An absolute CLV less than 110 to 130 mL or 10% to 24% of delivered tidal volume is helpful in predicting postextubation stridor.
- Single- or multiple-dose steroids may reduce postextubation airway obstruction in pediatric patients.
- Steroid use in adults (1–4 mg dexamethasone IV) administered 6 hours prior to extubation—rather than 1 hour prior—may reduce postextubation stridor.

Risk Assessment: Direct Inspection of the Airway

- It is mandatory that the records of the known difficult-airway patient be reviewed.
- Some patients may need evaluation of their hypopharyngeal structures and supraglottic airway to assess airway patency and resolution of edema, swelling, and tissue injury.
 - Conventional laryngoscopy is a standard choice for evaluation but often fails due to a poor “line of sight.”
 - Flexible fiberoptic evaluation is useful but may be limited by secretions and edema.
 - Video-laryngoscopy and other indirect visualization techniques that allow one to see “around the corner” are especially helpful.

TABLE 2.9**TRACHEAL INTUBATION COMPLICATIONS SEEN AFTER EXTUBATION**

Time of occurrence	Complications
Early (0–72 h)	Numbness of tongue Sore throat Laryngitis Glottic edema Vocal cord paralysis
Late (>72 h)	Nostril stricture Laryngeal ulcer, granuloma, or polyp Laryngotracheal webs Laryngeal or tracheal stenosis Vocal cord synechiae

TABLE 2.10**RISK FACTORS FOR DIFFICULT EXTUBATION**

Known difficult airway
 Suspected difficult airway based on the following factors:
 Restricted access to airway
 Cervical collar, Halo-vest
 Head and neck trauma, procedures, or surgery
 ET size, duration of intubation
 Head and neck positioning (i.e., prone *vs.* supine)
 Traumatic intubation, self-extubation
 Patient bucking or coughing
 Drug or systemic reactions
 Angioedema
 Anaphylaxis
 Sepsis-related syndromes
 Excessive volume resuscitation

ET, endotracheal tube.

AMERICAN SOCIETY OF ANESTHESIOLOGISTS PRACTICE GUIDELINES STATEMENT REGARDING EXTUBATION OF THE DIFFICULT AIRWAY

- The American Society of Anesthesiologists guidelines have suggested that a preformulated extubation strategy should include:
- Consideration of relative merits of awake extubation *versus* extubation before the return of consciousness (clearly more applicable to the OR setting than to the ICU)
- Consideration of the short-term use of a device that can serve as a guide to facilitate intubation and/or provide a conduit for ventilation/oxygenation

Clinical Decision Plan for the Difficult Extubation

- A variety of methods are available to assist the practitioner's ability to maintain continuous access to the airway after extubation, each with limitations and restrictions.

TABLE 2.11**THE DIFFICULT EXTUBATION: TWO CATEGORIES FOR EVALUATION**

1. Evaluate the patient's inability to tolerate extubation
 - a. Airway obstruction (partial or complete)
 - b. Hypoventilation syndromes
 - c. Hypoxemic respiratory failure
 - d. Failure of pulmonary toilet
 - e. Inability to protect airway
2. Evaluate for potential difficulty re-establishing the airway
 - a. Difficult airway
 - b. Limited access to the airway
 - c. Inexperienced personnel pertaining to airway skills
 - d. Airway injury, edema formation

TABLE 2.12**AIRWAY EXCHANGE CATHETER (AEC) – ASSISTED EXTUBATION: TIPS FOR SUCCESS**

1. Access to advanced airway equipment
2. Personnel
 - a. Respiratory therapist
 - b. Individual competent with surgical airway?
3. Prepare circumferential tape to secure the airway catheter after extubation
4. Sit patient upright; discuss with patient
5. Suction ET, nasopharynx, and oropharynx
6. Pass lubricated AEC to 23–26 cm depth
7. Remove the ET while maintaining the AEC in its original position
8. Secure the AEC with the tape (circumferential); mark AEC “airway only”
9. Administer oxygen:
 - a. Nasal cannula
 - b. Face mask
 - c. Humidified O₂ via AEC (1–2 L/min)
10. Maintain NPO
11. Aggressive pulmonary toilet

ET, endotracheal tube.

- The LMA offers the ability for fiberoptic-assisted visualization of the supraglottic structures while serving as a ventilating and reintubating conduit.
- The bronchoscope is useful for periglottic assessment after extubation but requires advanced skills and minimal secretions.
- The airway exchange catheter (AEC) allows continuous control of the airway after extubation, is well tolerated in most patients, and serves as an adjunct for reintubation and oxygen administration. Dislodgment may occur, resultant from an uncooperative patient or a poorly secured catheter. Observation in a monitored environment with experienced personnel is top priority (Table 2.12).
- Clinical judgment and the patient's cardiopulmonary and other systemic conditions, combined with the airway status, will guide in establishing a reasonable time period for maintaining a state of “reversible extubation” with the indwelling AEC (Table 2.13).

TABLE 2.13**SUGGESTED GUIDELINES FOR MAINTAINING PRESENCE OF AIRWAY EXCHANGE CATHETER**

Difficult airway only, no respiratory issues, no anticipated airway swelling	1–2 h
Difficult airway, no direct respiratory issues, potential for airway swelling	>2 h
Difficult airway, respiratory issues, multiple extubation failures	>4 h

TABLE 2.14

STRATEGY AND PREPARATION FOR
ENDOTRACHEAL TUBE (ET) EXCHANGE

1. Place on 100% oxygen
2. Review patient history, problem list, medications, and level of ventilatory support
3. Assemble conventional and rescue airway equipment including capnography
4. Assemble personnel (nursing, respiratory therapy, surgeon, airway colleagues)
5. Prepare sedation/analgesia \pm neuromuscular blocking agents
6. Optimal positioning; consider DL of airway
7. Discuss primary/rescue strategies and role of team members; choose new ET (soften in warm water)
8. Suction airway; advance lubricated large AEC via ET to 22–26 cm depth
9. Elevate airway tissues with laryngoscope/hand, remove old ET, and pass new ET
10. Remove AEC and check ET with capnography/bronchoscope or use a closed system and place small bronchoscope through swivel adapter while at the same time ventilating, checking for CO₂, with the AEC still in place

DL, direct laryngoscopy; AEC, airway exchange catheter.

EXCHANGING AN
ENDOTRACHEAL TUBE

- Exchanging an ET due to cuff rupture, occlusion, damage, kinking, a change in surgical or postoperative plans, or self-extubation masquerading as a cuff leak, or when a different size or alteration in location is required, is common.
- Four methods typify the airway manager's armamentarium of exchanging an ET (Table 2.14)
 - Direct laryngoscopy
 - Flexible or rigid fiberscope
 - Airway exchange catheter
 - A combination of these techniques

CHAPTER 3 ■ TEMPORARY CARDIAC
PACEMAKERS

INDICATIONS

- Most common indication for temporary pacing is hemodynamically unstable bradycardia
- May be the result of primary degenerative conduction system disease or secondary causes such as medications, metabolic abnormalities, or acute myocardial infarction (AMI)
 - Medications include antiarrhythmic drugs and β - or calcium channel blockers, in particular diltiazem or verapamil.
 - Hyperkalemia and other electrolyte disturbances cannot only cause bradycardia but also may contribute to high pacing thresholds.
 - Secondary causes of bradycardia must be corrected for pacing to be successful. Table 3.1 lists some indications for temporary cardiac pacing.
- Not all bradycardias in the setting of acute myocardial infarction require temporary pacing (Tables 3.2 and 3.3).

- Atrioventricular (AV) block
 - Occurring during an inferior wall myocardial infarction (MI) from a right coronary artery occlusion may be secondary to ischemia of the region supplied by the AV nodal artery. In this setting, AV block rarely progresses to high-degree AV block, typically resolves within 2 weeks, and probably will not require temporary pacing.
 - AV block in the setting of an anterior wall MI carries a worse prognosis. Anterior wall MIs can be more extensive, and AV block seen in this situation is usually from infarct involvement of the interventricular septum and infranodal conduction system. AV block from an anterior wall MI may rapidly deteriorate to asystole.
 - Temporary pacing in the setting of an anterior wall MI and complete heart block is strongly suggested.
- Other indications for temporary pacemakers are considered prophylactic.
 - There are some procedures performed in the cardiac catheterization or electrophysiology lab in which temporary pacing is strongly considered.

TABLE 3.1**INDICATIONS FOR TEMPORARY CARDIAC PACING****Bradyarrhythmias****Asystole**

Any symptomatic or hemodynamically unstable bradycardia
 Second-degree Mobitz type II or third-degree heart block
 Other conduction abnormalities at high risk for progression to complete heart block such as alternating bundle branch block or new bifascicular block

Tachyarrhythmias

Bradycardia or pause-dependent polymorphic ventricular tachycardia
 Ventricular tachycardia that is treatable with overdrive pacing
 Atrial tachycardias or atrial flutters that are treatable with overdrive pacing

Preventive

Patient undergoing right heart catheterization with a left bundle branch block
 Cardiac interventions with high risk of bradyarrhythmia such as rheolytic thrombectomy (AngioJet), rotational atherectomy (Rotablation), or alcohol septal ablation
 Pacemaker generator change in a patient who is pacemaker dependent

- A patient undergoing alcohol septal ablation has a risk for needing a pace maker of as high as 55% to 70%, but a much smaller percentage requires permanent cardiac pacing—11% to 17%.
- Other examples include percutaneous coronary rotational atherectomy (Rotablation), rheolytic thrombectomy (AngioJet), or a generator replacement in a patient who is pacemaker dependent.
- Temporary pacing is also commonly used after cardiac surgery.
 - Incidence of hemodynamically unstable bradycardia after cardiac surgery has been reported to be as high as 4%.

TABLE 3.2**STANDARD AMERICAN COLLEGE OF CARDIOLOGY/AMERICAN HEART ASSOCIATION CLASSIFICATION FOR RECOMMENDATIONS AND INDICATIONS**

Class I	Conditions for which there is evidence and/or general agreement that a given procedure or treatment is beneficial, useful, and effective
Class II	Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of a procedure or treatment
Class IIa	Weight of evidence/opinion is in favor of usefulness/efficacy
Class IIb	Usefulness/efficacy is less well established by evidence/opinion
Class III	Conditions for which there is evidence and/or general agreement that a procedure/treatment is not useful/effective and in some cases may be harmful

From Gregoratos G, Abrams J, Epstein AE, et al. ACC/AHA/NASPE 2002 guideline update for implantation of cardiac pacemakers and antiarrhythmia devices—summary article: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (ACC/AHA/NASPE Committee to Update the 1998 Pacemaker Guidelines). *J Am Coll Cardiol.* 2002;40:1703–1719.

- AV block is not uncommon after valvular heart surgery and is likely a result of either direct injury to the surrounding conduction system or edema.
- Sinus bradycardia occurs in 64% of postcardiac transplant patients.
 - Though this bradycardia often resolves, temporary pacing may be required to maintain adequate heart rates for optimal cardiac output in the immediate posttransplant recovery period.
 - In addition, temporary atrial pacing may reduce the incidence of postoperative atrial fibrillation.
- Temporary pacemakers may also be used for other reasons besides bradycardia and heart block.

TABLE 3.3**INDICATIONS FOR PACING IN ACUTE MYOCARDIAL INFARCTION**

Class I	Class IIb	Class III
Asystole	Persistent second- or third-degree AV block at the AV node level	Transient AV block in the absence of intraventricular conduction defects
Persistent second-degree AV block in the His-Purkinje system with bilateral bundle branch block or third-degree AV block within or below the His-Purkinje system after acute myocardial infarction		Transient AV block in the presence of isolated left anterior fascicular block
Transient advanced (second- or third-degree) infranodal AV block and associated bundle branch block. If the site of block is uncertain, an electrophysiologic study may be necessary		Acquired left anterior fascicular block in the absence of AV block
Persistent and symptomatic second- or third-degree AV block		Persistent first-degree AV block in the presence of bundle branch block that is old or age indeterminate

AV, atrioventricular.

From Gregoratos G, Abrams J, Epstein AE, et al. ACC/AHA/NASPE 2002 guideline update for implantation of cardiac pacemakers and antiarrhythmia devices—summary article: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (ACC/AHA/NASPE Committee to Update the 1998 Pacemaker Guidelines). *J Am Coll Cardiol.* 2002;40:1703–1719.

- Pause or bradycardia-dependent polymorphic ventricular tachycardia, such as that occurring in the long QT syndrome, can be treated with temporary pacing, which will shorten the QT interval.
- Overdrive or rapid ventricular pacing may also prevent ventricular tachycardias triggered by premature ventricular contractions; some ventricular tachycardias may be terminated by ventricular pacing.
- Certain atrial tachycardias, such as atrial flutter, can be terminated with rapid atrial pacing.

TEMPORARY PACING CATHETERS

Deciding on Atrial, Ventricular, or Dual-Chamber Pacing

- Most ICU pacing needs can be met with single-chamber, right ventricular pacing
 - In some clinical situations, dual-chamber pacing is necessary.
- Some patients with congestive heart failure, significant diastolic dysfunction, and right ventricular infarction with AV block rely on AV synchrony and atrial contraction to maintain optimal physiologic cardiac contraction for adequate cardiac output.
 - Dual-chamber pacing is most readily available in postcardiac surgical patients, as temporary epicardial wires are routinely placed at the time of surgery.
 - Otherwise, insertion of two separate pacing catheters or a specialized dual-chamber pacing catheter will be necessary.
 - Single-chamber atrial pacing can also be used in many of the aforementioned situations, as long as the only conduction system abnormality is from sinus node dysfunction and not AV block.
 - Single-chamber atrial pacing may be preferred if the patient has a mechanical tricuspid valve to avoid catheter entrapment or tricuspid valve endocarditis to avoid dislodgement of the vegetation.
 - Table 3.4 summarizes the available pacing modes for temporary pacing.

Ventricular

- Most temporary transvenous pacing catheters are designed for placement in the right ventricle (RV).
 - These are constructed of a wire insulated with a polymer such as polyethylene or polyvinyl chloride and are available in various sizes.
 - In general, these catheters should be placed with fluoroscopic guidance.
 - Balloon-tipped catheters are available to allow for flow-assisted placement, which is critical if fluoroscopy is not available (Fig. 3.1).
 - Specialized pulmonary artery catheters that have dedicated pacing ports for the placement of a pacing wire electrode while still allowing for routine hemodynamic monitoring are available

Atrial

- Multiple catheter designs for atrial pacing
 - Some pacing catheters are preformed to facilitate placement into the right atrial appendage or coronary sinus, thus allowing atrial pacing.
 - A new design consists of several electrodes positioned 10 to 20 cm proximal to the distal-tip electrodes. These electrodes are positioned to lie along the lateral right atrial wall, allowing atrial sensing and pacing.
 - The vast majority of temporary pacing catheters are designed to lie against the ventricular myocardium once positioned (passive fix).
 - Newer designs, especially those for right atrial pacing, have a deployable screw that is embedded in the myocardium (active fix) (Fig. 3.2). All leads placed in the heart carry a risk of migration and perforation, but active fix leads may reduce the risk of dislodgement.

EXTERNAL PACEMAKER UNIT

- The external temporary pacemaker unit controls the pacing mode, stimulus output, stimulus frequency, and threshold for sensing intrinsic activity.
 - Pacing modes can be synchronous (demand/inhibited) or asynchronous to pace the atrium, ventricle, or both.

TABLE 3.4

COMMON PACING MODES AVAILABLE FOR TEMPORARY PACING

Mode	Chamber paced	Chamber sensed	Synchronous or asynchronous	Advantages	Disadvantages
VVI	Ventricle	Ventricle	Synchronous	Technically simple	Nonphysiologic; may exacerbate CHF
AAI	Atrium	Atrium	Synchronous	Physiologic (AV node intact)	Technically more difficult; requires intact AV nodal conduction
DDD	Atrium and ventricle	Atrium and ventricle	Synchronous	Physiologic	Technically more difficult; may require two pacing catheters
VOO	Ventricle	n/a	Asynchronous	Same as VVI	Same as VVI
AOO	Atrium	n/a	Asynchronous	Same as AAI	Same as AAI
DOO	Atrium and ventricle	n/a	Asynchronous	Same as DDD	Same as DDD

CHF, congestive heart failure; AV, atrioventricular.

FIGURE 3.1. Close-up view of the tips of the torque-guided and balloon-tipped pacing catheter.

- Range of output varies from 0 to 20 mA.
- Frequency can be adjusted from 30 to 180 beats/minute.
- Sensing threshold can be varied from no sensing (asynchronous) to <1.5 mV.

ASSESSMENT OF THE PATIENT

- A complete patient assessment must be made prior to pacemaker placement.
 - Bradycardia alone is not sufficient.

FIGURE 3.2. An example of an active fixation lead with a screw helix. (Compliments of Medtronic, Inc., Minneapolis, MN.)

- Hemodynamic instability, symptoms, or evidence of significant conduction system disease on the electrocardiogram (ECG) (bundle branch block, high-degree heart block) favors therapy.
- Reversible causes, especially medications, should be sought.
 - Glucagon may be effective for β -blocker overdose, calcium for calcium channel overdose, and digoxin immune Fab (Digibind) for digitalis glycoside overdose
 - Some bradycardias can be treated medically with agents such as isoproterenol, a β_1 -receptor agonist that increases heart rate.
 - Electrolyte abnormalities such as hyperkalemia and other adverse metabolic states, such as severe acidosis, should be corrected.

PREPARING EQUIPMENT

- All the necessary equipment should be available and inspected.
 - The external pacing unit should be programmed to the desired settings and turned to the “on” position.
 - A new battery should be installed.
 - The lead should be examined for any defects.
 - The connector cables should be inserted into the pacing generator to make sure that they are compatible.
- Continuous ECG monitoring and a defibrillator at the bedside are required.
 - Fluoroscopy is preferred but is not mandatory.

VENOUS ACCESS

- Access is obtained using the Seldinger technique.
 - Placing an introducer sheath that is large enough to accommodate the size of the pacing catheter, usually No. 4 to 7 French

TABLE 3.5

COMMON SITES FOR CENTRAL VENOUS ACCESS WHEN PLACING A TEMPORARY PACING CATHETER

Access site	Advantages	Disadvantages
Internal jugular vein	Relatively easy placement; fluoroscopy generally not necessary	Pneumothorax
Subclavian vein	Relatively easy placement; fluoroscopy generally not necessary	Pneumothorax; site commonly used for permanent pacing
Femoral vein	Relatively easy access	Leg immobilization; high risk of infection; fluoroscopy needed for placement

- Common placement sites
 - Internal jugular vein
 - Subclavian vein
 - Femoral vein
- Advantages and disadvantages of various access sites are given in Table 3.5.
- For bedside placement
 - Right internal jugular vein or left subclavian vein is the preferred site.
 - In the cardiac catheterization lab, the femoral vein is commonly used.
 - If the patient is likely to require permanent transvenous pacing, the subclavian vein should be avoided on the side of the planned permanent implantation.
 - Other potential sites
 - The basilic or cephalic veins
 - The downside is that access of these vessels usually requires a surgical cut-down approach.

PLACEMENT OF THE TRANSVENOUS PACING CATHETER

- Once the sheath is in place
 - The pacing catheter is advanced through the sheath into the venous system.
 - The lead is attached to the connector cables, inserted into the pacing unit.
 - The lead is gradually advanced under continuous electrocardiographic monitoring, with care not to use excessive force, as this may lead to perforation.
 - If performed under fluoroscopic guidance, an inferior or septal position in the distal third of the apex is preferred.
 - Apical right ventricular capture is noted by a left bundle branch, superior axis pattern.
 - If no fluoroscopy is available, a balloon-tipped catheter must be used.

- Placement into the right ventricle is confirmed by ventricular capture on the ECG with a left bundle branch block, superior axis pattern.

- Once ventricular capture is obtained, threshold testing is performed.
- The balloon is deflated to avoid advancement into the pulmonary artery.

PACE SENSING AND THRESHOLD DETERMINANTS

- With good anatomic positioning of the pacing catheter, determine a stimulation threshold
- With continuous ECG monitoring
 - Begin pacing at a rate at least 10 beats/minute faster than the patient's intrinsic heart rate.
 - Output set at 5 mA
 - Pacemaker output is gradually decreased until the stimuli fail to produce ventricular (or atrial) capture (Fig. 3.3).
 - Current setting at which capture fails to occur is the *pacing threshold*
 - Should be less than 1 mA
 - Pacemaker output should be set at three to five times the pacing threshold.
- If pacemaker is to be used in a demand mode
 - It is important that there is adequate sensing of the endocardial electrogram.
 - To ensure good sensing, the pacing rate is set lower than the patient's intrinsic rate.
 - Sensitivity of the pacing unit is set at its most sensitive level (lowest value) and is then decreased (higher values) gradually.
 - Setting at which the pacemaker fails to sense and begins pacing competitively with the patient's intrinsic rhythm is called the *sensing threshold*.

FIGURE 3.3. Loss of capture during threshold testing. Temporary pacing rate was set at 100 beats/min. Loss of capture is obvious with change in QRS morphology. *P* is the last paced ventricular beat. The patient's own rhythm comes through with loss of ventricular pacing. *R* denotes an intrinsic ventricular beat.

- For demand pacing, the sensitivity should be set at a more sensitive level than the sensing threshold.

POSTINSERTION CARE

- The electrode catheter and its introducer should be secured to the skin under sterile conditions.
- Coiling the proximal electrode catheter around the insertion site and firmly taping to the skin prevents dislodgement of the distal catheter.
- An extension cable should be used to connect the catheter electrode pins to the pulse generator.
 - The pulse generator should be secured to a location where it will unlikely be moved or disconnected inadvertently.
- The plastic shield provided with the pulse generator should be slipped over its controls to prevent accidental control movement
- Obtain a portable chest radiograph to ensure proper positioning of the pacing catheter and assess for complications, particularly pneumothorax.
- A baseline 12-lead ECG should be obtained to document the QRS morphologic features, with the pacing catheter in proper position.
 - A right bundle branch block morphology in lead V₁ with ventricular pacing may indicate pacing of the left ventricle (via an atrial septal defect, ventral septal defect, etc.) and increases the patient's risk of a thromboembolic stroke.
 - A change in the morphology of the paced QRS may be the first sign of electrode displacement.
 - Continuous electrocardiographic monitoring of the patient is imperative.
- Daily evaluation includes:
 - Inspection of the entry site, cardiac auscultation, threshold determinations, and evaluation of intrinsic rhythm
 - Complications of the pacemaker can often be determined by auscultation.
 - Pericardial friction rub may indicate ventricular penetration.
 - A clicking sound may imply intercostal muscle stimulation.
 - Marked changes in thresholds may occur with catheter movement or perforation.
 - The intrinsic rhythm can be evaluated by reducing the rate of the pacemaker until the underlying rhythm emerges.

TROUBLESHOOTING

- A stepwise approach to determine the nature of problems
 - The two most common problems are
 - Failure to capture (pacing artifact without a conducted QRS)
 - Failure to pace (no pacing artifact)
 - Common reasons for noncapture
 - Lead dislodgement
 - Lack of apposition of the catheter against tissue or cardiac perforation
 - Change in pacing threshold, or *undersensing*
 - Changes in the patient's clinical status or introduction of new medications can lead to increased pacing thresholds.

- Electrolyte abnormalities and acidosis may prevent pacing.
- Antiarrhythmic medications, especially sodium channel blockers such as flecainide or propafenone, may also increase pacing thresholds.
- Failure to pace may occur from
 - Loss of output from the pacemaker generator
 - Loss of power (low batteries) or disconnection of the pacing catheter from the generator
 - Break in the circuit
 - *Oversensing*—the inhibition of the pacemaker by events that the pacemaker should ignore
 - May be caused by electromagnetic interference in the intensive care unit, T waves, and myopotentials
- Troubleshooting begins with a thorough review of the patient's clinical status and medications.
 - Also includes the following steps:
 - Check labs to evaluate for electrolyte abnormalities such as hyper- or hypokalemia and correct any reversible causes of increased pacing thresholds.
 - Increase the output of the generator to restore capture.
 - Review the settings on the generator box for appropriate programming and to see whether the device has been turned on.
 - Replace the batteries if they are suspected to be depleted.
 - Inspect the box for any obvious abnormalities and examine the connectors from the generator to the pacing catheter for any loose connections, fractures, or insulation breaks.
 - A chest radiograph should be part of any workup for pacing problems; it is useful to evaluate for not only lead dislodgment but also pneumothorax
 - An echocardiogram may help in determining whether there is a new effusion, which may be seen if a perforation has occurred.

COMPLICATIONS

- Although the insertion of a temporary transvenous pacing catheter is generally a safe and well-tolerated procedure, there are potential complications that can occur.
- A complication can occur at any point during the procedure from the time of initial catheter insertion to the time that the catheter is finally removed.
- These include:
 - Vascular injury
 - Inadvertent arterial puncture
 - Bleeding
 - Infection
 - Cardiac tamponade
 - Tricuspid valve injury
 - Pneumothorax
 - Hemothorax
 - Air embolism
 - Phrenic nerve injury
 - Thoracic duct injury
 - Guidewire fracture
 - Thromboembolism
 - Atrial or ventricular arrhythmia
- Insertion of a temporary pacemaker in the setting of an acute MI may increase the risk of certain complications.

- Bleeding risk is increased because the patient is usually anticoagulated.
- Infarcted myocardium may be soft and necrotic, increasing the risk of cardiac perforation.
- Infarcted tissue may result in high pacing thresholds or inability to capture.
- Myocardium may be irritable, increasing the risk of arrhythmia.
- Metabolic and electrolyte abnormalities may also result in high pacing thresholds or myocardial irritability, and must be corrected.

ALTERNATIVE TEMPORARY PACING METHODS

External Noninvasive (Transcutaneous) Pacing

- External transcutaneous pacing was introduced by Zoll in 1952.
- Pacing is achieved through two large, self-adhesive electrode pads, usually placed in an anteroposterior position, which are connected to an external pulse generator.
- Successful pacing with this method has been reported to be as high as 94%.
- However, pectoral muscle stimulation is common and may require sedation.
- Reliable capture is still not as consistent as with other pacing methods.

Transesophageal Pacing

- Possible because of the posterior position of the esophagus to the left atrium
- Advantages are that its placement is relatively noninvasive and has minimum complications.
- The major disadvantage is that ventricular capture is unreliable.

- Therefore, most useful for patients who need atrial pacing only.
- This technique requires a special transesophageal pacing electrode and generator, which provide higher outputs necessary for transesophageal pacing—usually between 2 and 530 mA.
- The electrode is introduced orally or nasally and is advanced to the proximity of the left atrium.
- Optimal electrode position occurs at a location with the largest atrial electrograms.

Transthoracic Pacing

- This approach has been used successfully on many occasions, but less invasive temporary pacing techniques have made this procedure quite uncommon.
- Highly invasive technique is performed by direct percutaneous placement of pacing catheters or wires into the right ventricle through a transthoracic needle.
 - Approaching from the precordium or from the subxiphoid region
 - A needle and stylet are introduced into the right ventricle.
 - As needle and stylet are being advanced, they are connected to the V₁ lead of a standard ECG.
 - A current of injury pattern is seen upon penetration of the right ventricular wall, provided that there is no complete ventricular asystole.
 - Removal of the stylet and aspiration of blood verify intracardiac positioning.
 - A pacing catheter is then passed through the needle and the needle is removed.
 - Electrodes are connected to a standard pacing box.
 - Several complications that are potentially severe
 - Pneumothorax
 - Coronary artery perforation
 - Mediastinal bleeding
 - Cardiac tamponade
- Approach should be used **only** when other pacing options are not available.

CHAPTER 4 ■ ALTERED CONSCIOUSNESS AND COMA IN THE INTENSIVE CARE UNIT

MAJOR PROBLEMS

- Impaired consciousness is a very common neurologic problem in the ICU.
- Assessment is a complex undertaking.
- Multiple factors include:
 - Prolonged accumulation of sedative agents with impaired renal or hepatic function
 - Allowance of time for metabolism would lead to improvement
 - Hypoxic/ischemic injury to the brain more likely than commonly appreciated
 - Clinical spectrum of the neurologic aspect of critical illness

ANATOMY OF COMA

- In general, structural lesions interrupt the ascending reticular-activating system.
- System consists of the reticular formation, neuronal network that signals the thalamus, and cortex.
 - The thalamus participates in arousal.
 - Without this neuronal network, a person cannot be aroused.
 - The thalamus, through the interlaminar nuclei, maintains arousal and relays sensory, motor, and critical cortical circuits.
- Generally, altered consciousness is caused by lesions that are dorsally located in the pons and thalamus or are bihemispheric.
 - Bilateral lesions of the thalamus, bilateral white-matter lesions, or bilateral cortical lesions necessary to impair consciousness.
 - Alternatively, a hemispheric mass could produce bilateral injury when brain shift occurs or when obstructed ventricular system results in acute hydrocephalus.
- The mechanism of derangement of the brain in acute metabolic abnormalities is not well understood.
- Not uncommonly, a structural lesion is involved.
- Examples include:
 - Patients with rapid sodium correction that causes osmotic demyelination, central pontine myelinolysis, or extensive white-matter disease
 - Cerebral edema may also occur in patients with acute ketoacidosis or in those with fulminant hepatic failure.

DEFINITIONS

- Major categories of altered level of consciousness arbitrarily defined for interphysician communication
- **Acute confusional state:** Impairment of attention, inability to retain memory, and incoherent conversation. Patient not following commands, including tracking a finger
- **Delirium:** Hallucinations occur and are accompanied by signs of autonomic hyperactivity (tachycardia, hypertension, sweating). Patients may be combative, noisy, and have a markedly abnormal sleep pattern. Hallucinations can be vivid and often visual, particularly in cyclosporin toxicity.
 - Delirium tremens probably more common than appreciated. Warning signs are increased pulse to more than 120 beats/minute, systolic blood pressure more than 160 mm Hg, respiratory rate of more than 30 breaths/minute, fever, new-onset seizures, and a need for incremental doses of lorazepam or other benzodiazepines to control confusion.
- **Coma:** Unresponsive, eyes closed. Painful stimuli should not produce a localizing response to the pain stimulus, or eye opening, grimacing, or—absent an endotracheal tube—speech. The patient is unable to fixate on an object.
 - With prolonged comatose state, the patient will eventually open eyes, start to fixate on persons around the bedside, and gradually show improvement by following commands and uttering a few words
- **Persistent vegetative state:** Variation on the comatose state. Patients with pathologic motor responses—extensor (decer-

brate) posturing or flexor (decorticate) posturing—who remain comatose may open their eyes, then typically start to develop sleep–wake cycles

- Periods when patient has eyes open without fixation and periods in which the eyes are closed and the patient in a deep sleep
- No recognition of external stimuli, no meaningful expression, no visual tracking
- Brainstem function, including respiration, preserved
- If vegetative state persists 1 year after traumatic brain injury (TBI) and 3 months after anoxic ischemic injury, it is termed *permanent*.
- Anoxic-ischemic encephalopathy after CPR or asphyxia spares the brainstem but damages cortex; common cause of vegetative state
- After TBI, often some improvement in the level of consciousness
 - Termed *minimally conscious state*
 - Some communication possible, but profound disability
- **Brain death:** All brain function is lost
 - Occurs in patients with catastrophic neurologic injury, such as a sudden increase in intracranial pressure due to TBI or cerebral hemorrhage
 - Clinical diagnosis can be made, allowing for legal declaration of patient's death.
- **Locked-in syndrome:** State that mimics coma. Patients have normal consciousness but complete paralysis, except for vertical eye movements. Unable to move limbs, grimace, or swallow but able to look up and down and blink; lesion is typically in base of the pons—often an embolus to the basilar artery—with sparing of the ascending reticular formation, so consciousness unimpaired and patients fully alert

CLINICAL EXAMINATION

- Consists of two parts
 - First to evaluate in a broad manner using coma scales
 - The Glasgow Coma Scale has been used for many years and is a useful means of conducting such an examination.
 - The FOUR (Full Outline of UnResponsiveness) score—devised and validated both in emergency departments, medical, and surgical ICUs
 - Four components, each of which has 4 as the maximal grade (Figure 4.1)
 - Neurologic examination
 - Brainstem reflexes
- Pupillary responses typically present
 - Bilateral myosis often seen in patients treated with opioids.
 - Unilateral myosis represents Horner syndrome when ptosis is present.
 - Commonly reflects damage to sympathetic pathway after placement of an internal jugular (IJ) vein catheter
 - Extensive thoracic surgery or brachial plexopathies are also causes for unilateral myosis.
 - Bilateral mydriasis with good light responses due to delirium or anxiety
 - Fixed, dilated pupil indicates third cranial nerve involvement.
- Direct compression from herniated brain tissue or due to shift of brainstem in which third nerve is tethered

FIGURE 4.1. The FOUR score components are eye response, motor response, brainstem reflexes, and respiration. The eye responses are E0 for eyelids that remain closed with pain; E1 for eyelids closed but open to pain; E2 for eyelids closed but open to loud voice; E3 for eyelids open but not tracking; E4 for eyelids open or open to tracking or blinking to commands. The motor responses are M0 for no response to pain or a generalized myoclonic status epilepticus; M1 for extension response to pain; M2 for flexion response to pain; M3 for localizing to pain; M4 for thumbs up, fist, or peace sign. The brainstem reflexes are B0 for absent pupil, corneal, or cough reflex; B1 for pupil and corneal reflexes absent; B2 for pupil or corneal reflexes absent; B3 for one pupil wide and fixed; B4 for pupil and corneal reflexes present. And finally, respiration responses are R0 for breathes at a ventilator rate or apnea; R1 for breathes above ventilator rate; R2 for not intubated and irregular breathing; R3 for not intubated and Cheyne-Stokes breathing pattern; and R4 for not intubated, regular breathing pattern.

- Important clinical sign indicating brainstem distortion and the presence of a new structural mass
- Major pitfall in ICU is unilateral pupillary dilatation: can be seen with aerosolized anticholinergics and may cause alarm.
 - Mist condenses on eyelids and then touches the cornea, causing a dilated pupil
- Gaze deviation an important clinical sign.
 - Has little localizing value

- May be seen in acute hepatic or renal failure without structural brain lesion
- *Downward gaze* indicates a lesion in the thalamus or dorsal midbrain, frequently seen after hypoxic/ischemic injury
- *Gaze preference* indicates a lesion in one hemisphere, usually a lesion of frontal lobe
 - Eyes turn *toward* abnormality because one eye field is unopposed
 - *Skew deviation*, in which the eyes at rest are not lined up correctly, classic sign of a midbrain or pons lesion
- Spontaneous eye movement abnormalities
 - *Ping pong*: Horizontal conjunctive deviation of the eyes alternating every few seconds
 - *Convergence nystagmus*: Ocular divergence in slow motion followed by rapid convergent jerk
 - *Ocular bobbing*: Rapid downward conjugate movement with slow return to baseline
 - *Ocular dipping*: Slow downward conjunctive movements with rapid return
- These abnormalities indicative of bihemispheric lesion
 - Rarely observed in toxic encephalopathies
 - Motor tone
- Patient observed for the presence of rigidity or flaccidity
- Marked flaccidity often indicates poisoning or drug intoxication, critical illness polyneuropathy.
- Twitching of the face and mouth may indicate seizures.
 - More often represents myoclonus status epilepticus
 - With repetitive twitching in face, arm, and legs an important clinical sign
 - Seen in drug intoxications, after CPR
 - A poor prognostic sign
 - Localization principles
- Major categories of coma are noted in Table 4.1.
- Table 4.2 shows a systematic diagnostic approach
 - Imaging
 - After the cause of the coma state is localized on examination
- CT or MRI scans, CSF testing, or electrodiagnostic tests may be helpful.
 - MRI may help determine the immediate action to undertake.
 - MRI requires anesthesia support in many patients.
 - Abnormalities seen on neuroimaging studies of comatose patients are shown in Table 4.3
 - The EEG can be performed to detect nonconvulsive status epilepticus.
 - In which the patient has subtle eye blinking or eye movements or gaze preference associated with epileptic discharges
- Laboratory tests that should be known are shown in Table 4.4

FAILURE TO AWAKEN AFTER SURGERY

- Common problem in general or vascular surgical procedure
 - Vast majority of patients
 - Anoxic/ischemic injury or multiple infarcts are detected
 - May also be due to multiple emboli to the brain
 - Risk of embolization is most significant in patients with severe atherosclerotic disease of the ascending aorta and

From Wijdicks EFM. *Catastrophic Neurologic Disorders in the Emergency Department*. 2nd ed. Oxford University Press; 2004, with permission.

TABLE 4.2**DIAGNOSTIC APPROACH TO COMA IN CRITICAL ILLNESS**

- Chart sedative drugs and doses
- Assess function of the liver and kidneys, body temperature, serum albumin concentration, and acid-base balance
- Reconstruct plausible drug interactions
- Consider antagonists for benzodiazepines (flumazenil, 1 mg), narcotics (naloxone, 0.1–0.4 mg), and nondepolarizing muscle relaxants (neostigmine, 0.035–0.070 mg/kg, with atropine, 1 mg)
- Localize examination findings to one main category (see Table 22)
- Obtain CT scan of the brain
- Consider MRI (T₂-weighted, fluid attenuation, inversion recovery)
- Obtain electroencephalogram and somatosensory potentials (optional)
- Obtain spinal fluid for cell count, glucose, Gram stain, and cultures (optional)

CT, computed tomography; MRI, magnetic resonance imaging.

thus is applicable to patients with major cardiovascular surgeries.

- Commonly, patients do not awaken because of the accumulation of narcotic and sedative agents.
 - Many of these patients have underlying liver dysfunction that further increases accumulation of these drugs.
- Acute postoperative hyponatremia due to administration of a large volume of hypertonic fluid to patients may be a cause of failure to awaken.

Failure to Awaken after Transplantation

- Vast majority of patients
 - Delirium that may evolve to coma due to immunosuppressive toxicity
- Other reasons for loss of consciousness
 - Hypoxic ischemic encephalopathy
 - Central pontine myelinolysis
 - Air embolization
 - Acute uremia
 - Acute graft failure
 - Multiple intracranial abscesses from aspergillosis
 - Immunosuppressive agents—cyclosporin and tacrolimus—can produce a marked neurotoxicity.
 - Patients evolve from rambling speech and visual hallucinations into a stuporous stage that is associated with marked MRI abnormalities.
 - MRI often shows diffuse lesions in the white matter that are fully reversible with discontinuation of the medication.
 - Tacrolimus and cyclosporin are known offenders; sirolimus much less frequently so.
- Central nervous system infections often caused by opportunistic infections.
 - Cytomegalovirus the most common viral infection after organ transplantation.
 - Rarely results in cytomegalovirus encephalitis

TABLE 4.3**FREQUENT ABNORMALITIES ON NEUROIMAGING STUDIES IN COMA**

Findings	Suggested disorders
Computed tomography	
Mass lesion (brain shift, herniation)	Hematoma, hemorrhagic contusion, MCA territory infarct
Hemorrhage in basal cisterns	Aneurysmal SAH
Intraventricular hemorrhage	Arteriovenous malformation
Multiple hemorrhagic infarcts	Cerebral venous thrombosis
Multiple cerebral infarcts	Endocarditis, coagulopathy, CNS vasculitis
Diffuse cerebral edema	Cardiac arrest, fulminant meningitis, acute hepatic necrosis, encephalitis
Acute hydrocephalus	Aqueduct obstruction, colloid cyst, pineal region tumor
Pontine or cerebellum hemorrhage	Hypertension, arteriovenous malformation
Shear lesions in the white matter	Head injury
Magnetic resonance imaging	
Bilateral caudate and putaminal lesions	Carbon monoxide poisoning, methanol
Hyperdense signal along sagittal, straight, and transverse sinuses	Cerebral venous thrombosis
Lesions in corpus callosum, white matter	Severe head injury
Diffuse confluent hyperintense lesions in white matter, basal ganglia	Acute disseminated encephalomyelitis immunosuppressive agent, or chemotherapeutic agent toxicity, metabolic leukodystrophies
Pontine trident-shaped lesion	Central pontine myelinolysis
Thalamus, occipital, pontine lesions	Acute basilar artery occlusion
Temporal, frontal lobe hyperintensities	Herpes simplex encephalitis

MCA, middle cerebral artery; SAH, subarachnoid hemorrhage; CNS, central nervous system.

TABLE 4.4**LABORATORY TESTS IN THE EVALUATION OF COMA**

Hematocrit, white blood cell count
Electrolytes (Na, KCl, CO₂, Ca, PO₄)
Glucose
Urea, creatinine
Aspartate transaminase and γ -glutamyltransferase
Osmolality
Arterial blood gases (pH, PCO₂, PO₂, HCO₃, HbCO) (optional)
Platelets, smear, fibrinogen degeneration products, activated partial thromboplastin time, prothrombin time (optional)
Plasma thyrotropin (optional)
Blood and cerebrospinal fluid cultures (optional)
Toxic screen in blood and urine (optional)
Cerebrospinal fluid (protein, cells, glucose, India ink stain, and cryptococcal antigen, viral titers) (optional)
PO₂/PCO₂, partial pressure of O₂/CO₂; HbCO, carbon monoxide hemoglobin.

From: Wijdicks EFM. *Neurologic Complications in Critical Illness*. Contemporary Neurology Series 64. 2nd ed. Oxford University Press; 2002.

- Infection with *Cryptococcus neoformans* or *Aspergillus fumigatus*
 - Leave multiple brain abscesses and multiple intracranial hemorrhages
 - Outcome from these infections is very poor.
- Sudden loss of consciousness
 - May indicate a new onset of seizures in transplant recipients
 - Incidence in liver transplantation is about 20%.
 - In cardiac transplantation, incidence is between 10% and 15%.
 - Usually an intracranial hemorrhage or bacterial abscess is causative.
 - An acute metabolic derangement—hyponatremia or hyperglycemia—may be implicated.
 - In cardiac transplantations, it is usually associated with an ischemic stroke.

Failure to Awaken in Multisystem Trauma

- Multitrauma patients are at high risk of TBI, so close observation is important.
- May need intracranial pressure monitoring
 - Particularly if no localization to or eye opening to pain or have brainstem reflex abnormalities
- Many traumatic parenchymal lesions are localized in the frontal and temporal lobes.

- Significant risk of secondary deterioration from swelling
- Most severe circumstances: Diffuse axonal injury is present.
 - Multiple *shear lesions* in the brain
 - Typically in the frontal cortex, white matter, basal ganglia, thalamus, and internal capsule
- Rarely failure to awaken after trauma due to fat embolization syndrome
 - Patients have large bone fractures.
- Often present 12 to 75 hours after the initial traumatic injury
 - Patients often have axillary or subconjunctival petechiae.
 - Are markedly hypoxemic
 - Frequently have pulmonary edema

Management of Coma

- Initial management is determined by the presence or absence of increased intracranial pressure.
- Supratentorial mass lesion or diffuse edema (Table 4.5).
 - Placement of an intracranial pressure monitor
 - 20% mannitol solution
 - Typically administered at a dose of 0.25 to 1 g/kg
 - Goal is to increase plasma osmolality to 310 mOsm/L.
 - Decreases brain volume by extracting water from brain
 - Generated through an osmotic gradient
 - Important initial intervention and can bridge the patient to neurosurgical evacuation
 - Hypertonic saline (7.5% or 23.4%) may be more effective
 - 30-mL bolus through a central line
 - Brief (hours) use of hyperventilation, with target PaCO₂ of 30 mm Hg
 - Surgical evacuation of the mass is indicated before further brainstem compression occurs and all brainstem function is lost.

TABLE 4.5

MANAGEMENT OF ACUTE SUPRATENTORIAL MASS WITH BRAIN SHIFT

Stabilizing measures

Protect airway: Intubate
 Correct hypoxemia with O₂ nasal cannulae, 3–4 L/min, or face mask
 Elevate head to 30 degrees
 Treat extreme agitation with lorazepam, 2 mg intravenously, or propofol, 0.3 mg/kg/h
 Correct coagulopathy with fresh-frozen plasma, vitamin K (if applicable), consider factor VIIa

Specific medical measures

Hyperventilation: Increase respiratory rate to 20 breaths/min, aim for a PaCO₂ of 25–30 mm Hg
 Mannitol 20%, 0.25 to 1 g/kg; if no effect, 2 g/kg; aim for a plasma osmolality of 310 mOsm/L
 Dexamethasone, 10 mg intravenously (in tumors only)

Specific surgical measures

Evacuation of hematoma
 Placement of drain in abscess
 Decompressive craniotomy in brain swelling of one hemisphere
 PaCO₂, arterial partial pressure of CO₂

- Corticosteroids role only for edema surrounding a metastatic lesion or primary brain tumor
 - No role in closed-head injury, cerebral infarction, or cerebral abscess

Coma from an Infectious Disease Such as Acute Bacterial Meningitis

- Immediate IV infusion with antibiotics
- Empiric treatment includes:
 - Cefotaxime (2 g IV every 6 h)
 - Vancomycin (2 g IV every 12 h)
 - Corticosteroids
 - If herpes simplex encephalitis considered, acyclovir (10 mg/kg IV every 8 h) is administered.
- In most patients with an infectious cause but no clear etiologic factors, both antibacterial and antiviral treatments initiated until CSF examination reveals the true cause of infection.

Neurosurgeon's Role in the Treatment of Comatose Patients

- Removal of the mass
- Placement of a ventriculostomy, particularly in patients with a subtentorial mass or brainstem lesion
- Craniotomy to remove a bone flap can be performed to allow for swelling
 - This is an option in patients with massive middle-cerebral artery infarction or those with a swollen traumatic contusion.
- For brain abscess in the setting of organ transplantation, a drain can be placed in the abscess. The management of patients in coma from a subtentorial lesion is noted in Table 4.6.

Prognosis

- Prognosis may be determined before hospital admission.
 - Time without circulation and poor airway control may all play an important role in outcome.
 - In TBI, outcome is related to prehospital hypoxemia.

TABLE 4.6

MANAGEMENT OF ACUTE SUBTENTORIAL MASS OR BRAINSTEM LESION

Stabilizing measures

Intubation and mechanical ventilation
 Correct hypoxemia with 3 L of O₂/min
 Flat body position (in acute basilar artery occlusion)

Specific medical measures

Intra-arterial tpa (in basilar artery occlusion)
 Mannitol 20%, 0.25–1 g/kg (in acute cerebellar mass)
 Hyperventilation to PaCO₂ of 25–50 mm Hg (in acute cerebellar mass)

Specific surgical measures

Ventriculostomy
 Suboccipital craniotomy
 PaCO₂, arterial partial pressure of CO₂

- Certain neurologic conditions may be associated with no hope for good recovery:
 - Patients with myoclonus status epilepticus and brain swelling after cardiac arrest
 - Patients with multiple territorial infarcts and brain swelling after cardiac surgery
 - Occlusion of the basilar artery and coma
 - Multiple intracranial hemorrhages associated with tissue plasminogen activator (tPA)
 - Pontine hemorrhages with hypertension and extension to the midbrain and thalamus
 - Multiple hemorrhagic contusion and associated extracranial hematomas
 - Patients with gunshot wounds
 - Intraventricular extension
- In any of these circumstances, outcome is poor, and the level of care should be discussed with family members.

Brain Death

- May occur after traumatic brain injury, severe anoxic/ischemic injury, cardiac resuscitation, catastrophic intracranial hemorrhages, massive hemispheric infarcts, cerebral edema, and fulminant hepatic failure
- Brain death equivalent to death
 - Time of its determination is the time of death
- Definition of brain death implies
 - Documentation of loss of consciousness
 - No motor response to painful stimuli
 - No brainstem reflexes
 - Apnea
- Structural lesion on CT scan is commonly found
- The diagnosis of brain death is made in the following steps:
 - First, the cause has to be identified, and coma has to be irreversible.

- Major confounding factors have to be excluded, and there should be no reversible medical illness.
- Core temperature should be at least 32°C.
- No confounding pharmaceutical agents should have been administered or lingering.
- On examination
 - There is no motor response to pain applied to the face and limbs.
 - Any movement seen must be attributable only to a spinal cord response.
 - There should be:
 - Absent pupil response
 - Absent cold caloric oculovestibular response
 - Absent corneal reflex
 - Absent cough to bronchial suctioning
 - Apnea with a PaCO₂ of 60 mm Hg—or a 20 mm Hg increase from pretest baseline
 - Apnea test is done under controlled circumstances using the oxygen diffusion method.
- If patient fulfills all these criteria, brain death can be diagnosed.
- Useful to have two examinations 6 hours apart; the American Academy of Neurology considers this optional
- In younger children, electrophysiologic tests are required.

Withdrawal of Care

- Discussion of withdrawal of care must involve senior clinician to explain to the family members the findings and how they play a role in the assessment
- Palliative care includes:
 - Lorazepam and phenytoin to prevent seizures
 - Propofol to reduce myoclonus status epilepticus

CHAPTER 5 ■ BIOTERRORISM

IMMEDIATE CONCERNS

- The emergency department (ED) is the key component in protecting the hospital from contamination
 - Isolation/decontamination areas for early suspicious cases must be available to prevent dissemination throughout the facility and community
- Depending on the type of agent released.
 - Affected population may present acutely, with a large number of simultaneous cases.
 - Insidiously over a period of days to weeks.
 - Latter presentation is far more dangerous.

- May not trigger hospital defense systems.
- Resulting in a severe compromise of the facility.

KEY COMPONENTS TO BE ADDRESSED IN ANY PLAN

- Implementation of the Hospital Incident Command System (Fig. 5.1)
- Notification and coordination with public and other authorities (Fig. 5.2)
- Delineation of perimeters and facility access

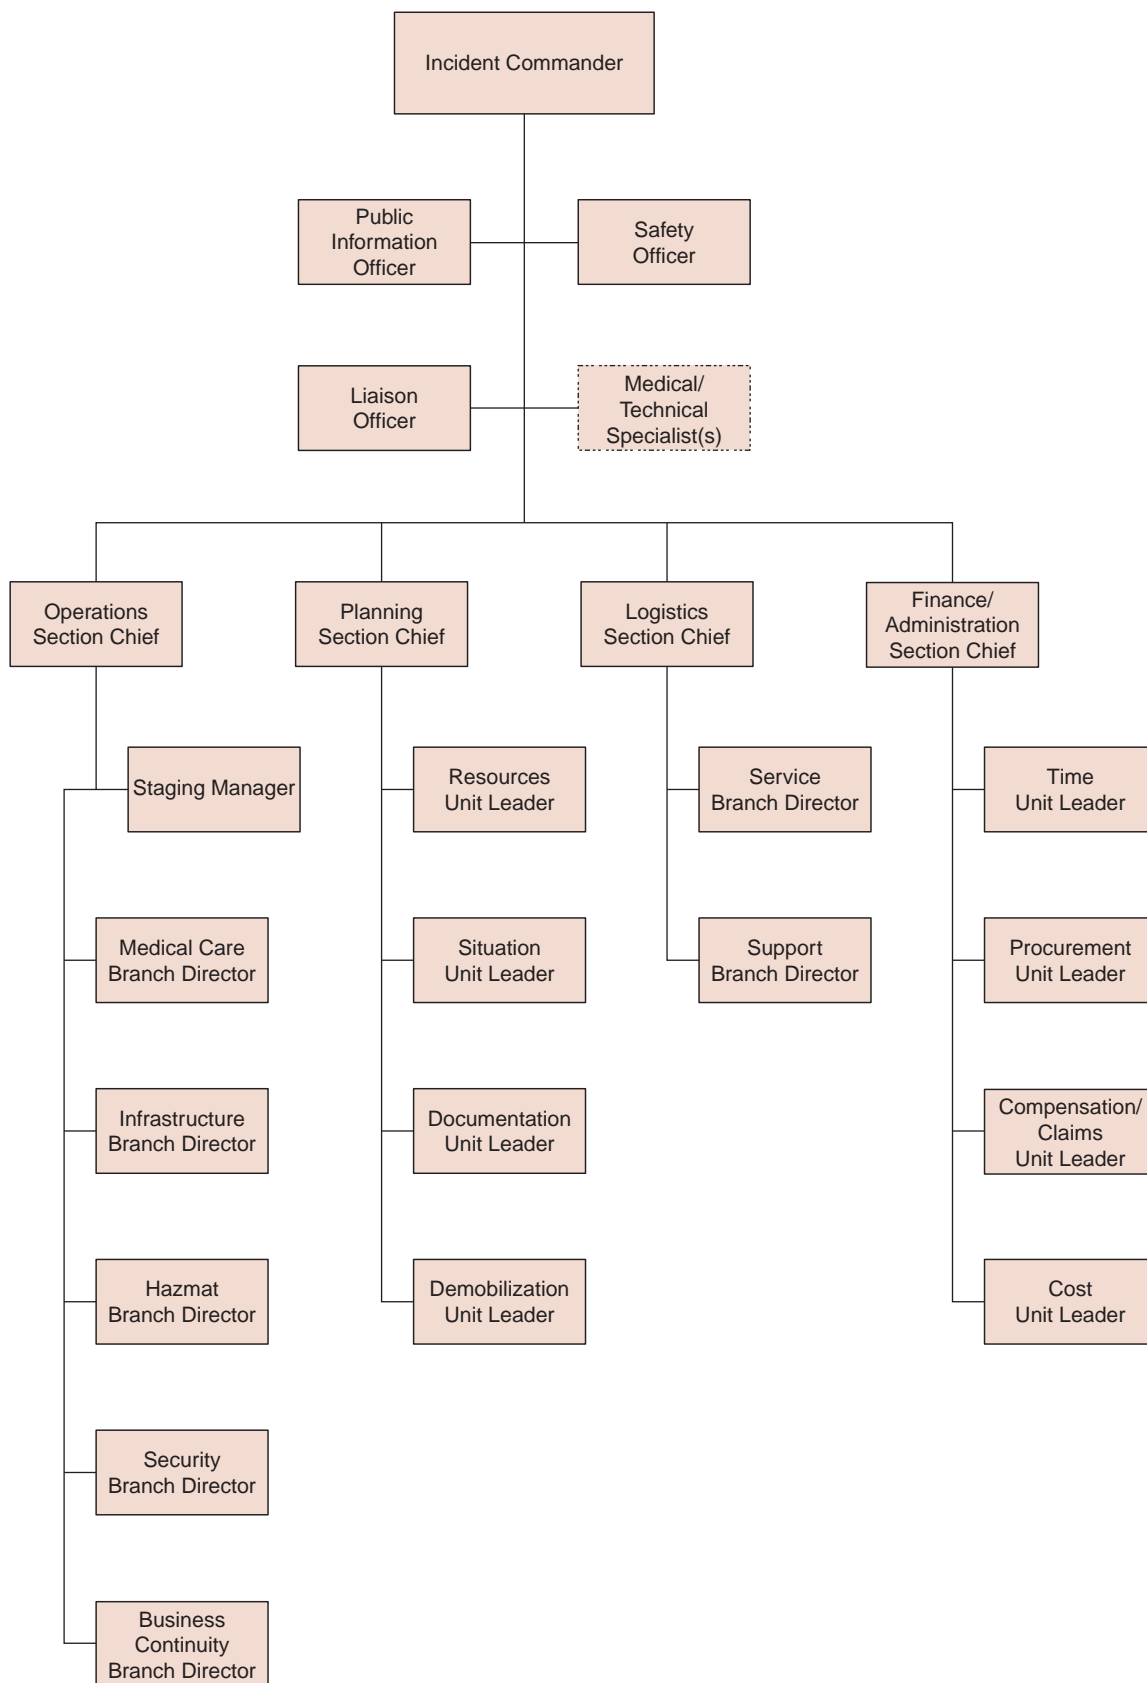

FIGURE 5.1. Basic elements of the Hospital Incident Command System. (From *HICS Guide Book* 2006: 21. http://www.emsa.ca.gov/HICS/files/Guidebook_Glossary.pdf. Accessed October 27, 2008.)

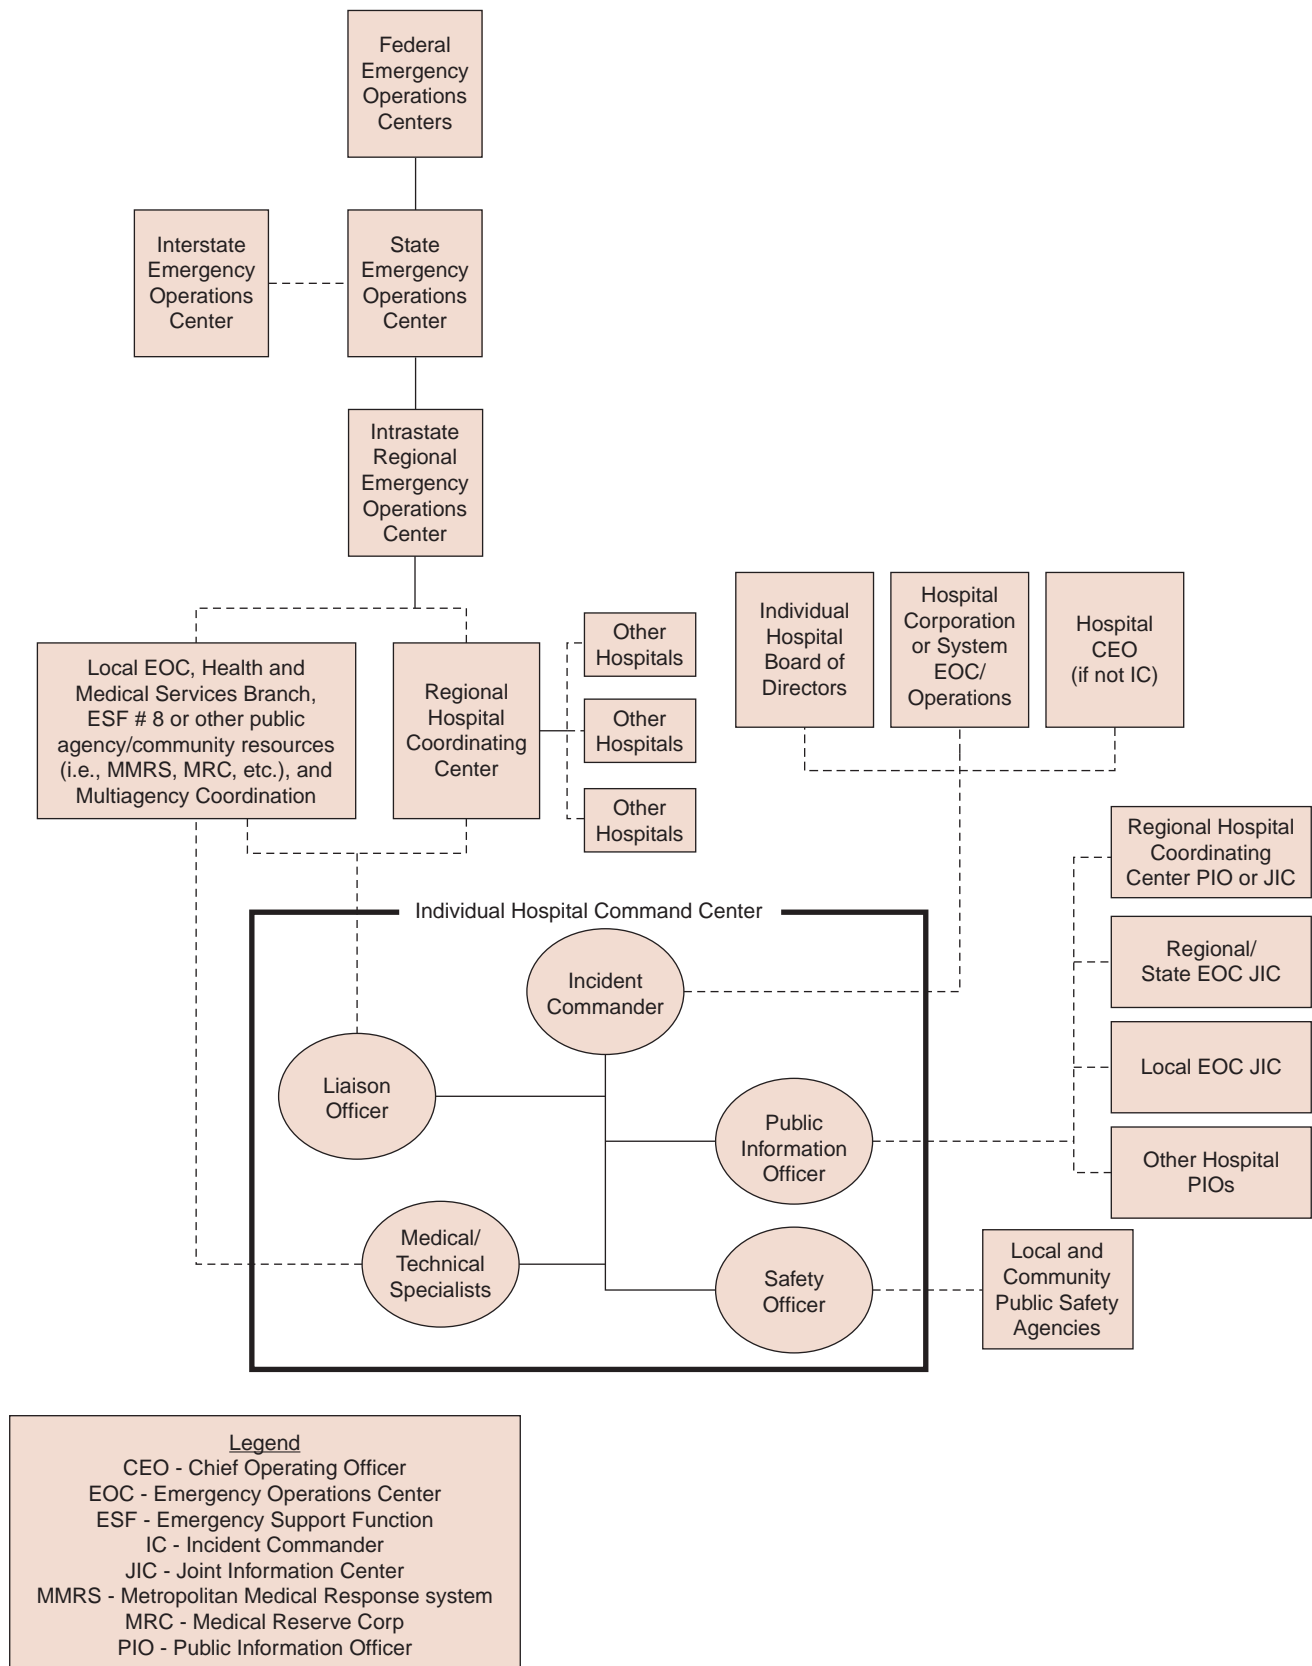

FIGURE 5.2. Diagram illustrating the potential coordination of the Hospital Incident Command System with organizations to the facility. (From *HICS Guidebook* 2006: 21. http://www.emsa.ca.gov/HICS/files/Guidebook_Glossary.pdf. Accessed October 27, 2008).

- Deployment of decontamination equipment, first receivers, and personal protective equipment (PPE)
- Distribution of surge teams, equipment, and medications
- Establishment of patient flows to designated surge areas, including discharge and transfer of patients
- Critical care equipment, designated areas, and personnel: crucial parts of the response
- Large number of these patients require a high level of support.
- Especially airway management, mechanical ventilation, and hemodynamic interventions

DECONTAMINATION AND FIRST RECEIVERS

- Process begins with the designation and enforcement of perimeters around hospital.
 - To ensure that patients flow through a predetermined corridor
 - Usually *any* patient should go through a thorough, supervised, and complete decontamination prior to accessing the inside of the facility.

Hospital Perimeters

- Hospital perimeter is divided into three areas, or zones
 - *Hot zone*: Everything outside the facility's perimeter. Patients have not been through decontamination or triage, and credentials for access have not been verified by security or screening personnel.
 - *Warm zone*: Transition zone, where decontamination and triage happens, where security personnel verify credentials and health-screening clearance for access, depending on the nature of the event
 - *Cold zone*: The "inside" of the hospital. Patients' access this zone only after decontamination is completed and verified. Health care providers are granted access after credentials and health status are corroborated.

Types of Decontamination

- **Primary decontamination**: Occurs when an individual's clothes are removed, in conjunction with showers with a low-pressure, large-volume water delivery system.
 - In colder climates, it is important to ensure warm water delivery systems and to consider of indoor or pool decontamination techniques.
 - Privacy is another major consideration that will help improve compliance by the establishment of corridors and barriers installed to protect patients' dignity after clothing has been removed for decontamination.
- **Secondary decontamination**: Performed by either health care workers following specific guidelines for nonambulatory patients or by the ambulatory patients themselves
 - Recommended that plain water, in conjunction with scrubbing, be used
 - Usually implemented very quickly to expedite the removal of the agent and decrease any possible absorption
 - Mild soapy solutions can be used for oily residues, but decontamination process should not be delayed to add soap.

- **Chemical decontamination**: Begins with the identification of the potential agent
 - Accomplished by evaluation of the clinical presentation
 - Or by using definitive colorimetric chemical identification kits similar to the military type M-8/M-9 paper, or through electrochemical sensors, radiologic detectors, surface acoustic wave technology, infrared mass spectroscopy, and/or ion mobility spectroscopy units
- **Radiologic decontamination**: The presence of radioactive material requires very specific equipment to ensure proper decontamination.
 - Multiparticulate detectors (e.g., the Geiger-Mueller counter) can be used for initial detection and to ensure adequate decontamination.
 - Extreme care should be used to prevent contamination of devices.
 - Scanning should be performed close to but without any skin contact, with a plastic disposable cover.
 - External decontamination is carried out with plain water and scrubbing and should be repeated until the skin shows no evidence of emissions.

Protective Equipment for Decontamination

- First receivers include hospital employees working at a site remote from where the "release" occurred.
 - The primary first receivers have the highest risk and, thus, require a higher level of protection.
- Levels of PPE include class A, B, and C ensembles.
 - Level A ensembles include the highest level of respiratory protection—a self-contained breathing apparatus that is worn inside vapor-protective chemical clothing.
 - Level B ensembles involve heavy-splash chemical protective clothing with the use of self-contained breathing apparatus (some PPE in this level may be encapsulated but should not be confused with the garment rating of vapor protective).
 - Level C ensembles involve light-splash chemical clothing in conjunction with either a filter cartridge face mask or powered air-purifying respirator (PAPR) in which the appropriate filter that provides respiratory protection must be used for the specific product involved within a qualified atmosphere containing an appropriate level of oxygen.
 - Level C ensembles usually suitable for hospital first receivers and consist of:
 - A chemical-resistant suit
 - Two layers of gloves
 - Chemical-resistant boots
 - A breathing device

PLANNING AND AUGMENTING RESPONSES

- In the United States, most medical facilities are functioning at full or near-full capacity during routine operations.
- Recommendations to increase capacity to respond are summarized in Table 5.1.

TABLE 5.1

PLANNING ASSUMPTIONS AND RECOMMENDATIONS FOR MASS CRITICAL CARE

Planning assumptions regarding the current critical care medicine response capacity for bioterrorism

1. Future bioterrorist attacks may be covert and could result in hundreds, thousands, or more critically ill victims.
2. Critical care will play a key role in decreasing morbidity and mortality rates after a bioterrorist attack.
3. Mass critical care could not be provided without substantial planning and new approaches to providing critical care.
4. A hospital would have limited ability to divert or transfer patients to other hospitals in the aftermath of a bioterrorist attack.
5. Currently deployable medical teams of the federal government would have a limited role in increasing a hospital's immediate ability to provide critical care to large numbers of victims of a bioterrorist attack.
6. Hospitals may need to depend on nonfederal sources or reserves of medications and equipment necessary to provide critical care for the first 48 h after discovery of a bioterrorist attack.

Recommendations for hospital planning and response for emergency mass critical care*Modifying usual standards of care*

1. Hospitals should develop a set of emergency mass critical care practices that could be implemented in the event critical care capacity of that hospital is exceeded.

Decisions regarding which critical care interventions should be provided: essential elements of critical care

2. To ensure the availability of essential critical care interventions, the Working Group recommends that hospitals give priority to interventions that fulfill the following criteria: (a) interventions that have been shown or are deemed by critical care experts' best professional judgment to improve survival and without which death is likely; (b) interventions that do not require extraordinarily expensive equipment; and (c) interventions that can be implemented without consuming extensive staff or hospital resources.
3. Hospitals should plan to be able to deliver the following during emergency mass critical care: basic modes of mechanical ventilation, hemodynamic support, antibiotic or other disease-specific countermeasure therapy, and a small set of prophylactic interventions that are recognized to reduce the serious adverse consequences of critical illness.
4. Hospitals should plan to be able to administer intravenous fluids resuscitation and vasopressor to large numbers of hemodynamically unstable victims and should stockpile sufficient equipment to do this without relying on external resources for at least the first 48 h of the hospital medical response.
5. Hospitals should plan to provide at least two widely accepted prophylactic interventions that are used every day in critical care: maintaining the head of a mechanically ventilated patient's bed at 45 degrees to prevent ventilator-associated pneumonia and thromboembolism prophylaxis.

Decisions regarding who receives critical care services

6. If there are limited hospital resources and many critically ill patients in need, triage decisions regarding the provision of critical care should be guided by the principle of seeking to help the greatest number of people survive the crisis. This would include patients already receiving ICU care who are not casualties of an attack.

Who should provide emergency mass critical care

7. In the event that critical care needs in a hospital cannot be met by intensivists and critical care nurses, usual ICU staffing should be modified to include non-intensivist clinicians and non-critical care nurses, using a two-tiered staffing model.
8. When there are inadequate numbers of intensivists, hospitals should plan for non-intensivists to manage approximately six critically ill patients and to have intensivists coordinate the efforts of up to four non-intensivists.
9. If a hospital has insufficient numbers of critical care nurses to appropriately manage patients, noncritical care nurses should be assigned primary responsibility for patient assessment, nursing care documentation, administration of medications, and bedside care (e.g., head of bed at 45 degrees, moving patient to prevent pressure ulcers), and critical care nurses should advise non-critical care nurses on critical care issues such as vasopressor and sedation administration.
10. If possible, a non-critical care nurse should be assigned to no more than two critically ill patients, and up to three noncritical care nurses would work in collaboration with one critical care nurse.
11. Bioterrorism training for noncritical care practitioners should include basic principles of critical care management.

Infection control for emergency mass critical care

12. Hospitals should develop pre-event plans to augment usual or modified airborne infection isolation capacity for critically ill victims of a bioattack with a contagious pathogen.
13. Hospitals should stockpile enough PPE to care for mass casualties of a bioterrorist attack for up to 48 h. Also, all hospital clinical staff should receive initial and periodic training on principles of health care delivery using PPE.

Where emergency mass critical care should be located

14. When traditional critical care capacity is full, additional critically ill patients should receive care in non-ICU hospital rooms that are concentrated on specific hospital wards or floors.
15. Hospitals should plan to be able to measure oxygen saturation, temperature, blood pressure, and urine output for the victims of bioattacks in emergency mass critical care conditions.

Learning during emergency mass critical care

16. Hospitals should have information technology capabilities for analyzing clinical data for patients receiving emergency mass critical care and for quickly sharing new observations with a broader clinical community.

Medications for emergency mass critical care

17. Hospitals should develop a list of drugs to stockpile for up to a 48-h response to a mass casualty event using selection criteria that include likelihood the drug would be required for care of most patients, proven or generally accepted efficacy by most practitioners, cost, ease of administration, ability to rotate into the hospital's formulary prior to expiration, and resources required for medication storage.

ICU, intensive care unit; PPE, personal protective equipment.

From Rubinson L, Nuzzo J, Talmor D, et al. Augmentation of hospital critical care capacity after bioterrorist attacks or epidemics: recommendations of the Working Group on Emergency Mass Critical Care. *Crit Care Med*. 2005;33(Suppl.):E2393.

Classification and Initial Treatment for Bioterrorism Agents

- Bioterrorism agents are classified as category A, B, or C based on:
 - Availability
 - Potential for dissemination and infectivity
 - Ability to cause events of large magnitude
 - Category A agents are the most severe

- Early warnings of a bioterrorism event, signs and symptoms of syndromes caused by biologic agents, and initial steps to take if an illness is suspected to be related to a bioterrorism activity are summarized in Table 5.2.
- Tables 5.3 and 5.4 enumerate the clinical presentations, diagnostic tests, and available treatments for category A, and categories B and C, respectively.
- Table 5.5 details dosing of drugs for treatment of potential bioterrorism agents.

TABLE 5.2

GUIDELINES FOR IDENTIFICATION OF A BIOTERRORISM EVENT

- Unusual temporal or geographic clustering of illness
 - Unusual age distribution of common disease (e.g., an illness that appears to be chickenpox in adults but is really smallpox)
 - Large epidemic, with greater caseloads than expected, especially in a discrete population
 - Disease more severe than expected
 - Unusual route of exposure
 - A disease that is outside its normal transmission season or is impossible to transmit naturally in the absence of its normal vector
 - Multiple simultaneous epidemics of different diseases
 - A disease outbreak with health consequences to humans and animals
 - Unusual strains or variants of organisms or antimicrobial resistance patterns
- A. Sentinel clues for a category A biologic agent**
- Pneumonia or influenzalike syndromes**
- Chest pain, dry cough, possible nausea, and abdominal pain, followed by sepsis, shock, widened mediastinum, hemorrhagic pleural effusions, and respiratory failure
- Gram-positive bacillus may be isolated.
Consider inhalation anthrax.
- Pneumonia associated with mucopurulent sputum, chest pain, and hemoptysis, particularly in an otherwise normal host
- Gram-negative bacillus isolated
Consider pneumonic plague.
- Bronchopneumonia associated with pleuritis and hilar lymphadenopathy, particularly in an otherwise normal host
- Gram-negative coccobacillus isolated
Consider tularemia.
- Cutaneous ulcer or ulceroglandular syndromes**
- Painless ulcer covered by a black eschar, surrounded by extensive nonpitting edema that is out of proportion to the size of the ulcer. Fever and regional lymphadenopathy may be present.
- Consider cutaneous anthrax.*
- Fever and rash syndromes**
- An abrupt, influenzalike illness with fever, dizziness, myalgias, headache, nausea, abdominal pain, diarrhea, and prostration. Evidence of “leaky capillary syndrome” with edema or signs of bleeding ranging from conjunctival hemorrhage, mild hypotension, flushing, petechiae, and ecchymoses to shock and generalized mucous membrane hemorrhage and evidence of pulmonary, hematopoietic, renal, and neurologic dysfunction
- Consider viral hemorrhagic fevers.*
- Febrile illness with myalgias, followed in 2 to 3 d by a generalized macular or papular-vesicular-pustular eruption, with greatest concentration of lesions on the face and distal extremities, including the palms. On any one part of the body (face, arms, chest), all lesions are at the same stage of development (all papules, vesicles, pustules, or scabs).
- Consider smallpox.*
- Paralytic syndromes**
- Paralytic illness characterized by symmetric, descending flaccid paralysis of motor and autonomic nerves, usually beginning with the cranial nerves
- Consider botulism.*
- B. Reporting protocols if bioterrorism is suspected as responsible for an illness**
- Establish isolation and personnel protection level.
 - Contact local public health department immediately.
 - Do not wait for confirmation.
 - Record data and order tests.
 - Alert clinical laboratory.
 - Arrange for consultations.
 - Follow hospital protocol.
 - Notify hospital epidemiologist/infection control specialist.
 - Discuss findings with all involved parties.

TABLE 5.3

BIOLOGICAL AGENTS CATEGORY A

Entity	Agent	Transmission	Minimum PPE (ideal PPE)	When to suspect	Presentation	Diagnosis	Treatment	Alternative treatment	Prophylaxis	Vaccine
Anthrax	<i>Bacillus anthracis</i>	Direct contact: Cutaneous anthrax Airborne: Inhalational anthrax (consider terrorist activity)	Standard precautions	Characteristic skin lesions Rapidly progressive pneumonia CXR: Widened mediastinum (lymphadenopathies) and pleural effusions	Pustule that progresses to a skin ulcer with black necrotic center Respiratory failure Septic shock Diarrhea	Gram stain cultures	Ciprofloxacin (1)	Doxycycline (2) + 1 or 2 additional antimicrobials	Ciprofloxacin (3) or Doxycycline (4) or Amoxicillin (if pregnant and sensitive strain)	Yes
Botulism	BoNT	Ingestion: Gastrointestinal anthrax and Oropharyngeal No person-to-person Ingestion of toxin (consider terrorist activity: water supply) Inhalation of toxin Infection with toxin production No person-to-person	Standard precautions (droplet if meningitis suspected)	Oculobulbar paralysis	Symmetric descending paralysis	Clinical BoNT detection (days)	Supportive antitoxin (early) (CDC)		Antitoxin monoclonal Ab (limited supply)	No
Plague	<i>Yersinia pestis</i>	Vector (rodent fleas) (bubonic plague) Inhalation (pneumonic plague) (consider terrorist activity) Person-to-person	Droplet (airborne)	Large inguinal and axillary lymphadenopathies (bubonic) Sepsis Unusual number of patients with a fulminant course of productive cough and pneumonia. Sepsis	Buboes DIC, sepsis Respiratory failure Pneumonia, sepsis	Gram stain Cultures Immunofluorescence	Streptomycin (5) or Gentamicin (6)	Doxycycline (2) or Chloramphenicol (7) or Ciprofloxacin (1)	Doxycycline (4) or Ciprofloxacin (3)	No

TABLE 5.4

BIOLOGIC AGENTS CATEGORIES B AND C

Entity	Agent	Transmission	Minimum PPE	When to suspect	Presentation	Diagnosis	Treatment	Alternative treatment	Prophylaxis	Vaccine
Brucellosis	<i>Brucella</i> sp.	Direct contact Ingestion (consider terrorist activity) <i>Person-to person</i> (extremely rare)	Standard precautions	Unusual number of patients with: fever, myalgias, malaise, sweats, sepsis	Nonspecific	Gram stain Blood cultures Anti-O Antibody titer ($\geq 1:160$)	Doxycycline (2) plus Rifampin (13)	Trimethoprim/sulfamethoxazole (14, 15) plus Gentamicin (6)	Doxycycline (4) plus Rifampin (13)	No
Ricin toxin	Toxin from castor bean plant <i>Ricinus communis</i>	Direct contact Ingestion Inhalation (consider terrorist activity)		Unusual number of patients with nausea, vomiting, abdominal pain, diarrhea	Gastrointestinal symptoms Hypovolemic shock Respiratory failure	Difficult Urinary ricinine (CDC) Environmental specimens to CDC for immunoassays and PCR				
Cholera	<i>Vibrio cholerae</i>	Ingestion	Standard precautions	Dyspnea, ALI, ARDS Abrupt, copious watery diarrhea	Abrupt, copious watery diarrhea Very rare abdominal pain or fever		Rehydration, aggressive Doxycycline 300 mg PO, 1 dose or Ciprofloxacin 1 g PO, 1 dose or Azithromycin 1 g PO—1 dose			Yes
Foodborne infections	<i>Escherichia coli</i> (O157:H7, enterotoxigenic) <i>Campylobacter</i> sp. <i>Salmonella typhi</i> & non-typhi <i>Shigella</i> sp. <i>Giardia lamblia</i> <i>Listeria</i> <i>monocytogenes</i> <i>Entamoeba histolytica</i> <i>Yersinia enterocolitica</i> <i>S. aureus</i> (enterotoxin B)	Ingestion	Standard precautions	Diarrhea, nausea, vomiting, fever, chills	Diarrhea, nausea, vomiting, fever, chills	Direct smear Stool cultures Blood cultures	Azithromycin (16) or Ciprofloxacin (3) or Ciprofloxacin (3) Metronidazole 500–750 mg PO tid Ampicillin 2 g IV q6h Metronidazole 500–750 mg PO tid Trimethoprim/sulfamethoxazole (15) Supportive Various other antibiotics		Ceftriaxone (16) Azithromycin (16) Paromomycin (16) Paromomycin (16)	No
Glanders	Others... <i>Burkholderia mallei</i>	Direct contact Ingestion Inhalation <i>Person-to-person</i>	Standard precautions Droplet in pulmonary cases	Massive numbers of patients with similar clinical presentation	Localized infection Pulmonary infection Bloodstream infection Chronic infection (extremities, spleen or liver)	Skin cultures Sputum cultures Blood cultures Urine cultures	Trimethoprim/sulfamethoxazole (14)	Tetracyclines (16) Ciprofloxacin (16) Streptomycin (16) Imipenem (16) Cefazidime (16)		No
Melioidosis	<i>Burkholderia pseudomallei</i>	Direct contact Ingestion Inhalation <i>Person-to-person</i>	Standard precautions Droplet in pulmonary cases	Massive numbers of patients with similar clinical presentation	Acute localized infection Pulmonary infection Acute bloodstream infection Chronic suppurative infection	Skin cultures Sputum cultures Blood cultures Urine cultures	Trimethoprim/sulfamethoxazole (14) or Cefazidime (16)	Imipenem (16) Meropenem (16) Chloramphenicol (16)		No

PPE, personal protective equipment; ALI, acute lung injury; ARDS, adult respiratory distress syndrome; CDC, centers for disease control; PCR, polymerase chain reaction.

(Accessed 1–5–08)

TABLE 5.5**TREATING AGENTS**

1. Ciprofloxacin	
Adults	400 mg IV q12h
Pregnancy	400 mg IV q12h
2. Doxycycline	
Adults	100 mg IV q12h
Pregnancy	100 mg IV q12h
3. Ciprofloxacin	
Adults	500 mg PO bid
Pregnancy	500 mg PO bid
4. Doxycycline	
Adults	100 mg PO bid
Pregnancy	100 mg PO bid
5. Streptomycin	
Adults	1 g IM q12h
6. Gentamicin	
Adults	5 mg/kg IM or IV q24h
Pregnancy	5 mg/kg IM or IV q24h
7. Chloramphenicol	
Adults	25 mg/kg IV q6h
8. VIG	
Adults	0.6 mL/kg IM
9. VIGIV	
Adults	100 mg/kg IV at rate: 1 mL/kg/h for 30 min, then 2 mL/kg/h for 30 min, then 3 mL/kg/h for 30 min
10. Cidofovir	
Adults	5 mg/kg IV over 1 h
11. Ribavirin	
Adults	30 mg/kg IV loading dose 16 mg/kg IV q4h for 4 d, then 8 mg/kg IV q4h for 6 d
12. Ribavirin	
Adults	500 mg PO q6h for 7 d

Note: These are starting doses for adults only; for length of therapy, pediatric therapies, and further indications, consult with health authorities or infectious disease specialists.

- If possible, the ICU area designated should be turned into a negative-pressure environment.
- Patient rooms should function as negative-pressure areas either by design or by installing portable negative-pressure units.
- Entire ICU is a “warm” zone, where all staff—including medical, nursing, respiratory therapy, secretarial, and housekeeping—wear a basic layer of PPE that includes
 - Scrubs
 - Gown
 - Gloves, with longitudinal taping
 - N-95-type mask
 - Nonabsorbent-material shoes
- Donning and doffing of PPE should follow a checklist (Table 5.7).
- If a patient’s room needs to be accessed for routine care **not** resulting in the generation and dispersion of aerosols, a second layer of PPE is recommended.
 - Eye protection (taped goggles)
 - Hair-covering device (hair net or hat)
 - A second gown
 - A second layer of gloves, with longitudinal taping
- If patient’s room needs be accessed where there is a **high risk** for aerosolization of secretions (e.g., the use of bag-valve-mask, endotracheal intubation, open-circuit suctioning, bronchoscopy, or disconnection from ventilator), a higher level of PPE should be used.
 - PAPR
 - The second layer noted earlier
 - The PAPR used indoors in the ED or ICU should be of a light material and should not be confused with the PAPR used in decontamination lines at the entrance of the hospital.
- The doffing (removal) of the PPE is probably—and remarkably—the most important phase.
 - The likelihood of contamination increases significantly if procedures are not properly followed (see Table 5.7).

Classification and Initial Treatment for Chemical Agents

- The chemical agents are divided into five different groups (Table 5.6).
 - Nerve agents: Anticholinesterase activity
 - Asphyxiants or blood agents: cyanide-based
 - Choking or pulmonary-damaging agents: direct airway cytotoxicity
 - Blistering or vesicant agents: direct skin cytotoxicity; may also affect airway
 - Incapacitating agents: for riot control

PERSONAL PROTECTIVE EQUIPMENT IN THE INTENSIVE CARE UNIT

- The Society for Critical Care Medicine (SCCM) and the World Federation of Societies of Intensive and Critical Care Medicine have adopted new recommendations for PPE.

VENTILATOR TRIAGE

- Distribution of mechanical ventilators requires evaluation when demand exceeds availability.
- Well-defined, objective criteria need be used for their assignment (Table 5.8).
- In a major mass casualty incident (MCI), where the number of patients far exceeds the available resources
 - Imperative to utilize a protocol with easy-to-follow tools, with clear definitions based on objective criteria
 - Sequential organ failure assessment (SOFA) may be used as the base for the initial classification of patients.
 - With follow-up at 48 and 120 hours
 - Once a patient has passed the inclusion and exclusion criteria, the SOFA-based initial (Tables 5.9) and 5.10) evaluation is performed.
 - There are repeat evaluations at 48 and 120 hours (Tables 5.11 and 5.12, respectively).

TABLE 5.6

CHEMICAL AGENTS

Type	Acronym	Other name	Military detection	Classic findings	Other signs and symptoms	Decontamination	Treatment	Miscellaneous
Nerve	GA	Tabun	M256A1	Miosis	Blurred vision	Remove clothing	Atropine	In high exposures: Unconsciousness Flaccid paralysis
	GB	Sarin	CAM	Sialorrhea	Headache	Gently wash skin	2 mg IV/IM every 5 min	
	GD	Soman	M8 paper	Rhinorrhea	Nausea and vomiting	(avoid abrading skin)	Repeat as needed based on symptoms	
	GF	Cyclohexyl sarin	M9 paper	Fasciculation	Sialorrhea	Flush eyes with water or saline	Pralidoxime 600–1,800 mg IM or 1 g IV (max 2 g/h)	
	VX	Methylphosphonothioic acid	M8A1 alarm M8 alarm		Diaphoresis Diarrhea Seizures Dyspnea		MARK-I kit contents: AtroPen—atropine sulfate 2 mg in 0.7 mL ComboPen—pralidoxime chloride (2-PAM) 600 mg in 2 mL Benzodiazepines for seizures Oxygen Ventilatory support	
Blood/asphyxiant	AC	Arsine	M256A1 Ticket	Cherry-red skin	Few; Giddiness	Remove clothing	Oxygen	Metabolic acidosis Venous oximetry above normal Arsine and cyanogen may cause delayed pulmonary edema
	CK	Hydrogen cyanide Cyanogen chloride	NOT—M8A1 NOT—CAM	or Cyanosis or Frostbite (when applied in liquid form)	Palpitations Dizziness Nausea and vomiting Gasping Hyperventilation Drowsiness Seizures (terminal)	(if no frostbite) Gently wash skin (avoid abrading skin) Flush eyes with water or saline	<i>Antidotes:</i> Amyl nitrate by inhalation 1 amp (0.2 mL) every 5 min Sodium nitrate 300 mg IV over 5–10 min Sodium thiosulfate 12.5 g IV over 10–20 min Repeat sodium nitrate based on patient's weight and hemoglobin level

TABLE 5.7

PERSONAL PROTECTIVE EQUIPMENT (PPE): DONNING AND DOFFING AND ENHANCED AIRBORNE PRECAUTIONS WITH POWERED AIR-PURIFYING RESPIRATOR (PAPR)^a

Prior to entering the room

(For leaving the room, proceed to step VI)

Step I

The following articles must be put on in the anteroom. If there is no anteroom, they should be donned prior to entering the ICU

1. Properly fitted N-95 mask (minimum)
2. Impervious isolation gown
3. Gloves (place two strips of tape onto the glove and the gown, one anterior and one posterior)

Step II

Routine-care PPE (second layer)

The following articles are to be worn in addition to PPE in step I, prior to entering the patient's room for *routine* patient care

WARNING: If you anticipate aerosolization of secretions (e.g., endotracheal intubation, cardiac arrest, tracheostomy, bronchoscopy, endotracheal tube exchange), skip this section and *proceed to steps III, IV, and V* prior to entering the room

1. Disposable goggles (place a strip of tape onto goggles and forehead)
2. Second impervious isolation gown (see picture 2 on PAPR sheet)
3. Second set of gloves (place two strips of tape onto the glove and the gown, one anterior and one posterior; see picture 3A,B on PAPR sheet)
4. Hair net or hat (optional)

You may now enter the room for routine care

Step III

Testing the HEPA filter and electric pump battery efficiency

1. Attach breathing tube (black) to the air pump/filter/battery (PAPR) assembly box (gray) with a twist-and-lock motion
2. Turn the power switch ON
3. Check airflow by inserting floater cone inside the free end of the black tube. Floater device should remain suspended, with the lower indicator line *not* touching the tube's end. This indicates proper functioning of the unit. If cone does not float, *do not use this unit* and send for servicing
4. Turn the power switch OFF and set unit aside.

Step IV

Donning the hood (*requires assistance*)

1. Secure long hair
2. Put on a hair cover (optional)
3. Peel off protective layer from face shield
4. Attach breathing tube to the top of the hood; a snap should be heard
5. Place the pump/filter/battery assembly (gray) (PAPR) box around waist and adjust belt. Leave the box in the back
6. Turn the power switch ON
7. Ensure the breathing tube is free from twists, kinks, or damage
8. With assistance, put hood on, face first. Ensure that the elasticized edge of the face seal is under the chin and along the cheeks. Ensure the N-95 mask remains securely in place (4)
9. Center inner headband around forehead and verify that straps on top of the hood are in contact with the top of the head

Step V

PAPR PPE (second layer)

1. Lift the outer shroud of the hood
2. Put on a second impervious isolation gown, ensuring that it covers the inner shroud *only* (5)
3. Allow the outer shroud to cover the top portion of the isolation gown
4. Apply second pair of gloves (place two strips of tape onto the glove and the gown, one anterior and one posterior)

You may now enter the room to perform procedures where aerosolization of secretions are anticipated.

Prior to leaving the room

Step VI

Removal of routine-care PPE

1. Grasp front of second isolation gown (top layer) with both hands and pull forward to remove from shoulders
2. Remove second isolation gown with taped gloves as one unit, as you roll inside out, prior to discarding
3. Remove disposable goggles, grasping above the ear. *Do not* touch the frame area around the eyes. Discard goggles

Step VII

Removal of PAPR PPE (*requires assistance*)

1. Second person detaches breathing tube from the assembly unit and turns OFF unit
2. From the outside, grasp the hood at the top of the head and under chin simultaneously and remove hood
3. Dispose of hood respirator and breathing tube
4. Second person unties second isolation gown (top layer)
5. Grasp front of second isolation gown with both hands and pull forward to remove from shoulders.
6. Remove second isolation gown with taped gloves as one unit, as you roll inside out, prior to discarding
7. Remove air pump/filter/battery assembly box and place inside double plastic bags while in the room
8. Exit the room, maintaining the first PPE layer (N-95 mask, hair net, goggles, and gown); bring the double-bagged air pump/filter/battery assembly box for processing

ICU, intensive care unit.

^aThe following guidelines are intended to illustrate a suggested donning and doffing sequence for enhanced airborne precautions, using the 3M BE-10 Series PAPR. They are not intended to substitute the recommendations of the Infection Control or Critical Care Groups of your institution. Please refer to the manufacturer's instructions for further details of assembly, handling, and cleaning.

TABLE 5.8

VENTILATOR AND INTENSIVE CARE TRIAGE TOOL

Inclusion criteria

The patient must meet one of either criteria A or B

A. Requirement for invasive ventilatory support

- Refractory hypoxemia ($\text{SpO}_2 < 90\%$ on nonrebreather mask/ $\text{FiO}_2 > 0.85$)
- Respiratory acidosis with $\text{pH} < 7.2$
- Clinical evidence of impending respiratory failure
- Inability to protect or maintain airway

B. Hypotension

Hypotension (systolic blood pressure [SBP] < 90 or relative hypotension) with clinical evidence of shock (altered level of consciousness, decreased urine output, or other end-organ failure) refractory to volume resuscitation requiring vasopressor/inotrope support *that cannot be managed on the ward*

Exclusion criteria

The patient is excluded from admission/transfer to critical care if *any* of the following (*) is present:

*Severe trauma (defined by each center based on their experience with the Injury Severity Score [ISS], Trauma and Injury Severity Scoring system [TRISS], or similar)

*Severe burns

A patient with any two of the following:

- i. Age > 60 years
- ii. Total body surface area (TBSA) $> 40\%$
- iii. Inhalation injury

*Cardiac arrest

*Unwitnessed cardiac arrest

*Witnessed cardiac arrest not responsive to electrical therapy (defibrillation, cardioversion, or pacing)

*Recurrent cardiac arrest

*Severe cognitive impairment

*Advanced untreatable neuromuscular disease

*Metastatic malignancy

*Advanced and irreversible immunocompromise

*Severe and irreversible neurologic event/condition

*End-stage organ failure meeting following criteria:

*Cardiac:

- i. New York Heart Association (NYHA) class III or IV heart failure

*Lung:

- i. Chronic obstructive pulmonary disease (COPD) with forced expiratory volume in 1 second (FEV_1) $< 25\%$ predicted, baseline $\text{PaO}_2 < 55$ mm Hg, or secondary pulmonary hypertension
- ii. Cystic fibrosis with post-bronchodilator $\text{FEV}_1 < 30\%$ or baseline $\text{PaO}_2 < 55$ mm Hg
- iii. Pulmonary fibrosis with vital capacity (VC) or total lung capacity TLC $< 60\%$ predicted, baseline $\text{PaO}_2 < 55$ mm Hg, or secondary pulmonary hypertension
- iv. Primary pulmonary hypertension with NYHA class III to IV heart failure, or right atrial pressure > 10 mm Hg, or mean pulmonary arterial pressure of > 50 mm Hg

*Liver

- i. Child Pugh score > 7

*Age > 85 years

*Requirement for transfusion of > 6 units packed red blood cells within 24-h period

*Elective palliative surgery

SECTION II ■ CARDIOVASCULAR MONITORING: INVASIVE AND NONINVASIVE

CHAPTER 6 ■ INVASIVE PRESSURE MONITORING: GENERAL PRINCIPLES

PRINCIPLES OF ARTERIAL WAVE TRANSMISSION

Natural Frequency

- A pressure wave travels down the conducting tubing and deflects the transducer diaphragm, which rebounds and generates a reflected wave. When this reflected wave reaches the tip of the catheter, another reflected wave travels back toward the transducer.
- The *natural frequency* (f_n) of a system is the frequency at which a signal, such as a change in pressure, will oscillate in a uniform, frictionless tube. This frequency is measured in hertz (Hz) cycles per second. Natural frequency decreases with increasing tube length, since at any given wave speed, a round trip in a longer tube simply takes more time.
- Natural frequency increases with wave speed, which in turn increases with tube radius and tube wall stiffness and decreases with the density of the conducting medium. Thus, short, wide, rigid tubing; a stiff transducer; and dense conducting media (e.g., saline rather than air) yield a higher f_n .

Damping

- The friction generated by the movement of the conducting medium decreases the amplitude of the reflected pressure wave, or *damps* it. Stiffer transducer diaphragms and stiffer conducting tubing will result in less damping as smaller volumes are required to displace them. Damping is also influenced by the mass of the conducting medium and tubing resistance, which impedes the minute amount of reciprocative flow needed for pressure wave transmission, causes dissipation of energy from the pressure wave, and increases damping.

TROUBLESHOOTING

- Simplicity and uniformity in transducer and catheter setup are key to minimizing opportunity for errors. Tubing should be stiff tubing designed for pressure monitoring, used with a minimum length and few stopcocks and connectors.

Zeroing

- A common source of error is the zero reference level for pressure measurement. All pressures are measured relative to the horizontal plane at which the transducer is set to zero.

When the transducer is connected to a fluid-filled catheter, any hydrostatic pressure imposed by the catheter will be sensed by the transducer. The recorded pressure will rise as the transducer is lowered, and vice versa. This continues to occur when the catheter is attached to a patient.

- Most agree that vascular pressure should be referenced to the level of the heart; that is, the recording system should read zero pressure when the open end of a transduced fluid-filled tube is held at the horizontal plane of the heart. The optimal external anatomic landmark representing this plane remains a subject of debate. Many suggest the midaxillary line, but others have recommended estimation of the uppermost boundary of the heart. For simplicity and uniformity, the midaxillary line is best for general use.
- This anatomic reference level should be on the same horizontal plane, not of the transducer diaphragm but of the port or stopcock that is opened to atmospheric pressure when the electronics are zeroed. One simple way to provide consistency is to secure the transducer to the patient's arm near the heart and zero it using the port molded into the transducer body. This will allow fewer errors than attaching the transducer to an IV pole, in which case elevating the bed or sitting the patient up will change his or her horizontal relationship to the zero point. However, re-zeroing to the cardiac level will be needed when patient orientation is changed (such as lateral decubitus or prone positions). Care must also be taken that the transducer has not rotated to a dependent position on the arm or slipped to the elbow in a patient who is anything but completely flat.

Testing the Frequency Response

- Intensive care units, operating rooms, and other monitoring settings combine various components from various manufacturers into their systems for vascular pressure measurement. The parts may vary between units or perhaps even from patient to patient or nurse to nurse and will change as suppliers change over time. The performance specifications of individual components such as transducers and amplifiers are provided in their user manuals, but the performance of the integrated system is usually untested.
- Fortunately, the catheter-tubing-transducer system allows simple bedside study. By using the flush device, one can apply a near square-wave pressure signal, and the features of the recorded output can be examined. When the flush device resistor is bypassed, a high-pressure signal is produced, which goes off-scale on the bedside monitor. When the lever is released, however, a square-wave low-pressure signal is

generated, which falls within the range of the display. Proper functioning is indicated when this signal rapidly reverberates a few times and then decays back to the underlying vascular pressure.

Overdamping and Underdamping Errors

- Overdamping is a common problem that causes errors in the measurement of systolic and diastolic pressure. Overdamping is suggested during a bedside flush test by a gradual pressure decay or an undershoot and slow return to baseline without any oscillation. The effect of overdamping on the waveform is to first cause the wave to lose details such as the dicrotic notch and a brisk systolic upstroke, or the a, v, and c waves of a venous pressure. With more damping, the wave will appear sinusoidal, systolic pressure will fall, and diastolic pressure rise toward the mean arterial pressure. Even with extreme overdamping, the mean pressure remains accurate.
- Numerous problems in the catheter–tubing–transducer system can cause overdamping. These include air bubbles, blood clots, or fibrin within the catheter or tubing, catheter tips abutting a vessel wall, or kinks or partially closed stopcocks. Flushing or changing the tubing and obsessively purging air bubbles solves many overdamping problems. If the damped waveform is associated with kinking or thrombosis of the catheter, poor blood return, or sensitivity to minor catheter movement, it may need replacement.
- In tachycardic, hyperdynamic patients, excessive oscillation may be apparent in the pulse recording, especially at peak systole. This problem occurs when important harmonics of the pulse approach the transducer system's f_d . Underdamping causes systolic and diastolic pressure to be over- and underestimated, respectively. The excessive oscillations will also interfere with the algorithms used to calculate a digital display of systolic and diastolic pressure. Even manual estimation of these pressures from the bedside oscilloscope or printed record is inaccurate, since the pulse pressure is exaggerated.
- The characteristics of the transducer system can be studied and optimized to reduce under-damping errors. During observation of a fast flush, oscillations that are widely spaced indicate a low f_d , which may poorly suit a patient whose pulse is dynamic with upper harmonics of high amplitude. Natural frequency is reduced by lengthy or compliant tubing or by bubbles. Removing unneeded tubing extensions and diligently clearing bubbles will bring the flush test oscillations closer together, and the waveform will show more detail with greater accuracy.
- The reverberations in the pulse can be smoothed away by injecting a tiny bubble of air into the transducer or catheter. However, this practice is not recommended. While the air bubble will increase the damping, it also decreases f_d . The waveform will be made to appear more normal but may be no more accurate. If larger bubbles are introduced, the excessive damping causes the pulse pressure to narrow toward the mean arterial pressure. One would like to increase the damping of the system without decreasing its natural frequency. This effect can be achieved by reducing the amplifier high-pass filtration frequency just enough to eliminate the reverberations, as is outlined in most monitoring equipment users' manuals. Too much electronic damping will degrade the waveform just as would excess mechanical damping. Filtering should generally not be reduced below 12 Hz to avoid removing the higher-order harmonics contributing to the systolic waveform. There are also mechanical devices that attach to a stopcock near the transducer and increase damping. These devices are designed to match the transducer impedance to that of the tubing, decreasing wave reflections without altering f_d .
- Artifact that appears similar to under-damping can also occur when long, flexible catheters are vibrated by high-velocity blood flow, termed "catheter whip." This phenomenon should be suspected when long intravascular catheters are used in high-flow vessels of much larger diameter, such as long femoral or pulmonary artery catheters. Contributions of under-damping to the waveform appearance can be ruled out by inspecting the fast flush and optimizing the external tubing system. Artifact due to movement of the catheter tip is difficult to eliminate. In the pulmonary artery, stabilizing the catheter tip by inflating the balloon to measure a pulmonary artery occlusion pressure will remove the "whip." Measurement of mean pressures will also remain accurate.

CHAPTER 7 ■ HEMODYNAMIC MONITORING: ARTERIAL AND PULMONARY ARTERY CATHETERS

CLINICAL USE OF ARTERIAL LINES

Pressure Measurement

- Continuous measures of systolic blood pressure (SBP), diastolic blood pressure (DBP), and mean arterial pressure (MAP) are displayed with invasive arterial catheters.
- Waveform analysis (Fig. 7.1) demonstrates the typical points associated with (a) systolic upstroke, (b) systolic peak, (c) systolic decline, (d) dicrotic notch, (e) diastolic runoff, and (f) end diastole. Examination of the arterial waveform provides useful information regarding a patient's clinical status. Left ventricular ejection produces the first, sharp upstroke at the beginning of aortic valve opening (see Fig. 7.1, points 1 and 2). As the ventricular flow is dispersed peripherally, the waveform declines (point 3); this is also when the heart is in isovolumetric relaxation and diastolic filling. Just prior to closure of the aortic valve and as a result of isovolumetric relaxation, there is a slight drop in pressure known as the incisura (at the aorta) or dicrotic notch (at the periphery; point 4). Further decrease in the pressure waveform reflects the runoff to distal arterioles (points 5 and 6). More peripheral arteries exhibit narrower waveforms and higher systolic pressures and wider pulse pressures, although the MAP remains similar to central vessels. The etiology of varying pulse contours in the periphery is related to the elasticity, amplification, and distortion of smaller arteries.
- Various cardiac conditions produce characteristic arterial waveforms. In aortic stenosis, narrow waveform and loss of the dicrotic notch secondary to diseased valve are seen. Aortic

FIGURE 7.1. Arterial waveform analysis (see text for explanation of points 1–6).

regurgitation may exhibit widened pulse pressures and a sharp upstroke, sometimes accompanied by two peaks.

- Arterial cannulation is relatively safe, with nonocclusive thrombosis and hematoma being the most common complications. Selection of anatomic site is an important consideration; percutaneous arterial catheters can be introduced in the radial, brachial, axillary, femoral, and dorsalis pedis arteries. Placement in brachial arteries is ill advised; it is an end artery, and patients may develop ipsilateral hand ischemia in up to 40% of insertions. The radial artery remains the most popular placement site due to its ease of access and relatively low complication rates. A pre-procedure Allen test assesses the patency of collateral arteries, but this test has poor correlation with distal flow and likelihood of hand ischemia.

Systolic Pressure Variation

- Variations in systolic blood pressure and ventricular stroke volume are of greater magnitude in hypovolemic states. Originally, SPV was described as two components (Fig. 7.2): delta up (Δ up) and delta down (Δ down)—while emphasizing the strong correlation between Δ down and hypovolemic states. Δ up is the difference between maximum SBP and a reference SBP (usually at expiratory pause during mechanical ventilation). Δ down is similarly the difference between minimum SBP and reference SBP and represents a decrease in stroke volume during expiration. SPV >0 mm Hg indicates hypovolemia and suggests responsiveness to fluid challenge. SPV also has significant correlation with the left ventricular end-diastolic area by echocardiogram and pulmonary artery occlusion pressure (PAOP). Note that SPV, like stroke volume variation, may be sensitive to changes in volume status but may not necessarily equate to actual intravascular blood volume.

STROKE VOLUME VARIATION

- Arterial pressure variation during the respiratory cycle is a well-documented phenomenon. Pulsus paradoxicus describes falls in arterial pressures (>0 mm Hg) during inspiration and rises in pressures during expiration in spontaneously breathing patients. Reverse pulsus paradoxicus occurs in ventilated patients. Stroke volume variation (SVV) is not a measurement of absolute preload; rather, it is an assessment of response to fluid resuscitation. SVV $>9.5\%$ to 15% is associated with fluid responsiveness. SVV is approved for use only in sedated, mechanically ventilated patients who are in sinus rhythm

FIGURE 7.2. Systolic pressure variation (SPV) (see text).

(rhythm must be regular or the variation may be due to irregular rate rather than volume status).

$$SVV = \frac{(SV \text{ maximum} - SV \text{ minimum})}{[(SV \text{ maximum} + SV \text{ minimum})/2]} \times 100$$

PULMONARY ARTERY CATHETER

- Inherent in the use of the pulmonary artery catheter (PAC) is the assumption that flow-related variables such as cardiac output/cardiac index and oxygen delivery (DO_2) to the tissues are important for survival. The biggest criticism of the supply dependency concept was the mathematical coupling between DO_2 and VO_2 as cardiac output is on both sides of the equation. An easier clinical end point of resuscitation is the central ($ScvO_2$) or mixed venous oxygen saturation (SvO_2) or which reflects the balance between DO_2 and VO_2 .
- Review of all the literature studying resuscitation to CI, DO_2 , and SvO_2 goals is summarized in the practice guidelines for the PAC. The controversy is not whether DO_2 is important to

tissues but rather *how much* is necessary to meet the demands of individual tissues. It is also clear that global values of DO_2 may not translate into transport of oxygen to the individual tissue beds, but until we have a tool to measure all tissue oxygenation states (or one tissue bed that is a surrogate marker for the rest of the body), the amount of oxygen delivery necessary for tissue perfusion will remain controversial.

- Over the decades, clinicians have progressed from treatment of BP, HR, and urine output to markers of anaerobic metabolism such as lactic acid and base deficit and then to flow-related variables such as DO_2 , VO_2 , and SvO_2 .

INDICATIONS FOR PULMONARY ARTERY CATHETER INSERTION

- Indications for PAC insertion have been broadly categorized in Table 7.1.

TABLE 7.1

INDICATIONS FOR PULMONARY ARTERY CATHETER INSERTION

Precautionary reasons

For prevention of multisystem organ failure in high-risk patients (perforated viscus)
 For preoperative assessment of high-risk patients with cardiac, pulmonary, and renal dysfunction
 For management of high-risk patients postoperatively (major hemorrhage)
 For patients with expected large fluid shifts: sepsis, bleeding, multiple trauma, burns, and cirrhosis

Treatment of shock

Hypotension not relieved with fluid
 Suspected cardiac event or cardiac compromise contributing to shock
 Oliguria not responding to fluid
 Patients with multiple organ dysfunction
 For continuous SvO_2 monitoring

To guide treatment in pulmonary dysfunction

To differentiate cardiogenic causes of hypoxia from acute respiratory distress syndrome and guide fluid management
 For monitoring cardiac output in patients requiring high positive end-expiratory pressure (≥ 15 cm H_2O)

Treatment of cardiac dysfunction

Complicated myocardial infarction
 Congestive heart failure with poor response to afterload reduction and diuretic therapy
 Suspected tamponade or contusion from blunt chest injury
 Pulmonary hypertension with myocardial dysfunction

TABLE 7.2**NORMAL HEMODYNAMIC VALUES**

Hemodynamic parameter	Normal range
Systolic blood pressure	100–140 mm Hg
Diastolic blood pressure	60–90 mm Hg
Mean arterial pressure (MAP)	70–105 mm Hg
Heart rate	60–100 beats/min
Right atrial (RA) or central venous pressure (CVP)	0–8 mm Hg
Right ventricle systolic pressure	15–30 mm Hg
Right ventricular diastolic pressure	0–8 mm Hg
Pulmonary artery (PA) systolic pressure	15–30 mm Hg
PA diastolic pressure	4–12 mm Hg
Mean PA	9–16 mm Hg
Pulmonary artery occlusion pressure (PAOP, wedge)	6–12 mm Hg
Left atrial pressure (LAP)	6–12 mm Hg
Cardiac output (L/min)	Varies with patient size
Cardiac index (L/min/m ²)	2.8–4.2 L/min/m ²
Right ventricular ejection fraction (RVEF)	40%–60%
Right ventricular end-diastolic volume indexed to body surface area (RVEDVI)	60–100 mL/m ²
Hemoglobin	12–16 g/dL
Arterial oxygen tension (PaO ₂)	70–100 mm Hg
Arterial oxygen saturation	93%–98%
Mixed venous oxygen tension (PvO ₂)	36–42 mm Hg
Mixed venous oxygen saturation (SvO ₂)	70%–75%

PRESSURE MEASUREMENTS

- Normal hemodynamic values are presented in (Table 7.2).
- While passing from the vena cava to a branch of the pulmonary artery, characteristic waveforms are displayed on the monitor (Figs. 7.3 and 7.4).
- Whether the patient is on mechanical ventilation (positive intrathoracic pressure) or spontaneously breathing (negative intrathoracic pressure), all pressure measurements should occur at end expiration when the intrathoracic pressure is closest to atmospheric pressure (Fig. 7.5) (unless the patient is on higher levels of positive end-expiratory pressure [PEEP]).
- The first characteristic waveform seen when inserting a PAC is the right atrium (RA) tracing (Fig. 7.6). The tracing can be

seen while inserting the catheter or by transducing the right atrial pressure once the PAC is in position. There are two main positive pressure deflections, called the a and v waves. The a wave follows the P wave of the electrocardiogram and is due to the pressure increase during atrial systole (Figs. 7.6 and 7.7). The v wave results from atrial filling against a closed tricuspid valve during ventricular systole. Between these two positive deflections is a small c wave due to tricuspid closure. Two negative deflections called the x and y descents occur when pressure in the atrium decreases. The x descent occurs during atrial relaxation. The y descent is seen when the tricuspid valve opens and blood flows from the atrium to the ventricle.

- The pressures observed in the RA range from 0 to 8 mm Hg. Higher pressures may not necessarily mean fluid overload but reflect the volume of the right heart and the ability of the

**FIGURE 7.3.** Waveforms seen during pulmonary artery catheter insertion.

FIGURE 7.4. Over-wedged tracing. PA, pulmonary artery; PAOP, pulmonary artery occlusion pressure.

FIGURE 7.5. Reading of pulmonary artery occlusion pressure (PAOP) at end expiration. During spontaneous breaths, PAOP dips down during peak inspiration due to negative intrathoracic pressure. During mechanical ventilation, PAOP goes up during peak inspiration due to positive pressure ventilation and intrathoracic pressure. In both situations, PAOP should be read at end expiration.

A) Atrial Fibrillation

B) Atrial Flutter

C) Complete AV Block

D) Tricuspid Regurgitation

E) Pericardial Tamponade

F) Constrictive Pericarditis

NORMAL

FIGURE 7.6. Pressure tracings from the right atrial port in normal and pathologic conditions (refer to text).

FIGURE 7.7. Reading of central venous pressure (CVP) and pulmonary artery occlusion pressure (PAOP) in relationship to the cardiac cycle (electrocardiogram).

ventricle to eject that volume. There is little relationship between the central venous pressure (CVP) and PAOP or left heart pressures in patients with valvular or coronary artery disease or when pulmonary artery pressures are elevated. It is in these situations of right heart failure, severe pulmonary disease, and in most of the critically ill patients when monitoring the CVP only (and not the PAOP) would be misleading.

- The next waveform seen is that of the right ventricle (see Fig. 7.3). The pressures here are higher with a wider difference between systolic and diastolic. If no RV waveform is seen after inserting the catheter 30 cm from the internal jugular or subclavian vein entry site, the catheter may be curling in the atrium or passing into the inferior vena cava. The catheter should be quickly advanced through the ventricle both to avoid dysrhythmias and to keep the catheter from warming and losing its stiffness. The right ventricular (RV) systolic pressures generally range from 15 to 30 mm Hg and diastolic pressures from 4 to 12 mm Hg. In right heart failure, the RV diastolic pressures may be high enough that the waveform mimics the pulmonary artery (PA). Low RV pressures will be seen in hypovolemic shock and they will also be close to PA pressures. One concern at this point of insertion is causing a right bundle branch block or even complete heart block in patients with pre-existing left bundle branch block. However, the incidence of complete heart block appears to be no greater in patients with left bundle branch block than without.
- Once the catheter enters the pulmonary artery, the waveform shows an increase in diastolic pressure while the systolic pressure remains about the same as in the ventricle, sometimes referred to as the “step up” (see Fig. 7.3). This transition may be difficult to discern when there is hypovolemia, tamponade, RV failure, or catheter whip. If there is no change in waveform after inserting the catheter 50 cm, it may be coiling in the ventricle and is at risk of knotting. A chest radiograph will discern the problem, and fluoroscopy may be used to guide placement. Normal PA pressures range from 15 to 25 mm Hg systolic over 8 to 15 mm Hg diastolic. The beginning of diastole is marked by a dicrotic notch on the PA tracing, corresponding to the closure of the pulmonic valve. This incisura distinguishes the PA from the RV when RV diastolic pressures are elevated. As blood flows through the lungs to

the left atrium, the PA pressure drops until it reaches a nadir at the end of diastole. Since the pulmonary circulation has low resistance, the diastolic pressure is able to decrease until it is just higher than PAOP. The highest PA systolic pressure occurs during the T wave of the corresponding electrocardiogram (ECG). The pulmonary circulation is very dynamic and is affected by acidosis, hypoxia, sepsis, and vasoactive drugs. An increase in cardiac output (CO) may also seemingly paradoxically lower the PA pressures by a reflexive decrease in pulmonary vascular resistance with fluid resuscitation and decreased sympathetic nervous system discharge.

- The transition to the wedge position is noted by a drop in mean pressure from the PA. The PAOP usually ranges from 6 to 12 mm Hg in normal states. PAOP most closely reflects left ventricular end-diastolic volume (LVEDP) after atrial contraction and before ventricular contraction (see Fig. 7.7). There are often no clear a, c, or v waves. When v waves are prominent such as in mitral insufficiency, the bottom of the v wave or the a wave may be used to measure the PAOP (Fig. 7.8). A prominent v wave may fool the novice into thinking that the catheter is not wedging. It is important to note the change in wave form from PA to v wave tracing (although the two waves may look remarkably similar). One way of differentiation is that the v wave occurs later in the ECG cycle after the T wave while the PA wave occurs right after QRS (Fig. 7.8). There may be large a waves secondary to a decrease in left ventricle compliance; the point 0.05 seconds after initiation of QRS again best reflects LVEDP. Even though the measurements are correlated with the ECG and are done during end expiration, the PAOP may be exaggerated by respiratory muscle activity, especially during active or labored exhalation.

Principles of Measuring Pulmonary Artery Occlusion Pressure

- When the balloon is inflated, the blood flow in that segment of the pulmonary artery is occluded, and the PAOP is measured. Since there is no flow, the pressure between the occluded pulmonary artery segment and the left atrium will equalize (Fig. 7.9), analogous to closing off a pipe with pressures

FIGURE 7.8. Regurgitant mitral valve generating a v wave seen during wedging. PA, pulmonary artery.

equalizing between the two ends. With the closed pipe analogy, there is a list of assumptions that may not necessarily hold true in a critically ill patient, regardless if mechanically ventilated or otherwise: $PAOP \cong PcP \cong LAP \cong LVEDP \cong LVEDV$, where PcP is pulmonary capillary pressure, LAP is left atrial pressure, and $LVEDV$ is left ventricular end-diastolic volume. As long as there is no obstruction in this conduit, the relationship between $PAOP$ and $LVEDP$ may hold. The final assumption is equating pressure to volume by estimating $LVEDV$ or “preload” with $LVEDP$. We will now assess the pitfalls with each one of these assumptions.

- $PAOP \cong PcP \cong LAP$ occurs only in the dependent areas of the lung, where the pressures from blood flow in the RA and

pulmonary artery are greater than the alveolar pressure, or zone 3 in the West classification. Placement of the catheter in other areas of the lung (zone 1 or 2) may cause errors in estimation of $PAOP$ to LAP due to pulmonary venous obstruction and respiratory variation as well as high ventilator support ($PAOP$ reads higher than LAP).

- Increased intrathoracic pressure secondary to respiratory failure and the addition of PEEP in ventilated patients affects pulmonary vascular pressures. Up to about 15 cm H_2O , $PAOP$ closely correlates with LAP . During higher PEEP states, the $PAOP$ may not reflect the true filling pressure of the heart (i.e., pressure outside minus pressure inside the heart).

FIGURE 7.9. Closed pipe analogy: blocking of flow by the balloon with theoretical equalization of pressure in the conduit. RA, right atrium; RV, right ventricle; PAOP, pulmonary artery occlusion pressure; Pc, pulmonary capillary; LAP, left atrial pressure; LV, left ventricle.

FIGURE 7.10. The same pulmonary artery occlusion pressure of 20 mm Hg reflecting three different clinical conditions. A: Distended hypervolemic ventricle in a normal heart. B: Normal volume in a noncompliant heart (ventricular hypertrophy). C: Low volume in a normal ventricle with high juxtacardiac pressures such as high positive end-expiratory pressure.

- **LAP \square LVEDP.** LAP (and thus PAOP) will overestimate LVEDP if there is an obstruction between the left atrium and the left ventricle such as a myxoma or mitral stenosis. Mitral valve regurgitation also causes the PAOP to read higher than the true LVEDP because of the additional pressure of the retrograde flow of blood across the valve resulting in a large v wave (see previous). LAP (and thus PAOP) will underestimate LVEDP when severe aortic regurgitation causes premature closure of the mitral valve when the left ventricle is still filling. LAP (and PAOP) is higher when there is a left atrial kick in a failing heart and decreased ventricle compliance such as in ischemic states, left ventricular hypertrophy, and restrictive cardiomyopathies. This is especially true when LVEDP is greater than 25 mm Hg.
- **LVEDP \square LVEDV.** The pressure–volume relationship depends on the compliance of the ventricle and the transmural ventricular distending force. The compliance of the ventricles will change with ischemia, infarct, and hypertrophy. A stiff heart (myocardial hypertrophy) will need higher pressures to obtain the same amount of volume as a normal heart (Fig. 7.10). The transmural ventricular distending force (intracavitary pressure minus juxtacardiac pressure) will depend on the pressure inside and outside the heart. External forces elevating juxtacardiac pressures may be high ventilator support or pericardial tamponade, which may cause elevation of PAOP but may not reflect ventricular filling pressure.

Clinical Use of the Pulmonary Artery Occlusion Pressure

- As long as the previously mentioned assumptions regarding the relationship between PAOP, LAP, and LVEDP have been evaluated, the PAOP may be used as an estimate of LAP with reasonable correlation. The optimum wedge pressure depends on the patient but has been defined as the pressure where there is minimal increase in stroke volume or left ventricular stroke work. Although the normal PAOP values may be 10 to 14 mm Hg, some patients require a high pressure to reach the optimum stroke volume (Fig. 7.11).
- The Starling curve—plotting stroke volume index to PAOP (as an estimate of LVEDP) may help identify the optimum wedge, but some patients may have a flat curve. If vasoactive agents are started, the heart may now be on a different curve requiring new assessment of the optimum PAOP. The optimum PAOP varies not only from patient to patient but temporally within the same patient as the clinical condition changes (such as vasoactive agents, myocardial compliance, and external forces around the heart). There are no set numbers to treat to, but each patient must be individually assessed and assessed *repeatedly*, making the PAC a highly user-dependent tool.
- Elevated wedge pressures may help differentiate hydrostatic pulmonary edema from that caused by increased permeability. A PAOP of 24 mm Hg or higher is associated with a tendency for hydrostatic edema. Lower pressures may imply

FIGURE 7.11. Frank–Starling curves (family of curves) showing the relationship between left ventricular end-diastolic pressure (LVEDP) to stroke volume (SV, mL/beat). Augmenting preload increases LVEDP with a concomitant increase in SV (up to a certain point). The effects of manipulating preload, afterload, and contractility and shifting to another curve can be seen.

Modified Stewart-Hamilton equation

$$Q = \frac{VI(TB - TI) \times SI \times CI \times 60 \times CT \times K}{SB \times CB \int_0^{\infty} \Delta TB \, dt}$$

Q = Cardiac Output**VI = volume of injectate****TI = injectate temperature****TB = blood temperature****CI = specific heat of the injectate (D5W = 0.965, saline = 0.997)****SI = specific gravity of the injectate (D5W = 1.018, saline 1.005)****60 = seconds/minute****CT = correction factor (loss of thermal indicator due to time lost in injecting, catheter length, patient's temperature)**

$$= \frac{TB - \text{mean temperature of the injectate delivered to the right atrium}}{TB - TI \text{ (pre-injectate temperature)}}$$

SB = specific gravity of blood (1.045)**CB = specific heat of the blood (0.87)** **$\int_0^{\infty} \Delta TB \, dt$ = integral of blood temperature change**

$$\text{Computation constant (K)} = \frac{SI \times CI \times 60 \times CT \times VI}{SB \times CB} = \text{changes with VI}$$

FIGURE 7.12. The modified Stewart-Hamilton equation for estimating cardiac output.

increased capillary permeability and traditionally, a PAOP of <18 mm Hg has implied a pulmonary (or noncardiogenic) cause of lung edema. When there is an increase in PVR, the wedge pressure underestimates P_c , and hydrostatic pulmonary edema may therefore occur at lower wedge pressures.

- Volumetric PACs are designed with the ability to measure right ventricular ejection fraction, from which the right ventricular end-diastolic volume indexed to body surface area is calculated.

Cardiac Output

- The ability of the heart to meet increasing tissue oxygen demand is perhaps the single most important determinant in oxygen delivery and tissue perfusion.
- Crystalloid solution (usually 10 mL, but 5 mL may be used in volume-restricted patients) is injected into the RA port at similar parts of the respiratory cycle (end expiration), within 4 seconds in a smooth manner. The thermistor near the tip of the PAC detects the change in temperature, and the change in blood temperature over time is proportional to the blood flow from the ventricle. Several measurements (three to five) should be taken and the average of the values (within 10% of each other) used. Principles of the modified Stewart-Hamilton equation calculate the cardiac output (Fig. 7.12).
- Falsely low CO will occur if an error in the system increases the change in temperature (which is in the denominator of the Stewart-Hamilton equation): The temperature probe reading the injectate is cooler than the actual injectate (or the solution is warmer than the temperature reading of the injectate), more than allotted “dye” amount is injected (>10 mL fluid), there is too rapid an injection, or the injection occurs during positive pressure ventilation. Falsely high CO may occur if the temperature probe measuring injectate reads warmer than the actual injectate (if the solution is cooler than the tempera-

ture reading of the injectate), less than the allotted amount of “dye” (<10 mL) is used, or the catheter has migrated distally with less change in temperature difference. Most institutions use temperature probes at the site of injection (RA port) so that variations in injectate temperature should not contribute to errors in CO measurements.

- Another development in the evolution of measuring CO is the PAC with continuous cardiac output monitoring.

Starling Curves

- Drs. Frank and Starling described the relationship between myocardial stretch and contractility (see Fig. 7.11). Myocardial stretch is an independent determinant of stroke work, and the actin-myosin interaction has a linear correlation with the strength of systolic contraction up to a certain point. Given the heart's dynamic environment, a family of curves is more representative of the true preload-to-stroke volume relationship. Increasing afterload or decreasing contractility shifts the curve down and to the right (i.e., more stretch is necessary to produce a similar difference in stroke volume). One cannot stress enough the importance of reassessment after each therapy. For example, initiating afterload reduction may put the heart on a different Starling curve (to the left and up; see Fig. 7.11) but may decrease the preload. Unless more fluid is given to optimize the LVEDP (i.e., PAOP), the best stroke volume may not be achieved.

MIXED VENOUS OXYGEN SATURATION

- The SvO_2 value indicates the balance between oxygen delivery to the tissues and the amount consumed by the tissues before returning to the heart.

FIGURE 7.13. Intrapulmonary shunt (Q_s/Q_t) is the percent of cardiac output (CO) not involved with gas exchange (goes through collapsed alveoli), with ventilation/perfusion $V/Q = 0$. LA, left atrium; RV, right ventricle.

Rearranging the Fick Equation

$$SvO_2(\%) = \frac{VO_2}{CO (L/min) \times Hgb (g/dL) \times 1.36 (mLO_2/g Hgb) \times 10}$$

Four factors determine the SvO_2 value: three parameters contributing to oxygen delivery (CO, hemoglobin, and SaO_2) and one parameter for O_2 consumption. Low SvO_2 suggests insufficient O_2 delivery or increased O_2 consumption. SvO_2 is also a harbinger of shock and may decrease before overt shock is apparent. Mixed venous oxygen saturation has also regained popularity as an end goal of resuscitation with decreased mortality.

- Inadequate oxygen delivery can be the result of decreased cardiac output, low hemoglobin, or low oxygen saturation. Increased consumption may occur due to activity, fever, hyperthyroid state, or repayment of oxygen debt. High SvO_2 suggests low cellular consumption such as in late sepsis,

arteriovenous shunts (cirrhosis), or excessive inotrope use. Hypothermia, sedation, paralysis, anesthesia, hypothyroidism, and cyanide poisoning can also reduce VO_2 .

- The catheter should also be checked to ensure that distal migration has not occurred leading to sampling of pulmonary capillary blood that is normally highly saturated (~100%). Inflating the balloon (wedging) should determine that the catheter is in too far if the PAOP tracing is seen with <1.25 mL of air. The oximeter should be calibrated daily in vivo.

INTRAPULMONARY SHUNT

- “Shunt” refers to the portion (in %) of blood that flows (CO) from the right side of the heart to the left completely deoxygenated (Fig. 7.13). Physiologic shunt = anatomic shunt + intrapulmonary shunt. “Anatomic shunt” refers to the direct drainage of the venous system to the left ventricle through the bronchial, thebesian, and pleural veins (~2%–5% of CO).

FIGURE 7.14. The effect of FiO_2 on PaO_2 depending on the degree of intrapulmonary shunts of 20%, 30%, and 50%. This assumes that other parameters that affect SvO_2 such as cardiac output, hemoglobin, and oxygen consumption are remaining constant.

Intrapulmonary shunt (Q_s/Q_t) is expressed as the percentage of cardiac output passing through completely collapsed alveoli with no or little gas exchange so that the ventilation-to-perfusion ratio is zero (i.e., $V/Q = 0$).

- “Venoarterial admixture” or “shuntlike states” refer to blood flow passing through partially open alveoli (i.e., $V/Q < 1$). Acute shunt will not respond to FiO_2 , and the treatment is PEEP to open the alveoli and make them responsive to FiO_2 . Venous admixture will demonstrate some response to FiO_2 .

If the shunt is minimal (normal condition), there is almost a linear relationship between FiO_2 and PaO_2 , but as the shunt increases, FiO_2 no longer affects PaO_2 in a linear fashion (Fig. 7.14). This is an important concept as one cannot improve hypoxemia by increasing FiO_2 alone but needs to open the alveoli with PEEP. If the shunt equation is calculated on a FiO_2 of <1.0 , both the shunt and venous admixture will be captured in the equation. Intrapulmonary shunt (Q_s/Q_t) is calculated as $(CcO_2 - CaO_2)/(CcO_2 - CvO_2)$, where CcO_2 is

TABLE 7.3

DERIVED CALCULATIONS (ALL INDEXED TO BODY SURFACE AREA)

Parameter	Equation	Key	Normal	Units
Stroke volume indexed (SVI)	CI/HR or EDVI – ESVI	Amount of blood ejected with each contraction (per m^2)	30–65	$mL/beat/m^2$
Left ventricular stroke work index (LVSWI)	$SVI \times (MAP - PAOP) \times 0.0136$	External work for the left ventricle in 1 beat	43–61	$g \cdot m/m^2$
Right ventricular stroke work index (RVSWI)	$SVI \times (MPAP - CVP) \times 0.0136$	External work for the right ventricle in 1 beat	7–12	$g \cdot m/m^2$
Pulmonary vascular resistance indexed (PVRI)	$\frac{(MPAP - PAOP) \times 80}{CI}$	Resistance for right ventricle; 80 converts $mm\ Hg/min/L$ to $dynes \cdot sec/cm^5$	255–285	$dynes \cdot sec/cm^5$
Systemic vascular resistance (SVR)	$\frac{(MAP - CVP) \times 80}{CI}$	Resistance for left ventricle	1,970–2,390	$dynes \cdot sec/cm^5/m^2$
Arterial oxygen content of blood (CaO_2)	$(Hgb \times 1.36\ mL\ O_2/g\ Hgb \times SaO_2) + (0.0031 \times PaO_2)$	Amount of oxygen in arterial blood, majority is carried by Hgb (1.36 mL of O_2/g of Hgb if blood is 100% saturated), very little is dissolved ($0.0031 \times PaO_2$)	16–22	$mL\ O_2/dL\ blood$
Mixed venous oxygen content of blood (CvO_2)	$(Hgb \times 1.36\ mL\ O_2/g\ Hgb \times SvO_2) + (0.0031 \times PvO_2)$	Amount of oxygen in mixed venous blood (sampled at the pulmonary artery)	12–17	$mL\ O_2/dL\ blood$
Arterial-mixed venous oxygen content difference ($AVDO_2$)	$CaO_2 - CvO_2$	How much O_2 was consumed by the tissues before returning to the heart	3–5	$mL\ O_2/dL\ blood$
Delivery of oxygen indexed (DO_2I)	$CaO_2 \times CI \times 10$	Primary determinant of organ perfusion	500–600	$mL\ O_2/min/m^2$
Oxygen consumption indexed (VO_2I)	$(CaO_2 - CvO_2) \times CI \times 10$	Oxygen consumed by the tissues	120–160	$mL\ O_2/min/m^2$
Intrapulmonary shunt (Q_s/Q_t)	$(CcO_2 - CaO_2)/(CcO_2 - CvO_2)$ $CcO_2 = (Hgb \times 1.36 \times 100\% \text{ saturation}) + (0.0031 \times PAO_2)$ $PAO_2 = FiO_2 \times [(760\ mm\ Hg - 47\ mm\ Hg)] - (PaCO_2/RQ)$	% of CI that is not involved with gas exchange and goes to the arterial side deoxygenated; $>20\%$ usually requires ventilator support. Since pulmonary capillary blood cannot be sampled, 100% saturation is assumed. 760 is atmospheric pressure at sea level; 47 is water vapor pressure	3–5	% of cardiac output
Coronary perfusion pressure (CPP)	$CPP = DBP - PAOP$	The major determinant of flow in a fixed, diseased conduit is the pressure difference	50–60	$mm\ Hg$

CI, cardiac index ($mL/min/m^2$); HR, heart rate (beats/min); EDVI, end-diastolic volume index (mL/m^2); ESVI, end-systolic volume index (mL/m^2); MAP, mean arterial pressure; DBP, diastolic blood pressure ($mm\ Hg$); PAOP, pulmonary artery occlusion pressure ($mm\ Hg$); CVP, central venous pressure; Hgb, hemoglobin (g/dL); CcO_2 , pulmonary capillary content of oxygen; PAO_2 , partial pressure of oxygen in the alveoli; RQ, respiratory quotient VCO_2/VO_2 is 0.8 for a mixed fuel diet.

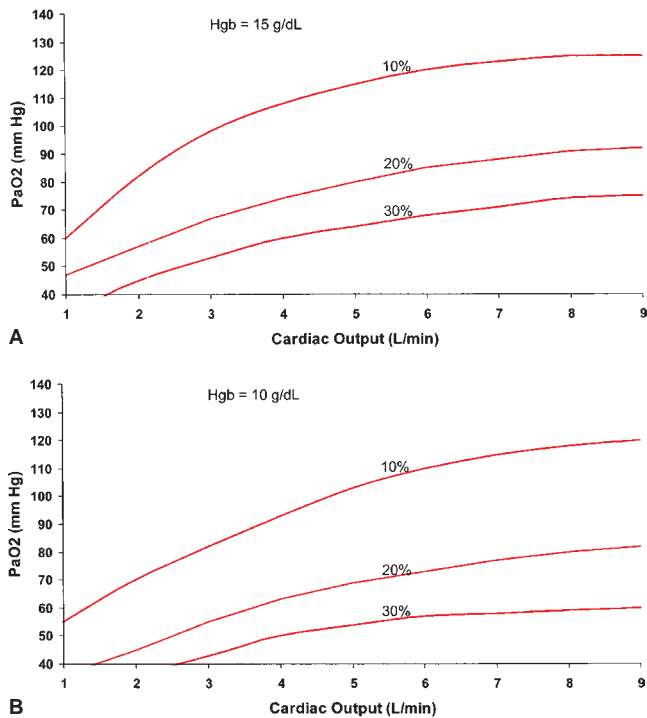

FIGURE 7.15. Relationship between PaO_2 , cardiac output, and three different intrapulmonary shunt states (10%, 20%, and 30%) for patients with a hemoglobin of 15 g/dL and 10 g/dL. This graph demonstrates “nonpulmonary” causes for PaO_2 changes where a low cardiac output or low hemoglobin will impact PaO_2 depending on the degree of shunt.

the pulmonary capillary content of O_2 , CaO_2 is the arterial content of O_2 , and CvO_2 is the mixed venous content of O_2 (Table 7.3).

- Since pulmonary capillary blood cannot be sampled, the saturation is assumed to be 100%, which usually holds true when the FiO_2 is 1.0. It is important to understand the contribution of a low SvO_2 to PaO_2 if there is a moderate shunt (>20%).
- Any decrease in SvO_2 in a patient with >20% shunt will allow more deoxygenated blood to go into the arterial circulation, resulting in a lower PaO_2 . This is called nonpulmonary cause

of hypoxia. For example, if a patient with a 20% intrapulmonary shunt and a hemoglobin of 15 g/dL has an acute cardiac event and the CO decreases from 5 to 3 L/minute, the PaO_2 will decrease from ~80 to 65 mm Hg (Fig. 7.15).

- In exactly the same scenario, if the patient’s hemoglobin is 10 g/dL, the PaO_2 will decrease from 70 to 55 mm Hg. This demonstrates the importance of low SvO_2 contributing to lower PaO_2 . If the PEEP had been increased in this patient to treat a low PaO_2 , a further decrease in CO would have resulted in worsening SvO_2 and PaO_2 . Treatment in this case is to optimize CO first to see whether PaO_2 improves. Another example: If a patient is agitated and the arterial saturation decreases, this may be due to increased oxygen consumption and low SvO_2 in a patient with a moderate intrapulmonary shunt and not from an acute pulmonary event. Treatment is to decrease agitation and VO_2 . There are times when severe cardiorespiratory compromise warrants titration of both cardiac output and PEEP simultaneously in patients with life-threatening hypoxia. It is important to understand the interaction of one organ on the other and the relationship between PaO_2 , hemoglobin, and cardiac output (see Fig. 7.15).

DERIVED VARIABLES

- See Table 7.3 for the equations and normal values.

COMPLICATIONS OF PULMONARY ARTERY INSERTION

- PAC insertion is an invasive procedure and carries inherent risks. The overall complication rate associated with PACs can be as high as 25%. The procedural risks are pneumothorax, hemothorax, and knotting of catheters. Multiple prospective and retrospective studies have reported the most common complications including infection, thrombosis, arrhythmias, new bundle branch blocks, and pulmonary artery rupture.
- Serious complications (PA rupture and cardiac perforation with tamponade) are infrequent, but they can be fatal if unrecognized.

CHAPTER 8 ■ NONINVASIVE CARDIOVASCULAR MONITORING

- Recent experiences have demonstrated that early intervention is associated with improved outcome. Identification of the adequacy of perfusion is a function of balancing oxygen delivery with oxygen demand. Invasive monitoring requires time and technology, often leading to delays that reduce the

potential benefit of the information gathered. In addition to the need for rapid monitoring, the challenge of continuous data collection and analysis as opposed to intermittent static observations is of major concern in the selection of monitoring techniques.

- Noninvasive hemodynamic monitoring can be safe for patients and staff, convenient, inexpensive, reasonably accurate, and available anywhere in the hospital, doctors' offices, or prehospital areas. Early recognition of abnormal hemodynamic or respiratory patterns allows therapy to be given earlier, more vigorously, and with greater effectiveness. Timing of treatment is as essential as the therapy itself in achieving good outcome.

TISSUE PERFUSION

Conventional Vital Signs

- Conventional vital signs include heart rate and mean arterial pressure; heart rate may be automatically derived from the electrocardiogram and the systolic, diastolic, and mean arterial pressure measured directly or automated by DynaMAP (Tampa, FL) or from an indwelling arterial catheter if one is already in place.

Arterial Hemoglobin Oxygen Saturation by Pulse Oximeter

- The standard pulse oximeter (Nellcor, Pleasanton, CA) is routinely used for continuous hemoglobin saturation (SpO_2) monitoring. Two different wavelengths of infrared light are reflected from the capillaries to identify and evaluate the oxygen saturation of the arterial component. Sudden changes in the arterial hemoglobin saturation are useful in assessing changes in pulmonary function. This has had a major impact on clinical practice both inside and outside the operating room. Unfortunately, arterial oxygen saturation by itself does not indicate the oxygen delivery (DO_2) or the oxygen consumption/demand (VO_2) and is not a reliable measure of tissue oxygenation/perfusion or the hemodynamic status.
- Oximetry is based on the Beer–Lambert law of optical wavelength-dependent absorption of light energy. The Beer–Lambert law describes that light intensity (I) decreases exponentially when transmitted through a measurement compartment. The rate of the exponential decrease depends on the concentration of material inside the measurement compartment (C) and a wavelength-dependent absorption coefficient (a). In addition, the decrease depends on the optical pathlength (L) of the compartment: Pulse oximetry fundamentally relies upon adequate perfusion of the vascular bed being monitored. Without sufficient blood flow, oxygen content cannot be adequately analyzed. Decreased perfusion may be caused by a variety of factors including hypotension, medications, ambient temperature, poor circulation, and so forth
- Pulse oximeters are calibrated using saturation curves of healthy adult volunteers. They are, therefore, the most accurate at high saturation levels and less so at low saturation levels. Unfortunately, from the clinical standpoint, the low saturation levels are where they are the most useful to us. Nonetheless, this is rarely of major consequence, as the clinical difference between a saturation of 83% and 80% is usually very minimal.
- Other sources of error include ambient light and motion artifact. Error rates with excess ambient light can be as high as 63% for heart rate and 57% for saturation. Additional sources of error include darkly pigmented skin, nail polish, thermal injuries to fingers and/or toes, and inaccessibility of the extremities.

CHAPTER 9 ■ PULSE OXIMETRY AND PHOTOPLETHYSMOGRAPHY

- Photoplethysmography is the measurement of volume changes with light transmission. The photoplethysmograph (PPG) is displayed on most pulse oximeter devices; however, it is frequently ignored as oxygen saturation and pulse rate are the numbers of interest.
- The pulsatile cardiac component (PCC) of light hitting the photodiode corresponds to changes in the arterial blood volume with each heartbeat. The magnitude of change of the PCC with each heartbeat is related to stroke volume, and the area under the curve of each heartbeat is related to the volume of blood entering the vascular bed with each beat. The PCC is therefore a representation of flow into a vascular bed while the low frequency component (LFC) is a representation of changes in venous volume

TISSUE OXYGEN MONITORS

- Experimental studies have shown that transcutaneous oxygen monitoring is sensitive to arterial oxygen tension during normal cardiac output but is more sensitive to perfusion in low-flow shock. In adult patients, PtcO_2 is approximately 80% of the arterial oxygen tension (PaO_2) during normal hemodynamic conditions. However, when blood flow is diminished, PtcO_2 also decreases. PtcO_2 is therefore related to both perfusion and oxygenation.
- When perfusion is normal, PtcO_2 varies with arterial oxygenation. When perfusion is inadequate, PtcO_2 varies with cardiac output. Hence, a normal PtcO_2 value indicates that

both oxygenation and perfusion are relatively normal. A low $PtcO_2$ indicates that either oxygenation and/or cardiac output is inadequate. If arterial oxygenation is normal (as indicated by blood gases or pulse oximetry), low $PtcO_2$ indicates low-flow shock.

- The relationship between $PtcO_2$ and PaO_2 can be quantitated, utilizing the $PtcO_2$ index, which is simply defined as $PaO_2/PtcO_2$. In a study that simultaneously measured cardiac index, $PtcO_2$, and PaO_2 in a large number of critically ill surgical patients, it was found that when cardiac output was relatively normal (cardiac index >2.2 L/min/m²), the $PtcO_2$ index averaged 0.79 ± 0.12 . In individual patients with these normal cardiac outputs, $PtcO_2$ varied linearly with PaO_2 . When cardiac output decreased, however, the $PtcO_2$ index decreased as well. For patients with a cardiac index between 1.5 and 2.2 L/minute/m², the $PtcO_2$ index averaged 0.48 ± 0.07 . For patients with a cardiac index below 1.5 L/minute/m², the $PtcO_2$ index was 0.12 ± 0.12 . These data confirm that when blood flow is relatively normal, $PtcO_2$ varies with arterial oxygenation. However, with low-flow shock, $PtcO_2$ becomes very sensitive to changes in cardiac output.
- Clinical studies have demonstrated the usefulness of transcutaneous oxygen monitoring in detecting shock. When $PtcO_2$ monitors are placed during acute emergency resuscitation, low $PtcO_2$ values detect both hypoxemia and hemorrhagic shock. Moreover, the response of $PtcO_2$ during fluid infusion is a sensitive indicator of the efficacy of shock resuscitation.
- Transcutaneous oxygen monitoring thus has benefit both as an early detector of shock and as a monitor to titrate resuscitation to a physiologic end point. It is noninvasive and inexpensive and is therefore widely applicable for patients at risk, such as during emergency resuscitation of trauma and acute surgical emergencies, in the perioperative and postanesthesia period, and in the intensive care unit. However, though end points of successful resuscitation utilizing transcutaneous oxygen monitoring have been suggested, such values have not been validated in large prospective studies. The only risk of transcutaneous oxygen monitoring is minor skin burn beneath the probe if probe temperatures exceed 44°C or if the device is left in place for excessive periods of time.
- Two techniques for direct tissue oxygen monitoring are available. Polarographic electrodes incorporated into needles have been most widely utilized. In addition, a technique utilizing the phenomenon of fluorescence quenching is available. Tissue oxygen probes contain a fluorescent compound that is O_2 -sensitive, such that its fluorescent emission is diminished in direct proportion to the amount of O_2 present. Energy from the monitor is transmitted through fiberoptic elements to the fluorescent compound in the probe, resulting in the emission of light, which is then measured by sensors in the tissue probe. The intensity of the emitted light is inversely proportional to the tissue pO_2 .
- Another method of tissue oxygen monitoring is transconjunctival. The conjunctiva of the eye does not have a stratum corneum, so oxygen is freely diffusible. Transconjunctival probes are placed against the eye and allow continuous tissue oxygen monitoring without heating; the technology has been utilized both during anesthesia and shock.

Near-infrared Spectroscopy

- Near-infrared spectroscopy (NIS) has been developed as a noninvasive measure of tissue oxygenation. NIS measures the ratio of oxygenated hemoglobin to total hemoglobin (StO_2) in the microcirculation of the underlying muscle by measuring the absorption and reflectance of light. Using cutaneous probes placed upon the thenar eminence, values of $87\% \pm 6\%$ have been measured in normal volunteers. Early clinical experience suggests that StO_2 values decrease during shock and increase with successful resuscitation. A recent multicenter trial in trauma patients suggested that an StO_2 value of 75% may be a therapeutic goal. Clinical data are limited. Tissue edema may be a confounding factor, as the distance between the probe and the underlying muscle affects measurements. Again, the sensitivity and specificity of this device compared to other tissue oxygen-monitoring devices has not been studied. NIS has been demonstrated to have a close relationship to base deficit in critically injured patients and predicting development of organ failure in traumatic shock patients.

Gastric Tonometry

- The mesenteric circulatory bed, particularly the gut mucosa, is prone to hypoperfusion and ischemia during shock. Tonometry has been developed as a technique to detect adequacy of gastrointestinal mucosal perfusion. The potential usefulness of gastric tonometry has been suggested in clinical studies in which it has been reported to reflect the severity of shock and to increase during successful resuscitation. However, the technique has not gained widespread acceptance, in part because the accuracy of the pHi measurement has been questioned.

Transcutaneous and End-tidal Carbon Dioxide

- In combination with low $PtcO_2$, increased transcutaneous pCO_2 gives additional evidence of circulatory shock. End-tidal CO_2 may also be utilized as a measure of perfusion; end-tidal CO_2 is decreased during low-flow states due to decreased pulmonary flow. Decreased end-tidal CO_2 values in combination with increased transcutaneous pCO_2 and normal arterial pCO_2 values are strong evidence of circulatory shock.

Cardiac Output Monitoring by Thoracic Electric Bioimpedance

- In thoracic electric bioimpedance methods, pairs of non-invasive disposable prewired hydrogel electrodes consisting of an outer injecting electrode and an inner sensing electrode are positioned on the anterior thoracic skin surface at the levels of the lung apex and the base; electrocardiogram leads are also placed on the precordium and shoulders. The outer pairs of electrodes pass a small-amplitude (0.2–5.0 mA) alternating current at 40 to 100 kHz through the patient's thorax to produce an electrical field. The injected electrical signals travel predominantly down the aorta, which has lower

electrical resistance than aerated lung. Each ventricular contraction propels the stroke volume down the aorta, increasing aortic blood volume and aortic flow and lowering impedance. The impedance is sensed by the inner recording electrodes that capture the baseline impedance (Z_0), the first derivative of the impedance waveform (dZ/dt), and the electrocardiogram. Changes in aortic blood flow throughout the cardiac cycle are quantitatively related to changes in the electrical impedance. It has been reported an average difference of 9.7% between thoracic electric bioimpedance and COTd and an average differ-

ence of 9.5% between rapidly repeated COTd measurements in the same patient.

- Lithium dilution cardiac output measurements, arterial pressure pulse, contour cardiac output system, and noninvasive partial CO_2 rebreathing cardiac output measurement have been recently introduced as noninvasive alternatives to pulmonary artery catheters. These techniques share the shortcomings of thermodilution with pulmonary artery catheters in that they give only episodic sets of measurements, require critical care conditions, and need frequent recalibration.

CHAPTER 10 ■ CAPNOGRAPHY

- *Capnometry* refers to the measurement of carbon dioxide, regardless of the method used.
- *Capnography* describes the method of obtaining a capnogram: that is, a tracing of carbon dioxide concentration as a function of time or volume.
- With modern methods, continuous readings of exhaled carbon dioxide tensions and volumes can be obtained. We speak of steady state when the tension is exerted by carbon dioxide in different tissue and organ compartments and blood and alveolar gas have reached equilibrium and when the input of carbon dioxide from metabolism equals the output of carbon dioxide via ventilation and, to a small extent, via skin, flatus, feces, and urine.
- A steady state can exist with high, normal, or low arterial, alveolar, or end-tidal carbon dioxide tension (PaCO_2 , PACO_2 , or PETCO_2). However, all too often, we do not have a steady state: Tissue depleted of carbon dioxide can absorb liters of carbon dioxide from blood until tissue PCO_2 and blood PCO_2 reach equilibrium; conversely, such tissue stores can contribute CO_2 to that generated by metabolism. For example, prolonged hyperventilation can exhaust tissue stores of carbon dioxide and bicarbonate. Under these conditions, the maintenance of a normal PaCO_2 requires less than normal ventilation because some of the metabolic carbon dioxide filters back into the tissues instead of being exhaled.
- Conversely, high tissue stores of carbon dioxide (e.g., after a cardiac and respiratory arrest) will call for greater-than-normal ventilation until steady state is once again reached. A depressed respiratory center (e.g., under the influence of an opiate) will lead to an imbalance of input and output

as the tissues take up some of the carbon dioxide while the rest leaves the body in the exhaled gas. Once the tissues and blood reach equilibrium, steady state will once again supervene in the presence of elevated levels of PaCO_2 , PACO_2 , and PETCO_2 .

- Renal compensation of metabolic acidosis or alkalosis will also lead to an unsteady state that can last for many hours. The point: Capnograms can hide as much as they reveal, and thus the interpretation of capnograms calls for discerning clinicians.
- Instead of plotting the respired gas as a function of time, we can also plot CO_2 as a function of volume. This calls for a method to measure, breath by breath, the respired volume of gas. Together with an arterial blood gas, the single-breath method enables the clinician to estimate the volume of carbon dioxide in the exhaled breath, the volume of the alveolar dead space, and the volume of the anatomic dead space.

SUMMARY

- Noninvasive systems are able to continuously display variables online in real time throughout the patient's hospital course and with information systems to predict outcome and support therapeutic decision making.
- Because they are simple, safe, easy to use, inexpensive, reasonably accurate, and available anywhere in the hospital, some form of noninvasive hemodynamic monitoring with an appropriate information system will replace invasive monitoring for acutely ill patients.

CHAPTER 11 ■ ECHOCARDIOGRAPHY IN THE ICU

- Two-dimensional Doppler echocardiography maps the anatomic relations of the heart by ultrasonic wave pulses sent out from transducers placed on the chest wall, esophageal tube, or endotracheal tube. The sound waves are bounced off the walls and valves of the heart and are captured by sensors as echoes that are electronically plotted to produce images corresponding to anatomic features of the heart, including the right and left atrium, the atrial septum, valves, pulmonary vessels, and the thoracic duct.
- Transesophageal echocardiography is useful in evaluating heart valve abnormalities, tumors, blood clots, and congenital defects and dissecting aortic aneurysms. Doppler techniques are for diagnostic imaging rather than a continuous hemodynamic assessment tool; the images may be distorted by obesity, chronic obstructive pulmonary disease, hyperinflation of the lungs, chest trauma, and surgical dressings.
- Doppler techniques are able to provide some qualitative information about flow through vessels but are limited by the need for expert interpretation of the images and the need for very sensitive transducer placement. These factors provide for a useful diagnostic tool but limit the reproducibility of the measurements and their use for continuous monitoring.

SECTION III ■ TECHNIQUES, PROCEDURES, AND TREATMENT

CHAPTER 12 ■ CLEAN AND ASEPTIC TECHNIQUES AT THE BEDSIDE

CATHETER-RELATED INFECTION

- Although bloodstream infection generally accounts for fewer than 15% of all cases of nosocomial infections, critically ill patients and persons with cancer have disproportionately higher rates of nosocomial bloodstream infections. Not only do bloodstream infections account for 20% of all cases of nosocomial infections among intensive care unit patients, but 87% of bacteremias originate from an infected central vascular catheter.
- Catheter-related bloodstream infection (CRBSI) is defined as the isolation of the same organism (i.e., the same species with identical antimicrobial susceptibility) from the colonized catheter and from peripheral blood in a patient with clinical manifestations of sepsis and no other apparent source of bloodstream infection.
- Until recently, catheter colonization was defined as the growth in cultures from either the tip or subcutaneous segment of the catheter of ≥ 15 colony-forming units/mL by the semiquantitative roll-plate method or $\geq 1,000$ colony-forming units/mL by the quantitative sonication method.
 - This method of diagnosing CRBSI requires removal and culture of the vascular catheter. Only 15% to 25% of central venous catheters removed because of suspected catheter-related infection yield growth.
- There are two potential methods that could indicate whether the catheter is the source of bloodstream infection *without removing the catheter*. Both methods require concurrent collection of peripheral and central (i.e., through the lumen of the catheter) blood cultures.
 - The first qualitative method—**differential time to positivity**—which relies on the understanding that the culture of a blood sample that contains higher bacterial concentration would become positive, as detected by production of carbon dioxide by multiplying organisms, at least 2 hours before this would occur in a culture from peripheral blood. The supposition is that the bacterial load of the infected catheter is higher than that seen in peripheral blood.
 - The other quantitative method—**paired quantitative blood cultures**—is based on the anticipation that the number of colony-forming units retrieved from a central blood culture would be greater than or equal to fivefold higher than that grown from cultured peripheral blood.
- Because the patient's skin around the catheter insertion site and the hands of medical personnel provide the two most common sources of pathogens, at least two-thirds of cases of catheter-related infection are caused by **staphylococcal organisms** (coagulase-negative Staphylococci and *Staphylococcus aureus*).

- Less common pathogens, including gram-negative bacteria and *Candida* spp., collectively cause about 25% of infection cases.

Approaches that Significantly Reduce Catheter-related Bloodstream Infections

- The most recent Centers for Disease Control and Prevention guidelines include new recommendations for using all of the following clinically protective measures, including cutaneous antisepsis with **chlorhexidine** (category IA), maximal sterile **barriers** (category IA), and catheters coated with the combinations of **chlorhexidine plus silver sulfadiazine**, or **minocycline plus rifampin** (category IB).
 - The superiority of *chlorhexidine* over iodophor and alcohol could be predicted by comparing their characteristics. Unlike iodophor and alcohol, chlorhexidine provides a residual and persistent antimicrobial activity that is not impaired by exposure to organic matter such as blood, does not irritate the skin, and has minimal absorption through the skin.
 - Although 2% chlorhexidine compounds appear to be optimal in terms of both efficacy and safety, only recently has aqueous chlorhexidine become available in the United States, where the most frequently used form of chlorhexidine is in combination with an alcohol, usually isopropyl alcohol.
- Another important Centers for Disease Control and Prevention guideline is the practice of maximal sterile precautions: the use of gloves, a **large drape**, a **cap**, a **mask**, and a **gown**.
- Finally, there are choices of antibiotic coated catheters. Catheters coated with **minocycline and rifampin** provide two agents both active against the vast majority of staphylococcal isolates, including methicillin-resistant *S. aureus* and *S. epidermidis*, thereby reducing the likelihood of developing superinfection by Gram-negative bacteria or *Candida* spp.
 - The clinical efficacy of this catheter was confirmed in a **prospective randomized trial** (PRT), with mean placement duration 6 days, where these central venous catheters were significantly less likely than uncoated catheters to become colonized (8% vs. 26%; $p < 0.001$) with less bloodstream infection (0% vs. 5%; $p < 0.01$). In another PRT, minocycline rifampin catheters were more protective than the first-generation chlorhexidine/silver sulfadiazine-coated catheters, with a threefold lower rate of catheter colonization (7.9% vs. 22.8%; $p < 0.001$) and a 12-fold lower rate of CRBSI (0.3% vs. 3.4%; $p < 0.002$).
- The second-generation chlorhexidine/silver sulfadiazine-coated catheters have a longer durability of antimicrobial

activity than the first-generation catheters. A PRT demonstrated that second-generation chlorhexidine/silver sulfadiazine-coated central venous catheters were less likely to become colonized than uncoated catheters (9% vs. 16%, $p < 0.01$) but had a statistically insignificant trend for a lower rate of CRBSIs (0.3% vs. 0.8%).

Other Practices

- A controversial practice is **guidewire exchange** of vascular catheters.
 - In hemodynamically stable patients with limited vascular access and in whom catheter-related infection is possible but not very likely, it is reasonable to insert the new catheter over a guidewire as long as the removed catheter is cultured; should culture of the removed catheter yield growth, it is recommended to remove the catheter that was newly inserted over a guidewire and place yet another catheter at a different site.
 - Although it is theoretically plausible that insertion at the same site of a vascular catheter with effective antimicrobial coating along both the external and internal catheter surfaces may obviate the need to manipulate another vascular site, this approach requires clinical investigation.
- Attachment of an **antimicrobial hub** containing iodinated alcohol to central venous catheters is another available tool.
 - Because this antimicrobial catheter hub protects only against organisms that migrate through the hub along the internal surface of the catheter but not against skin organisms that advance along the external surface of the catheter, the potential clinical benefit of using this preventive approach in the context of vascular catheters that remain in place for less than or equal to 7 to 10 days is doubtful.
- The relationship between **infection and thrombosis** of vascular catheters prompted numerous investigations of the clinical efficacy of flushing or locking the catheter lumen with various **antibiotic–anticoagulant combinations** that do not result in systemic levels of the antibiotic
 - Because this approach provides antimicrobial activity against only organisms that exist in the catheter lumen, clinical investigations have generally focused on long-term vascular catheters that are frequently infected by such a route. Clinical trials have yielded **discrepant results**.
 - Although there were no observed cases of infection of vancomycin-locked catheters by vancomycin-resistant organisms, the potential emergence of resistance to vancomycin, a drug that is still used to treat most cases of catheter infections, continues to underscore the equivocal role of this strategy.

CHAPTER 13 ■ VASCULAR CANNULATION

VENOUS CANNULATION

- The decision to place a central venous access device should be made after considering the risks and benefits to each patient. Indications include the following:
 - Patients who have **difficult peripheral intravenous (IV) access** such as obese patients or drug abusers
 - Administration of **chemotherapy or caustic drugs** such as amphotericin B, sulfamethoxazole trimethoprim, ciprofloxacin, dobutamine, doxycycline, erythromycin, ganciclovir, lidocaine, penicillins, pentamidine, phenegan, phenytoin, potassium (depending on dilution), ceftriaxone, vancomycin, and tobramycin
 - Infusates with an **osmolality >280 to 300 mOsm** such as parenteral nutrition
 - Performance of **plasmapheresis**, and **hemodialysis**

General Considerations

- Obtain **informed consent**: Informed consent is a process of communication between a patient (or patient's surrogate) and physician that results in the patient's authorization or agreement to undergo a specific medical intervention.
- Obtain **procedure-directed history and physical exam**, such as
 - Location and number of **previous** central venous catheters (CVCs) and ports
 - Location of known **venous thrombi**
 - History of **infected** ports and their sites
 - History of **clavicle fracture** (pertinent for subclavian approach)
 - History of **bleeding** associated with CVC placement
 - History of **pneumothorax** or other complications from previous CVCs
 - History of inferior vena cavae (IVC) **filter** placement
 - Current or recent use of warfarin, aspirin, clopidogrel bisulfate, heparin, low-molecular-weight heparin, or other **anti-coagulants**
 - History of **pacemaker** insertion
- Prior to starting the procedure, obtain all necessary items listed below and, using an aseptic technique, open them onto a working table in close proximity to the patient.
 - Sterile **gown** and **gloves**
 - **Hat** and **mask**

- Central line kit with a **large enough drape** to cover the insertion area and to prevent contamination of long wires
- 2% **chlorhexidine** or 10% povidone iodine
- Sterile **saline flush**

General Technique for Central Venous Catheters

- Prepare the skin with 2% **chlorhexidine** (preferred over povidone due to less infection rate) or 10% **povidone iodine** if patient is allergic to chlorhexidine.
- Ten percent povidone iodine has no immediate effect due to slow release of iodine and takes about 2 minutes to be fully effective. Appropriate time for drying prior to draping should be allowed.
- This gap can be filled as the time to obtain a **maximum sterile barrier**.
 - This includes the placement of a **sterile cap, mask, gown, and gloves** for every single procedure.
 - The use of all four elements consistently along with appropriately prepped skin reduces **catheter-related septicemia by sixfold**.
- The patient's scrub should include a generous area and extend **10 cm** outward in a circular manner from the planned insertion point. If the line is placed in an area with hair, the hair need not be removed.
- **Prepare the CVC kit prior** to starting the line placement as follows:
 - Load the 1% **lidocaine**.
 - Bring the wire onto the sterile field close to the insertion point to minimize movements after cannulation of the vein with the finder needle.
 - Adjust the wire by pulling the **J-curve of the tip into the hub** of the guidewire holder so that it is straightened out and ready for insertion.
 - Remove the distal port cap off the catheter for easier placement over the wire.
 - **Flush the ports** of the catheter with sterile saline to remove air.
 - Next, place the **large sterile drape** over the insertion site. Do not occlude the air supply or field of vision when draping neck areas of conscious patients. An assistant, electronic devices, or both must **monitor** relevant parameters of the patient's well-being continually through the procedure, because the operator may lose valuable clues while concentrating on the procedure and because much of the patient is obscured by drapes.
 - Local analgesia may be obtained by injecting 1 to 5 mL of 1% lidocaine without epinephrine subcutaneously so that a 1-cm wheal is raised. Use the **smallest needle** available (preferably 30 gauge) and **inject slowly** to minimize discomfort of tissue distention.
 - Attention should be paid to the **track** of local anesthetic instilled so that subsequent larger needles are not inserted into an area where there is minimum anesthetic.
 - Some operators use the smallest needle to create a skin wheal, leave that needle in the skin after removing the syringe, and then replace the small needle with a longer 21- to 22-gauge needle into the same site to further infiltrate the deeper tissues. This longer needle is then **left in**

the tissues after removing the syringe and serves as a **guide** to insert the final large needle precisely into the tissue that has been well anesthetized.

- Conscious sedation must be used with great caution in nonintubated patients.
- After accessing the vein, use the **Seldinger technique** for catheter insertion.

Seldinger Technique

- The desired vessel or cavity is punctured with a sharp hollow needle called a trocar.
 - A round-tipped (J-tipped) guidewire is then advanced through the lumen of the trocar, and the trocar is withdrawn.
 - Any hollow catheter or cannula can now be passed over the guidewire into the cavity or vessel. The guidewire is then withdrawn.
 - **Do not force** the wire through the finder needle; resistance of any type is an indication to stop, remove the needle and guidewire, and hold pressure on the vein.
 - Check the **distance of the catheter** inserted from skin entry site (Table 13.1).
 - After catheter insertion, verify that **all ports allow aspiration of blood** and can be flushed with saline without resistance.
 - Secure the catheter, cover with a **nonocclusive sterile dressing**. Antibiotic ointments (bacitracin, neomycin, and polymyxin) should not be used, as they increase the rate of catheter colonization by fungi, promote the emergence of antibiotic-resistant bacteria, and do not lower the rate of catheter-related bacteremia.
 - Obtain a **stat chest radiograph** to verify the position and exclude pneumothorax or other injuries (x-ray not needed with femoral approach).
 - **Document** the procedure appropriately in the chart.
- Caution:** Excessive **dilation** extending beyond the subcutaneous tissue and fat into the vein increases the risk of postprocedure complications (oozing, hematoma formation, arteriovenous fistula formation, and pseudoaneurysm formation).
- **Inadvertent arterial puncture** and subsequent hematoma or pseudoaneurysm formation can be prevented by providing **direct pressure** manually or with a standard device for at least 30 minutes.

TABLE 13.1

DISTANCE FROM SKIN PUNCTURE SITE TO ATRIA-CAVAL JUNCTION

Insertion site	Distance
Right internal jugular vein to atria-caval junction	16.0 cm
Right subclavian vein to atria-caval junction	18.4 cm
Left internal jugular vein to atria-caval junction	19.1 cm
Left subclavian vein to atria-caval junction	21.2 cm

From Tan BK, Hong SW, Huang MH, et al. Anatomic basis of safe percutaneous subclavian venous catheterization. *J Trauma*. 2000;48(1):82–86.

Technique of Central Venous Cannulation

Femoral Vein Cannulation

- The femoral vein is punctured in the femoral triangle (inferior to the inguinal ligament, lateral to the adductor longus, and medial to the sartorius muscles) where it lies medial to the femoral artery (Fig. 13.1).
- Locate the femoral artery, keep a finger on the artery, and introduce the finder needle attached to a 10-mL syringe at an angle 45 degrees to the skin, about 1 cm medial to the femoral artery pulsation, 2 cm below the inguinal ligament.
- Slowly advance the needle cephalad and posteriorly while continuously withdrawing the plunger. Too much suction applied to the plunger in a hypovolemic patient may lead to vein collapse with minimum blood return. This may mislead the operator into assuming the needle is not in the vessel lumen.
- Once venous blood is obtained, use the Seldinger technique to complete the procedure (see earlier discussion).

Caution: Stay below the inguinal ligament. The distal tip of the finder needle should not traverse cephalad to the inguinal ligament to avoid retroperitoneal hematoma and/or intra-abdominal injuries.

FIGURE 13.1. Anatomy of the femoral artery and vein. Use the mnemonic NAVEL (Nerve, Artery, vein, Empty space, Lymphatics) to recall structures as you move in a lateral to medial direction toward the navel.

Internal Jugular Vein Cannulation

- The anatomic relationship of the internal jugular (IJ) vein to the carotid artery varies. For purposes of IJ vein access, an important anatomic triangle is formed by the two heads of the sternocleidomastoid and the medial one-third of the clavicle. Within this triangle, the carotid artery lies medial and slightly posterior to the IJ vein, decreasing its chances of accidentally being punctured during catheter insertion (Fig. 13.2).
- **Ultrasonography (US)** lessens the complications of inadvertent puncture and/or cannulation of the carotid artery and is becoming the standard of care.
- Stand at the head of the bed.
- Place the patient in a **Trendelenburg** position, at least 15 degrees head down to distend the neck veins and to reduce the risk of air embolism.
- Slightly turn the head (**no more than 20 degrees**) away from the puncture site. Turning it too far increases the risk of arterial puncture.
- The syringe and needle should be stabilized by resting the hand on the mandible of the patient at its midpoint (Fig. 13.3)
- The vein is usually **within 2 to 3 cm** of the skin. If the vein is not found, redirect the needle more laterally.
- Use the **Seldinger technique** (see earlier discussion).
- If the patient is intubated and on **high positive end-expiratory pressure (PEEP)** settings, holding the inspiratory effort for a few seconds while cannulating the IJ vein may decrease the overinflation of the lung apex and decrease the chances of obtaining a pneumothorax. (This should be performed only if no deleterious effects occur toward the patient's oxygenation, ventilation, alveolar recruitment, or overall status.)

FIGURE 13.2. Anatomy of the internal jugular vein.

FIGURE 13.3. Attach a fresh 10-mL syringe to the large 18-gauge 2-inch finder needle and, using the previously placed 22-gauge needle as a guide, find the internal jugular vein.

Subclavian Vein Cannulation

- The subclavian vein is a continuation of the axillary vein and runs from the outer border of the first rib to the medial border of anterior scalene muscle where it joins with the IJ vein to form the innominate vein (brachiocephalic vein). The vein is separated posteriorly from the subclavian artery by the insertion of the scalenus anterior and posteromedially from the dome of the pleura by Sibson fascia (suprapleural membrane). The pleura lies only 5 mm posterior to the subclavian vein. Its diameter is approximately that of a man's small finger. The left subclavian vein is the site at which chyle, formed in the intestines from dietary fat and lipids, enters the blood stream via the thoracic duct.
- The position that provides the **greatest exposure** of the subclavian vein was with the shoulders in the **neutral position and slightly retracted**. However, in the **Trendelenburg** position, the shoulders assume a protracted (shrugging) position secondary to the effects of gravity. This must be actively reversed by **pulling the arm in a caudal direction** while performing the venipuncture to return the shoulder to a neutral position and maximize vein exposure from under the clavicle.
- This maneuver is extremely helpful even in patients who cannot be in the Trendelenburg position or who are unable to have a roll inserted between the scapulae.
- Second, a retracted position of the shoulder, as obtained by placing a rolled towel beneath the vertebral column between the scapulae to allow the **shoulders to fall back**, was shown to serve two very important purposes: (a) It prevents the interference between the path of the needle insertion and the humeral head of the shoulder, ensuring that the needle and syringe are always parallel to the coronal plane; and

(b) it brings the subclavian vein into close contact with the undersurface of the clavicle, which is desirable for accurate identification of the vein.

- Place a rolled towel beneath the vertebral column between the scapulae to allow the shoulders to fall back into a slight neutral-retracted position (*contraindicated* in patients with **cervical spine injuries** since elevation of the shoulders may lead to neck flexion and should not be done on trauma victims without spine clearance. Place the patient in a **Trendelenburg** position, at least 15 degrees head down to distend the subclavian veins and to reduce the risk of air embolism).
- Identify the **middle one-third** of the clavicle as it follows a **gentle curve up** toward the shoulder. **Have an assistant pull the arm caudad at the initiation of venipuncture.**
- Enter the skin at the anesthetized point along the upper border of the medial one-third of the clavicle at the junction of the sternocleidomastoid muscle and the clavicular head (Fig. 13.4). While maintaining **constant suction** on the syringe, point the needle tip **toward the suprasternal notch** and a parallel line to the coronal plane and the floor and gently advance the needle tip cephalad until it **hits the clavicle**. The index finger rests on the suprasternal notch and provides the direction toward which the tip of the finder needle is directed.
- **Withdraw the needle and syringe back 2 cm** from the clavicle prior to making an effort to pass under the leading edge. Not withdrawing the needle 2 to 4 cm is a common mistake and makes the maneuvering of the needle tip around the convex leading edge of the clavicle difficult.
- A common mistake, especially in overweight patients or patients with large stature, is to use a puncture site that is **too close to the clavicle**.
- This makes it extremely difficult to pass the finder needle under the clavicle while maintaining the needle and syringe parallel to the coronal plane and the floor.
- As the angle of entry between the patient's chest and the syringe increase in an effort to get under the clavicle, the

FIGURE 13.4. Enter the skin at the anesthetized point and point the needle tip toward the suprasternal notch. While maintaining constant suction on the syringe and a parallel line to the coronal plane and the floor, gently advance the needle tip cephalad until it passes under the clavicle and into the vein.

chances of producing a pneumothorax also increase proportionally.

- A distance more than 2 cm from the edge of the clavicle may be necessary in larger patients.

Caution: At all times maintain the needle and syringe parallel to the coronal plane and floor.

- Once the vein is accessed, use the Seldinger technique (see earlier discussion).

Pulmonary Artery Catheter Insertion

- Insert the **introducer** for the PAC in similar fashion as the central line (see earlier discussion). Flush the introducer with saline to prevent thrombosis.
- Take great care in maintaining sterile technique at all times while working closely with the nonsterile assistant. Protect the sterile portion of the catheter by resting it on the **large sterile field** while the transducers are attached.
- Have the assistant check the proximal and **distal ports** for patency by **flushing** them with sterile saline. Also have the assistant check the **patency of the balloon** using the syringe provided in the kit.
- Familiarize yourself with the markings on the PAC prior to placing the catheter. **Single thin lines** are used to indicate a distance of 10 cm, while a **single wide line** indicates a distance of 50 cm from the tip.
 - These lines are used in combination to indicate the distance from the tip (i.e., two thin lines indicate 20 cm from the tip). The wedge position is achieved in most patients at 45 to 55 cm from the tip.
- Place the sterile **plastic sleeve** over the catheter after flushing all ports to further protect the catheter in a sterile cover during manipulation (Fig. 13.5).
- The distal end of the PAC is then inserted into the central venous introducer hub and is threaded down the central vein into the superior vena cava.

FIGURE 13.5. Place the plastic sleeve cover over the catheter to maintain sterility during placement and to help secure and lock its final position onto the introducer.

- The PAC must be placed at **least 30 cm** (three thin lines) into the introducer for the **balloon** to clear the distal end of the introducer sheath prior to inflation.
- Once at 30 cm in the central vein, the balloon is inflated, and the catheter is advanced through the right atrium, past the tricuspid valve into the right ventricle, quickly through the right ventricle (to minimize occurrence of arrhythmias), and past the pulmonary valve into the pulmonary artery. The **waveforms and pressure** readings on the monitor provide the information on the position of the catheter in the vasculature (Fig. 13.6).
- Once in the pulmonary artery, the catheter should be carefully advanced until it wedges. At this point, the balloon can be deflated, and pulmonary artery tracings should reappear. If the balloon wedges before maximal reinflation, then the catheter is “**overwedged**” and should be pulled back slightly until it wedges only with maximal inflation (this helps prevent pulmonary artery rupture).
- General guidelines for the distance necessary to travel to reach the various structures of the heart are as follows:
 - The right atrium: 20 to 25 cm
 - The right ventricle: 30 to 35 cm
 - The pulmonary artery: 40 to 45 cm
 - The catheter usually wedges at 50 to 55 cm
- Once the PAC is in the correct position, the balloon should be deflated and the catheter **secured** in place by **locking the plastic sleeve tip** onto the hub of the introducer at two places to avoid movement.
- Correct catheter placement is confirmed with a chest radiograph.

Caution: AT NO POINT SHOULD THE PAC EVER BE WITHDRAWN WHILE THE BALLOON IS INFLATED! Always verify that the assistant has deflated the balloon prior to withdrawing the PAC. This avoids the complication of rupture of the pulmonary artery, which can lead to massive life-threatening hemorrhage and death.

Complications of Pulmonary Artery Catheterization

- Overall complication rate is 15%.
- Mechanical complication rate is 5% to 19%.
- Infectious complication rate is 5% to 26%.
- Thrombotic complication rate is 2% to 26%.
- Arrhythmias are the most common complication of PAC insertion and occur secondary to ventricular irritation as the catheter passes to the pulmonary artery (PA). More than 80% of these are premature ventricular contractions or non-sustained ventricular tachycardia. They are self-limiting and resolve with advancement of the catheter from the right ventricle (RV) into the PA or with prompt withdrawal of the catheter back into the right atrium. Significant arrhythmias requiring treatment occur in fewer than 1% of patients, usually those with concurrent cardiac ischemia.
- Right bundle branch block occurs in 5% of PAC insertions and usually is transient after positioning the catheter into the PA. The presence of a pre-existing left bundle branch block puts the patient at risk for complete heart block should right bundle branch block occur. In these patients, temporary pacing equipment should be kept nearby on standby.

FIGURE 13.6. Use the waveforms to guide the placement of the pulmonary artery catheter from the right atrium, through the right ventricle, to the pulmonary artery, and finally into the wedge position. RA, right atrium; RV, right ventricle; PA, pulmonary artery; PCW, pulmonary capillary wedge.

- The incidence of knotting of the PAC on itself, on intracardiac structures, or on pacing wires is less than 1%. This risk is increased in patients with dilated cardiac chambers. A persistent RV tracing despite advancement of the PAC further than 20 cm into the patient should alert the physician to this possibility.
- Pulmonary artery rupture is the most catastrophic complication of PAC insertion. Although it occurs in fewer than 1% of cases, it carries a mortality rate of 50%. Age over 60 years, anticoagulation therapy, and the presence of pulmonary hypertension increase the risk of rupture. The presence of sudden and large quantities of hemoptysis, especially immediately after PAC balloon inflation, greatly indicates this possibility. Management includes lateral decubitus positioning (bleeding side down), intubation with a double-lumen endotracheal tube, and increasing positive end-expiratory pressure. Embolization via bronchoscopy or angiography or lobectomy may be necessary if bleeding continues or is massive.
- PAC-related infection is a fairly common complication. The incidence of positive catheter tip culture result is 45% in some series. Fortunately, the risk for clinical sepsis is less than 0.5% per day of catheter use.
- The incidence of pulmonary infarction is less than 7%. Unintentional distal migration of the PAC tip is the usual cause. Some evidence indicates that catheter-related thrombi also may be a significant cause. Though postmortem studies have shown that the rate of endocardial lesions (e.g., thrombi, hemorrhage, vegetations) related to PAC use is significant, correlation with clinical events has not been established.

Central Line Complications

- More than 15% of all patients who receive CVCs have complications. At least 52% of the reported complications are related to practitioner **technique** and the level of **experience**. Physicians who have placed >50 CVCs are half as likely to have a mechanical complication as those who have performed <50. The incidence of mechanical complications after three or more **insertion attempts** is six times that after one attempt. An increasingly important tool for improving safe learning curves for CVC placement is the two-dimensional ultrasound imaging and guidance.
- **Mechanical complications** associated with CVC placement include **cardiac tamponade, hemothorax, pneumothorax, carotid artery injury, subclavian artery injury, venous rupture, air embolism, catheter malpositioning, catheter transection, and wire or catheter embolism**. Compared to the subclavian vein cannulation, the IJ route is more likely to be complicated by arterial puncture (3%–4% vs. 6%–9%) and less likely to be complicated by pneumothorax (1%–3% vs. 0.1%–0.2%). The femoral route, in comparison to the other two routes, is associated with a much higher rate of arterial puncture (9%–15%) and hematoma formation (3%–5%) but, in the emergent setting, offers the advantage of avoiding pneumothorax and hemothorax.
- The tip of an intact catheter can **migrate** into the opposite brachiocephalic vein, jugular vein, or azygous veins. Interventional radiology can play an important role in repositioning **misplaced catheters**.

- If a catheter was placed without imaging guidance, it may be placed into an **artery**. Appropriate consultation of the **vascular or cardiothoracic service** should be obtained prior to removing misplaced catheters from the subclavian artery and the carotid artery. Malposition of the catheter tip into the lumbar venous plexus resulting in paraplegia has also been described as a rare complication of CVC placement.
- **Perforation of the great vessels** occurs less than 1% of the time but carries nearly a 40% mortality rate. More commonly seen with the right subclavian vein approach, it usually is the result of guidewire kinking during advancement of the dilator.
- **Pinch-off syndrome** has been described with the subclavian route when the catheter is crushed between a narrow path between the clavicle and the first rib. The catheter can become occluded and, with repeated trauma, it can fracture and embolize distally. The fragment can become lodged in the heart, resulting in cardiac arrhythmias or perforation, or it can be embolized further into the pulmonary artery. If recognized early, the interventional radiologist can usually capture the catheter fragments and successfully remove them. If the fragments remain unrecognized, thrombus formation and fibrosis around the catheter can result in catheter attachment to the vessel wall.
- **Guidewires** used for venous access can become **trapped** in indwelling vena cava filters or electrodes from pacemakers and other implantable devices. Fluoroscopy often demonstrates that the J-wire has become trapped around the tip of an IVC filter. Pulling back on the wire in the hope of dislodging it can have catastrophic results, with migration of the filter, tears in the IVC, hemorrhage, and death. Several techniques are available to the interventional radiologist to remove broken wires or wires trapped in filters. The key is to **stop** if there is resistance or if the wire is trapped and difficult to remove and immediately enlist the assistance of the interventional radiologists.
- **Air embolism** may also occur as a rare complication during CVC placement. It is more common in conditions that diminish the central venous pressure, such as decreased intravascular volume and upright sitting position. Rapid introduction of air into the venous circulation of greater than 300 to 400 mL at a rate of 100 mL/second is considered to be fatal. Clinically, the patient will have immediate **hypoxemia** and/or **cardiovascular collapse**. The hypoxemia is a result of V/Q mismatch (ventilation without perfusion) due to mechanical obstruction of vessels by the air bubbles. The air further has a chemical activation of the pulmonary endothelium resulting in activation of complement, free radicals, and inflammatory mediators, which results in bronchoconstriction and/or noncardiogenic pulmonary edema. The physical exam reveals the wheezing and crackles of **heart failure**. The classic finding of **mill wheel murmur**, a churning sound heard throughout the entire cardiac cycle from air bubbles in the RV, is a relatively specific sign of air embolism but is insensitive and occurs late in the course. Management includes **securing the airway** and placing the patient in the **left lateral decubitus position with right side up**, making it more difficult for the air to enter the right ventricular outflow tract (pulmonary artery) because it is in a dependent position. The best intervention is **prevention**; placing the patient in 15 degrees of Trendelenburg position prior to placing the CVC increases the central

venous pressure and decreases the chance for air embolism to occur.

- **Catheter-related venous thrombosis**, diagnosed with US, occurs in approximately 15% of patients in the medical intensive care units. The risk of catheter-related thrombosis is directly proportional to the site of insertion; it occurred in 22% of patients with femoral venous catheters, and only 2% of patients with subclavian venous catheters. In a nonrandomized observational study, the IJ vein was associated with four times the risk of thrombosis as compared to the subclavian vein. Therefore, subclavian vein cannulation carries the lowest risk of catheter-related thrombosis.
- For catheter infections and prevention, see Chapter 75.

Peripherally Inserted Central Catheter

- A peripherally inserted central catheter (PICC) line provides long-term (1–6 mo) intravenous access for chemotherapy regimens, extended antibiotic therapy, or total parenteral nutrition. It is an alternative route of central access through a peripheral vein (brachial, basilic, or cephalic) with little risk of pneumothorax, air embolization, and cardiac arrhythmias. PICC lines are usually inserted under the guidance of fluoroscopy, US, or radiographs by radiologists or certified registered nurses.
- The rate of complications significantly increases as the number of PICC line days exceeds 30. More than 70% of complications occur after 30 days of placement. The infection rate for PICC lines is similar to conventionally placed CVCs; however, they have the added disadvantages of being more vulnerable to thrombosis and dislodgement and less useful for drawing blood specimens.
- Another concern is over usage that potentially exhausts upper-extremity venous access sites. This may have serious implications in chronically ill patients, especially those with renal failure who may eventually require arteriovenous fistulas for dialysis access. Complication rates (infection, sepsis, and thrombosis requiring removal) as high as 40% to 50% have been reported with the use of PICC lines in chemotherapy patients. Based on the foregoing evidence, we recommend strong caution against the routine use of PICC lines.

ARTERIAL CANNULATION

- Continuous blood pressure monitoring is essential for the management of critically ill patients. Significant differences may occur between arterial pressures measured by direct versus indirect invasive methods (see Chapters 6 and 8).
- The indications for peripheral arterial cannulation include:
 - **Continuous blood pressure (BP)** monitoring in postoperative and critically ill patients
 - **Hypotension or hypertension** requiring continuous drug infusion
 - Mechanically ventilated patients that require **repeated blood gases**
- Use **caution** in the following circumstances:
 - Extremities with burns or trauma
 - Extremities with carpal tunnel syndrome

- Broken or infected skin
- Coagulopathy
- Raynaud disease
- Near arterio-venous (AV) fistulas and synthetic grafts
- The most frequently used site for direct arterial cannulation and blood pressure measurement is the **radial artery**. Use of the femoral artery, axillary artery, dorsalis pedis artery, and temporal artery has also been described. Utilization of the **brachial artery** is *not recommended* due to poor collateral circulation and secondary ischemia to the radial and ulnar artery in the setting of obstruction, due to the potential for **loss of the hand**.
- With regard to radial artery cannulation, the value of the **Allen test** in predicting potential ischemic damage after cannulation is at best **unreliable**. The original test described in 1929 was for the purpose of evaluating palmar collateral circulation in thromboangiitis obliterans. In critically ill patients, the test has poor predictive power.

General Technique

- First **palpate** the artery at **two points** 2 cm apart.
- Using an 18-gauge needle, make a small superficial **break** through the **skin** over the artery. This penetrates the tough skin barrier and prevents shearing and damage of the tip of the catheter during subsequent arterial penetration.
- The catheter cannula is advanced through the puncture site along the course of the artery at a 30- to 45-degree angle to the skin.
- Once the anterior wall of the artery is penetrated, the needle is withdrawn, and the plastic cannula is gently advanced into the arterial vessel at a lower angle (15–30 degrees) to facilitate smooth passage.
- The catheter with the needle may pass through the **anterior and posterior walls** of the artery. In this case, after removing the inner needle, gently withdraw the plastic cannula until pulsatile blood flows freely from the open end. Then advance the plastic cannula at a lesser angle into the arterial lumen.
- The use of a guidewire and the Seldinger technique may be employed to assist with the threading of the cannula into the artery after penetration.
Caution: Never try to thread the guidewire against even slight resistance.
- If *complications* occur, such as distal ischemia, local infection, inability to withdraw blood effectively, or poor waveform, the arterial catheters should be changed to another site. Before removal, pressure should be applied proximally and distally to the insertion site. Attaching a syringe to the catheter and applying suction during extraction (for removal of developed clots) decreases the incidence of arterial thrombotic occlusion. After catheter removal, fingertip pressure should be applied for 10 minutes or as long as necessary to achieve hemostasis and prevent hematoma or aneurysm formation.

Radial Artery

- The radial artery is one of the best cannulation sites due to its accessibility and the safety of extensive collateralization.

- The **nondominant hand** of the patient should be cannulated first. Placing a small rolled towel under the wrist and securing it with tape onto a backboard in a **hyperextended position (about 20 degrees)** diminishes the arterial tortuosity and increases the cannulation success rate.
- The artery should be cannulated 1 to 2 cm proximal to the wrist flexion point where there is a lower risk for digital ischemia because of better collateral circulation.

Femoral Artery

- See the preceding section for identification and cannulation techniques for the femoral vein.
- The femoral artery is **lateral** to the femoral vein. The artery can be easily palpated in most patients.
- It should be punctured **below the inguinal ligament** to prevent intra-abdominal injury and retroperitoneal hematomas. The artery is usually reached 3 to 5 cm from the skin.
- The modified Seldinger technique is usually required for femoral cannulation.
- Consider using a **Doppler US** to guide cannulation in high-risk patients who are anticoagulated or obese.

Axillary Artery

- The axillary artery should be cannulated as **high as possible in the axilla**, close to the thoracic apex, because of a rich anastomotic network surrounding the artery in this region.
- The axillary artery is fraught with a number of complications. Care must be taken with needle punctures high in the apex of the thoracic cavity to avoid **pneumothorax** or hemothorax. Thromboembolism can also occur from the axillary artery down to the radial or ulnar artery. Hematoma from a puncture leak of the artery can fill the axillary sheath around the neurovascular bundle and compress the brachial plexus, resulting in nerve damage and peripheral neuropathy.
- Since the risk of **cerebral air embolism** from accidental air injection into the axillary artery is higher with **right-sided catheterization**, placement should be performed preferentially on the left side first.

Dorsalis Pedis Artery

- This small artery is congenitally absent in 3% to 12% of the population and is often difficult to cannulate; furthermore, blood pressure measured in the dorsalis pedis artery may differ significantly from that measured in more central arteries, especially in the presence of vasopressor infusion.

Temporal Artery

- Rich collateral circulation and easy accessibility make the temporal artery an attractive site for cannulation; tortuosity and its location, however, make cannulation and maintenance extremely difficult.

Complications of Arterial Catheters

- The most common complications include local ischemia, infection, hematoma, bleeding, thrombosis, distal embolism, ischemic necrosis, arteriovenous fistula formation, air embolism, and neuropathy. Of these, ischemic necrosis and thrombosis are two of the most concerning complications occurring 1% to 2.5% of the time. The incidence of local infection at the catheter insertion site is reported to be as high as 10% to 15%, whereas the incidence rate of catheter-related sepsis is 0.2% to 5%.

CHAPTER 14 ■ FEEDING TUBE PLACEMENT

For critically ill patients, enteral nutrition is preferable to parenteral whenever feasible. Although parenteral nutrition can effectively deliver protein and calories, it does not prevent intestinal mucosal atrophy. It is now well recognized that the healthy gut mucosal layer provides a barrier to pathogen invasion. Microbial invasion through the gut into the systemic circulation is thought to represent a major cause of the nosocomial sepsis, and possibly the multiple organ dysfunction, seen with critical illness.

- The initial consideration for determining the choice of an enteral access system is the anticipated duration of enteral feeding.

Short term: Patients predicted to need enteral feeding for **2 weeks or less** are said to have short-term requirements. These patients are best served with bedside placement of a **nasoenteric tube**.

Long term: Patients thought to need enteral feeding for greater than **6 to 8 weeks** are described as having long-term requirements. **Percutaneous or surgically placed** tubes are most appropriate for this subgroup of patients.

Intermediate: Patients with the anticipated need for enteral feeding for greater than 2 weeks but less than 6 to 8 weeks are said to have an intermediate requirement. These patients are well served by nasally, percutaneously, or surgically placed feeding tubes.

- Determine whether the patient can tolerate enteral nutrition.
 - Based on the patient's overall condition, associated medical conditions, the **functional status of the gastrointestinal tract**, and available hospital resources, the most appropriate type of feeding tube and placement technique can be chosen.
 - If the attempted placement technique is unsuccessful, reconsider the foregoing and choose another enteral access option.
 - Roughly half of critically ill patients have **gastric emptying dysfunction**.
 - Many underlying conditions such as diabetes mellitus, medication use, gastritis, sepsis, and electrolyte abnormalities also affect gastric emptying. For these patients, enteral tubes may need to be placed beyond the pylorus.
 - Although **postpyloric feedings** are generally favored, postpyloric tube placement should not unduly delay the start

of enteral nutrition as gastric feedings are often well tolerated.

- Though bolus gastric feeding may occasionally be used, continuous infusion of enteral feeds is better tolerated than bolus feeding.

NASOGASTRIC TUBE

- The least complicated and quickest feeding access is the **nasogastric tube**.
 - Although the stiffer, wider tubes used for gastric decompression also can be used for feeding, it may be preferable to replace these tubes with the thin, softer, more flexible tubes.
 - The tube is lubricated and then passed blindly through a nostril. It travels down the posterior pharynx into the esophagus and then into the stomach. Placement is aided by wire stylets or weighted tips.
- **Auscultation of air instilled** into the nasogastric or nasoenteric tube is useful for determining proper tube placement. It is important to confirm that the tube was not inadvertently placed into the bronchial tree.
- **Complications** are similar to those of the sump tube, such as **epistaxis, rhinitis, esophageal perforation or hemorrhage, pneumothorax**, and inadvertent placement into the **trachea or bronchus**.
 - After placement of a nasogastric or nasoenteric feeding tube, an abdominal **radiograph** should be obtained to confirm proper tube location **before infusing the enteral formula**
- If gastric feeding is used, the addition of **proton pump inhibitors** may be helpful.
- **Metoclopramide** increases upper gastrointestinal motility by blocking dopamine receptors. Metoclopramide is associated with movement disorders, which may be irreversible.
- **Erythromycin**, a macrolide antibiotic that is also a motilin agonist, increases gastric emptying and tolerance to gastric feeding. The commonly used dose is 200 mg, but **70 mg** may be just as effective.
 - Unfortunately, patients often develop **tachyphylaxis** to the drugs after several days, requiring close monitoring of gastric volumes and feeding tolerance.
- The long-term use of any antibiotic raises concerns about the development of resistance.

POSTPYLORIC TUBES

- A large variety of tube designs are commercially available. For nasal placement, tubes tend to be thin, soft, and flexible.
 - Most are polyvinyl chloride, silicone, or polyurethane.
 - Many are weighted at the tip with mercury, whereas others are unweighted.
 - Most contain a thin metal stylet to assist in placement.
 - All are radiopaque to enable confirmation of position by radiographic study.
 - Their soft, flexible construction and narrow diameter enables these tubes to be well tolerated by the patient. However, these tubes are prone to occlusion, particularly if feeding is interrupted without irrigating the tube free of formula and when the tube is used for the delivery of crushed or dissolved medications.
- Several bedside techniques have been described to aid in achieving **postpyloric placement of tubes** inserted through the nose. These techniques are highly successful in experienced hands.
- Manually passing the soft, thin, flexible tube across the length of the stomach and beyond the pylorus is often challenging (Fig. 14.1). Often, the tube coils back into the fundus or cannot easily be negotiated through the antrum and pylorus. In most cases, the difficulty in tube advancement into the duodenum is related to the blind nature of the passage and to the inability to steer or guide the tube.
- Several techniques have been described to aid in passage. Some authors have reported improved success with simple maneuvers such as placing the patient in the **right lateral decubitus position**, giving the tube a gentle **clockwise twist** as it is being passed, or **bending the tip** of the stylet.
 - House officers who learned the technique were able to achieve placement rates of 70% to 80%.

FIGURE 14.1. Nasoenteric feeding tube.

- The use of **ultrasound, electrocardiogram, or electromagnetic transmitter** for **location of the tip** of the tube during insertion have all been described and may decrease the time of insertion and the number of confirmatory radiographs. However, these techniques do not actually guide the tube in its course.
- A technique using an **industrial magnet to guide a magnet-tipped tube** into the duodenum has also been described.
 - All these techniques have reported success rates above 75%, but large trials comparing them to other techniques are lacking.
- **Continuous pH monitoring** using a specially designed tube that has a built-in pH sensor in the tip has been described to facilitate passage by enabling recognition of the tube tip location. Generally, **lower pH** values are found in the **stomach** compared with the duodenum even in patients receiving H₂-receptor antagonists.
 - This device may obviate the need for radiographic confirmation of tube location. Although the need for fewer radiographs may save money, the requirement for specialized tubes and a pH monitor may offset the savings.
 - These tubes are generally two to three times more expensive than traditional tubes, and most pH monitors cost a few hundred dollars.
 - Serial or continuous pH monitoring also can be used to **indicate whether the tube has migrated back into the stomach**. However, the ability to use pH values to determine location may be less accurate in the setting of H₂-blocker administration or with achlorhydria, where the stomach has less acid production and, hence, higher than normal pH readings.
- If there is concern that a nasoenteric tube has migrated back into the stomach, its position must be clarified with a **radiograph**.
- **Fluoroscopic or endoscopic** support may be necessary for passing the tip of the nasoenteric tube beyond the pylorus. Even with the assistance of these modalities, success is not guaranteed.
- **Fluoroscopic guidance** is an excellent method for placing the tip of the feeding tube beyond the pylorus. Because the tubes are **radiopaque**, they are easily seen under fluoroscopy. Tube passage can then be guided by **direct vision**.
 - Though this technique increases the likelihood of success, it has several drawbacks: The critically ill patient must be **transported** to the radiology department or the **radiography equipment** must be brought to the ICU. The technique also exposes the patient to **radiation**.
- **Endoscopy** provides an alternate means of delivering the tube past the pylorus, but it is also the most invasive. After positioning the tube into the stomach, an esophagogastroscope is performed. The tip of the tube, or a suture secured to the tip, can then be grasped with a biopsy forceps that was passed through the endoscope and **dragged into the duodenum**.
 - Although this technique is effective, the tube may get pulled back into the stomach by the withdrawal of the endoscope, and the procedure places the patient at risk for all of the complications associated with endoscopy, including injury to the esophagus, stomach, or duodenum; perforation; bleeding; and aspiration.
- Nasoenteric tubes also can be placed at the **time of laparotomy** for patients requiring temporary jejunal access. The surgeon will **manually thread** the catheter past the pylorus while the anesthesiologist pushes it in.

- Even after the successful nasogastric placement, tubes easily can be inadvertently removed or pulled back into the stomach
- No method for **tube immobilization** (i.e., sutures, bridles, or taping) is completely secure.
 - Occasionally, replacement requires considerable effort.
 - **Frequent checks** by nurses on the secure immobilization of the tubes assist with inadvertent dislodgement during turning.

PERCUTANEOUS PLACEMENT

- Percutaneous gastrostomy has been shown to be less costly and less time consuming and has **fewer complications** than surgical gastrostomy.
 - Placement requires **fluoroscopic or endoscopic** assistance to direct the tube into the appropriate lumen after skin puncture.
 - These tubes are less likely to dislodge but can **leak**, cause **pain** at the insertion site, and induce a local soft-tissue **infection**. With long-term use, they also may begin to decay.
 - Some models have separate ports for simultaneous jejunal feeding and gastric decompression.
 - Most are secured from within the lumen of the viscus by a small flange or balloon contained within the tip; removal may require endoscopy.
- **Percutaneous endoscopic gastrostomy** tube placement generally requires one of two techniques, termed “push” and “pull.” There are numerous commercially available insertion kits that contain the tube and the equipment necessary for **placement** (see Chapter 16).
- The incidence of **major complications** with this technique is generally described as between **1% and 3%**, and the reported mortality rate is about 0.5%.
- Complications include **colonic injury**, **gastric perforation**, **hemorrhage**, **leakage with peritonitis**, **necrotizing fasciitis**, and **skin infection**.
- Conditions that preclude the ability to perform upper endoscopy such as **obstruction**, **varices**, and severe *Candida*

esophagitis are contraindications to this procedure. Relative contraindications include **ascites** with its attendant risk of **peristomal leakage** and **peritonitis** from gastric leakage. Previous upper-abdominal surgery and adhesions may prevent the stomach from being manipulated up to the abdominal wall. If **transillumination** cannot be achieved, the procedure should be aborted.

- An alternative method for percutaneous gastrostomy is the **radiographic approach**. The stomach is distended with air using a nasogastric tube. Radiopaque contrast is then instilled in the stomach to enable it to be seen with fluoroscopy. The abdominal wall then can be pressed down onto the stomach. A needle is passed into the gastric lumen and a guidewire inserted through the needle. The tract is dilated to the appropriate diameter and the tube is pushed into the lumen.
 - This technique eliminates the need for endoscopy; however, many of the **same contraindications and complications** apply. In addition, this method does not allow inspection of the mucosa before tube placement or direct visualization of tube position after it is in place.

JEJUNOSTOMY

- Surgically placed jejunostomy tubes are excellent for long-term infusion feeding but expose the critically ill patient to the risks and complications of an **operative procedure**.
- In the early 1970s, the **needle catheter jejunostomy** was introduced. Although easy to insert, it is frequently **too narrow** to allow rapid flow of the more viscous feeding solutions, and the small diameter does not allow for medication administration through the tube.
- Other options for jejunostomy placement include soft rubber tubes (**red rubber or Robinson catheters**).
 - Their wider internal diameter improves infusion and decreases the likelihood of occlusion
- These tubes are prone to **dislodgement** and need to be secured diligently. Balloon and mushroom-tipped tubes are less susceptible to inadvertent removal because their tips are wider than their shafts, which help to anchor the tubes in place.

CHAPTER 15 ■ FLEXIBLE BRONCHOSCOPY

INDICATIONS

Potential indications for flexible bronchoscopy in the ICU include the following:

- **Airway management** (intubation, changing of endotracheal tubes [ETs], and extubation)
- Diagnosis and/or management of *respiratory infections*, certain *parenchymal lung disease*, acute *inhalational injury*,

airway injury from intubation or chest *trauma*, *hemoptysis*, *atelectasis*, *airway obstruction*, and *bronchopleural fistulae*

Both fiberoptic and video bronchoscopes are utilized for flexible bronchoscopy in the ICU. With the *video bronchoscope* and with attachment of a camera head to the fiberoptic bronchoscope, observation by multiple parties is possible, which decreases the possibility of missed findings and facilitates teaching and education.

CONTRAINDICATIONS

Only a few absolute contraindications to flexible bronchoscopy exist in critically ill patients:

- Absence of informed consent
- Unavailability of trained personnel
- Inability to maintain adequate oxygenation during the procedure
- Unstable cardiac conditions
- Uncontrolled bronchospasm
- Inability to correct coagulopathy to safe levels if biopsy or protected specimen brush (PSB) is planned (relative contraindication). A platelet count should be at least 50,000 cells/ μ L if biopsies are going to be performed.

GENERAL CONSIDERATIONS

- Obtain informed consent.
- Enteral feeding or oral intake should be discontinued for at least 4 hours before and 2 hours after the procedure.
- Patients with asthma should receive bronchodilators prior to bronchoscopy.
- Platelet counts and coagulation studies should be obtained in those patients with risk factors for bleeding if bronchoscopic biopsies are planned.
- Continuous monitoring with electrocardiogram, pulse oximetry, intra-arterial blood pressure, or intermittent cuff blood pressure every 3 to 5 minutes is advised.
- Monitoring intracranial pressure and end-tidal CO_2 is suggested for patients with a serious head injury. Bronchoscopy has been noted to increase intracranial pressure by at least 50%, in 88% of patients with head trauma, despite the use of deep sedation and paralysis.
- Equipment for reintubation and bag-valve-mask ventilation should be readily available, and suctioning equipment, including Yankauer and ETs, should be accessible at the bedside.
- In mechanically ventilated patients, a special swivel adapter with a perforated diaphragm through which the bronchoscope is passed should be used to prevent loss of delivered tidal volumes.
- The lumen of the ET should be 2 mm larger than the external diameter of the bronchoscope. Due to narrowing of the airway, bronchoscopy in the mechanically ventilated patient may cause hypoxemia, hypoventilation, generation of auto-positive end-expiratory pressure (PEEP), and potential barotrauma.
- The fraction of inspired oxygen (FiO_2) should be increased to 1.0 prior to and during the procedure to ensure adequate oxygenation. Exhaled tidal volumes should be monitored during the procedure. The bronchoscope should be withdrawn periodically to allow for adequate ventilation; prolonged suctioning through the bronchoscope can decrease delivered tidal volumes and oxygenation.
- Resuscitation medications, materials for chest thoracostomy should be readily available.

PREMEDICATION

- **Topical anesthesia** (lidocaine jelly and nebulized or sprayed lidocaine) of the nares and oropharynx is used to sup-

press the gag reflex and coughing in non-intubated patients.

- In intubated patients, 1% lidocaine can be administered through the ET or through the working channel of the bronchoscope after insertion into the ET.
- Lidocaine is absorbed through the mucous membranes and achieves peak serum concentrations that are similar to that of intravenous administration. The total dose of lidocaine should not exceed **3 to 4 mg/kg**. Patients with **cardiac or hepatic insufficiency** have reduced clearance of lidocaine, and the dose should not exceed **2 to 3 mg/kg**.
- The use of lidocaine should be kept to a minimum if samples for culture are to be obtained, as bacteriostatic lidocaine preparations may decrease culture yields.
- **Sedation and analgesic agents** are often used to provide anxiolysis, antegrade amnesia, analgesia, and cough suppression. A combination of opiates and benzodiazepines is typically used. Propofol may also be used in intubated patients and patients with adjunctive airway support; advantages include rapid onset and offset of action, with the potential disadvantage of drug-induced hypotension.

DIAGNOSTIC AND THERAPEUTIC FLEXIBLE BRONCHOSCOPY

Bronchoalveolar Lavage

- Bronchoalveolar lavage (BAL) allows for sampling of cellular and non-cellular components from the **lower respiratory tract**.
- The tip of the bronchoscope is wedged into a distal airway, and sterile saline solution (aliquots of 20–60 mL) is instilled through the bronchoscope and then aspirated with the syringe or suctioned into a sterile trap. Infusions of 120 mL to 240 mL are needed to ensure adequate sampling of secretions in the distal respiratory bronchioles.
- The first aliquot of aspirated fluid is likely to contain material from the proximal airways, and some authors recommend discarding this aliquot.
- In patients with emphysema, collapse of the airways with negative pressure during aspiration or suctioning may limit the amount of fluid obtained and give false-negative results.
- Suctioning prior to having the bronchoscope in the appropriate wedged position should be minimized to avoid contamination with upper-airway secretions and potential false-positive results.
- In addition to quantitative bacterial cultures for the diagnosis of ventilator-associated pneumonia, BAL samples may also be sent for **cytology, antigen tests, and polymerase chain reaction tests**, which provide additional information for the diagnosis of noninfectious pulmonary disease.

Protected Specimen Brush

- The protected specimen brush (PSB) is used to obtain a lower-respiratory tract specimen for microbiology that is not contaminated by organisms in the proximal airways.
- A retractable brush within a double-sheathed catheter has a distal dissolvable plug occluding the outer catheter.

- After the tip of the bronchoscope is positioned in the desired area, the catheter is advanced through the working channel and situated 1 to 3 cm beyond the distal end of the bronchoscope to prevent collection of secretions pooled around the distal end of the bronchoscope.
- The inner cannula containing the brush is advanced to eject the distal plug, and the brush is then advanced into the desired subsegment under direct visualization.
- Once the sample is obtained, the brush is retracted into the inner cannula, the inner cannula is then withdrawn into the outer sheath, and the entire catheter is removed from the bronchoscope.
- The distal ends of the outer and inner cannula are wiped with alcohol, cut with sterile scissors, and discarded. The brush is advanced beyond the remaining portion of the inner cannula, cut with sterile scissors, and placed in 1 mL of non-bacteriostatic sterile saline or transport media.

Cultures and Diagnosis of Pneumonia

- Specimens for culture should be rapidly processed within 30 minutes to prevent a decrease in pathogen viability or contaminant overgrowth.
- A quantitative culture result of more than 10^4 colony forming units (CFU)/mL is considered diagnostic for pneumonia with BAL, while whereas more than 10^3 CFU/mL is considered diagnostic for pneumonia with PSB.
- An evidence-based review of 23 prospective studies of BAL in suspected ventilator associated pneumonia (VAP) showed a sensitivity of 42% to 93% with a mean of $73\% \pm 18\%$, and a specificity of 45% to 100% with a mean of $82\% \pm 19\%$.
- In a review of studies evaluating PSB, the sensitivity ranged from 33% to 100% with a median sensitivity of 67%, whereas the specificity ranged from 50% to 100% with a median specificity of 95%.
- It is unclear whether BAL is superior to PSB or vice versa in the diagnosis of VAP. In a meta-analysis of 18 studies on PSB (795 patients) and 11 studies on BAL (435 patients), there was no difference in the accuracy of the two tests.
- Despite studies of BAL and PSB showing a greater accuracy than tracheal aspirates, the routine use of bronchoscopy for establishing the diagnosis of ventilator-associated pneumonia remains controversial. This controversy is in part due to critiques in study methodologies and in part due to conflicting results regarding outcomes.
- Performing microbiologic cultures of pulmonary secretions for diagnostic purposes after initiating new antibiotic therapy can lead to false-negative results. Culture positivity at 24 and 48 hours after the onset of antimicrobial treatment is markedly diminished.
- In an immunocompromised patient with pulmonary infiltrates risk for fungal, viral, protozoal, mycobacterial, and atypical bacterial pulmonary infections, BAL fluid should be sent for cytopathology to evaluate for viral cytologic changes and Gomori methenamine silver staining to evaluate for fungal organisms and *Pneumocystis jiroveci*. Alternatively, Papanicolaou, Giemsa, toluidine blue O, or direct fluorescent antibody staining may be used for detection of *Pneumocystis*.
- For the diagnosis of pulmonary fungal infections, BAL fluid should be sent for fungal stains and cultures in addition to cytology stains. Some fungi, such as *Mucor* and *Rhizopus*, are difficult to grow on culture, and diagnosis relies on BAL cytology or biopsy specimens. *Aspergillus* is the most commonly encountered pulmonary fungal infection. BAL cytology and culture are diagnostic in approximately 50% to 60% of cases of invasive pulmonary aspergillosis. The diagnostic yield from BAL appears to be increased with the use of galactomannan antigen and PCR testing. Antigen testing for histoplasmosis and blastomycosis on BAL samples is now available.
- To evaluate for viral infections, respiratory viral cultures and a respiratory syncytial virus antigen assay should be obtained. BAL cytology may demonstrate characteristic intracytoplasmic inclusions, but sensitivity is lacking. Immunofluorescence and polymerase chain reaction (PCR) for cytomegalovirus may be performed on BAL specimens.
- If there is suspicion for tuberculosis or nontuberculous mycobacteria, BAL samples should be sent for acid-fast bacillus stains and mycobacterial culture.
- For atypical bacterial infections, additional stains and cultures may be required. *Legionella* requires specific culture media. A direct fluorescence antibody stain is also available for *Legionella*. Some laboratories utilize specific media if *Nocardia* is suspected. *Nocardia* can often be identified with a combination of Gram stain and modified Ziehl-Neelsen stains and are observed as delicately branched, weakly Gram-positive, variably acid-fast bacilli. Methenamine-silver stains may demonstrate the organisms in tissue specimens.

Transbronchial and Endobronchial Biopsies

- Histologic samples of lung parenchyma may be obtained with transbronchial lung biopsies and offer a less invasive option to open lung biopsy. However, for some interstitial lung diseases and pulmonary vasculitides, transbronchial biopsy specimens are inadequate to make a definitive diagnosis.
- The major risks of transbronchial biopsies are bleeding and pneumothorax. A chest radiograph should be obtained after transbronchial lung biopsy. Rates of pneumothorax after transbronchial lung biopsy in mechanically ventilated patients have been reported up to 7% and 23%, but <5% in nonventilated patients.
- Samples of bronchial mucosa and endobronchial abnormalities may be obtained with endobronchial biopsies. Transbronchial and endobronchial biopsies may be sent for bacterial, mycobacterial, and fungal cultures as indicated, in addition to histology.
- Transbronchial biopsy may be able to establish other noninfectious diagnoses of pulmonary infiltrates in the ICU including idiopathic interstitial pneumonia and graft-versus-host disease in stem cell or bone marrow transplantation patients, leukemic infiltrates, drug-induced pneumonitis, bronchiolitis obliterans organizing pneumonia/cryptogenic organizing pneumonia, bronchoalveolar carcinoma, lymphangitic carcinomatosis, and acute rejection after lung transplantation.
- Transbronchial biopsy is associated with a 2.7% and 0.12% risk of morbidity and mortality.
- Transbronchial biopsy should be restricted to nonuremic patients with platelet counts $> 50,000$ cells/ μ L and prothrombin times and activated partial thromboplastin times less than twice that of controls.

Airway Management

Endotracheal intubation can be technically difficult in select patient groups (Table 15.1).

- *Spontaneous ventilation* keeps the airway open and assists the bronchoscopist in locating the glottis when airway anatomy is distorted.
- Bronchoscopic endotracheal intubation can be performed using either a nasal or oral approach. With the **nasal approach**, after preparation of the nasal mucosa with a local anesthetic such as lidocaine and a mucosal vasoconstrictor such as 1% phenylephrine, the bronchoscope is passed through the nares and situated directly above the glottic opening. It is then passed into the trachea, and the ET is passed

TABLE 15.1

Thyromegaly

over the bronchoscope into the trachea. The major limitation of this approach is epistaxis (especially in coagulopathic patients), potential for sinusitis with prolonged nasal intubation, dislocation of adenoids, and limited diameter of the nares.

- With the **oropharyngeal approach**, topical anesthesia is achieved with spraying of 4% lidocaine. A bite block is placed, and the flexible bronchoscopy is guided past the tongue and directly over the larynx, facilitating endotracheal intubation with the ET passed over the bronchoscope.
- Use of these airways in the completely awake patient with inadequate topical anesthesia may be problematic due to **gagging and vomiting**. This is less of a problem in the sedated or unconscious patient.
- Flexible bronchoscopy allows for **ET changes** in patients with ET cuff leaks, inadequate ET internal diameters, and nasotracheal tube-associated sinusitis.
- Before bronchoscopy, the oropharynx should be suctioned thoroughly. The ET should be advanced over the bronchoscope before its placement in the pharynx. The bronchoscope tip is advanced to the level of the cuff of the existing ET, and secretions are aspirated through the suction channel. If necessary, the cuff is deflated and the bronchoscope advanced into the tracheal lumen. The existing ET is then withdrawn with the cuff fully deflated, the bronchoscope tip advanced to the carina, and the new ET advanced over the bronchoscope into the trachea.
- **Percutaneous dilatational tracheostomy** has become a well-accepted method for performing bedside tracheostomy in the ICU. Bronchoscopic visualization ensures that the guide-wire needle is introduced in the appropriate interspace in a midline position and that the needle does not penetrate the membranous **posterior tracheal wall**, thereby decreasing the risk of misplacement of the tracheostomy tube and creation of a false paratracheal passage. Bronchoscopy also provides feedback to the operator during dilator passage so that pressure on the posterior wall is minimized and the potential for posterior wall tears is reduced.
- Flexible bronchoscopy can be extremely useful in the placement of a **double-lumen ET**. If a right-sided tube is used, adequate positioning of the tube with the tracheal port proximal to the carina and bronchial port proximal to the right upper lobe orifice can be confirmed by using a small-diameter (3.5-mm outer diameter) flexible bronchoscope to inspect the airway through each lumen. Positioning of left-sided tubes is not as problematic given the longer length of the left mainstem bronchus relative to the right mainstem bronchus and less likelihood of obstructing the left upper or left lower lobe.

Atelectasis

- Complete lung atelectasis will produce **opacification** of the hemithorax and usually **ipsilateral mediastinal shift**.
- In patients who do not improve after chest physiotherapy, endobronchial obstruction due to **inspissated mucus, endobronchial tumor, foreign body, or blood clot** should be excluded by bronchoscopy.
- With the exception of large, obstructing central airway mucous plugs, the radiographic response to successful removal of secretions is **delayed from 6 to 24 hours**.

- Instillation of saline or a dilute 10% solution of **acetylcysteine** through the working channel may help to clear thick, tenacious secretions. Acetylcysteine is a bronchial irritant, however, and may exacerbate bronchospasm in patients with reactive airway disease. Typically 10- to 20-mL aliquots of saline are used as the irrigant to facilitate clearing of mucous plugs. If saline irrigation fails, then instillation of acetylcysteine or **rhDNase (Pulmozyme)** may be considered. In some patients, holding continuous suction while withdrawing the bronchoscope through the ET allows removal of large mucous plugs that cannot be suctioned directly through the working channel.

Hemoptysis

- **Early** bronchoscopy should be considered regardless of the degree of hemoptysis, to localize the site of bleeding and attempt to determine the underlying etiology. It is important to guide temporizing therapy such as angiographic embolization and definitive therapy such as surgical resection.
- **Massive hemoptysis** is defined as expectoration of blood exceeding 200 to 1,000 mL over a 24-hour period, with expectoration of >600 mL in 24 hours as the most commonly used definition.
- Only 3% to 5% of patients with hemoptysis have **massive hemoptysis**, with the mortality rates approaching 80% in various case series.
- Causes of massive hemoptysis are presented in (Table 15.2)
- **Airway patency** must be ensured in patients with massive hemoptysis. While preparing for intubation and bronchoscopy, the patient may be positioned in the **lateral decubitus position** with the **bleeding side down**.
- The **largest possible ET** should be inserted to allow for introduction of bronchoscopes with a 2.8- to 3.0-mm working channel for more effective suctioning and to allow for better ventilation with the bronchoscope in the airway for prolonged periods of time. In severe cases, the mainstem bronchus of the nonbleeding lung can be **selectively intubated** under bronchoscopic guidance to preserve oxygenation and ventilation in the normal lung.
- **Endobronchial tamponade** with flexible bronchoscopy can prevent aspiration of blood into the contralateral lung and preserve gas exchange in patients with massive hemoptysis. This can be achieved with a **No. 4-French Fogarty balloon-tipped catheter**. The catheter may be passed directly through the working channel of the bronchoscope, or the catheter can be grasped by biopsy forceps placed through the working channel of the bronchoscope prior to introduction into the airway. The bronchoscope and catheter—with the latter held in place adjacent to the bronchoscope by the biopsy forceps—are then inserted as a unit into the airway. Care must be taken not to perforate the catheter or balloon by the forceps. The catheter tip is inserted into the bleeding segmental orifice, and the balloon is inflated. If passed through the suction channel, the proximal end of the catheter is clamped with a hemostat, the hub cut off, and a straight pin inserted into the catheter channel proximal to the hemostat to maintain inflation of the balloon catheter. The clamp is removed, and the bronchoscope is carefully withdrawn from the bronchus with the Fogarty catheter remaining in position, to provide endobronchial hemostasis. The catheter can safely remain in

position until hemostasis is ensured by surgical resection of the bleeding segment or bronchial artery embolization.

- Additional bronchoscopic techniques may be useful as a **temporizing measure** in patients with massive hemoptysis. Bronchoscopically administered **topical therapies** such as iced sterile saline lavage or topical 1:10,000 or 1:20,000 epinephrine solution may be helpful. Direct application of a solution of thrombin or a fibrinogen–thrombin combination solution and, recently, oxidized regenerated cellulose mesh has recently been described.
- For patients who have hemoptysis due to **endobronchial lesions**, particularly endobronchial **tumors**, hemostasis may be achieved with the use of neodymium-yttrium-aluminum-garnet (Nd:YAG) laser phototherapy, electrocautery, or cryotherapy via the bronchoscope.

Trauma

- The classic signs of tracheobronchial disruption include shortness of breath, **massive subcutaneous emphysema**, **persistent pneumothorax** despite chest tube insertion, and a large air leak after tube thoracoscopy.
- **Tracheobronchial disruption** rarely occurs as an isolated injury and is associated with fractures of the ribs, clavicle, sternum, and pulmonary contusion. Rapid **deceleration** results in shearing forces, acting predominantly at the distal trachea near the carina where the relatively fixed trachea joins the more mobile distal airways. If the trachea and mainstem bronchi are crushed between the chest wall and vertebral column and the glottis closed, airway pressure suddenly increases, and resultant rupture of the airway may occur.
- **Prompt diagnosis and surgical correction** of tracheobronchial disruption produce a better outcome, and delay in diagnosis is usually detrimental to the patient. Failure to diagnose disruption may result in a delayed stricture formation at the site of injury, resulting in dyspnea, distal atelectasis, and chronic recurrent infections.
- If a persistent **bronchopleural fistula** exists because of proximal airway trauma, the cuff of the ET sometimes can be positioned just distal to the rupture site and inflated, and adequate ventilation can be established before surgical repair.
- **Cervical tracheal rupture** is less common than rupture of the intrathoracic trachea. Cervical tracheal rupture, however, may be more difficult to diagnose once the patient is intubated because of the proximal location of the tear, and may itself be an impediment to intubation.

Bronchopleural Fistula

- In patients who are not candidates for surgical management of a bronchopleural fistula (BPF), flexible bronchoscopic techniques may offer alternative methods for closure of the BPF.
- Detection of a proximal BPF due to stump breakdown after lobectomy or pneumonectomy or a BPF due to bronchial dehiscence is usually relatively straightforward, as these abnormalities can be directly visualized. In the setting of a BPF due to a rent or tear on the lung periphery, locating the bronchial segment that provides ventilation to that area of the lung can be more difficult.
- **Airway stents** may be used to cover and seal the fistula in selected patients, depending on the location of the fistula.
- Successful endobronchial occlusion of BPFs has been reported with **cyanoacrylate-based tissue adhesives** (Histoacryl, Bucrylate), **fibrin sealants** (Tisseel, Hemaseel, thrombin plus fibrinogen or cryoprecipitate), absorbable **gelatin sponge** (Gelfoam), vascular occlusion **coils**, doxycycline and blood, **Nd:YAG laser**, **silver nitrate**, and lead shot. The agent initially seals the leak by acting as a plug and subsequently induces an inflammatory process with fibrosis and mucosal proliferation permanently sealing the area.

Foreign-body Removal

- Risk factors for foreign-body aspiration include age younger than 3 years, altered consciousness, trauma, and disordered swallowing mechanisms.

- Patients may present with **dyspnea**, **coughing**, **wheezing**, or **stridor**. Foreign-body aspiration may be relatively occult, with no obvious history for aspiration. Radiographically, there may be evidence of atelectasis, bronchiectasis, or recurrent pneumonitis.
- For most situations, the **rigid bronchoscope** remains the instrument of choice in young children and infants. In adults, flexible bronchoscopy has clearly been shown to be an effective diagnostic and therapeutic tool in cases of suspected foreign-body aspiration. Several **extraction devices** are available for use through the flexible bronchoscope. Biopsy forceps, graspers, and foreign-body baskets are most commonly employed.

Upper-airway Obstruction

- Causes of upper-airway obstruction include **epiglottitis**, **bilateral vocal cord paralysis**, **laryngeal edema**, and **foreign body**. In the pediatric patient, **subglottic stenosis** secondary to croup should also be considered.
- The flexible bronchoscope affords immediate direct visualization of the upper airway and, if performed with an ET placed over the bronchoscope, affords visualization and guidance for endotracheal intubation.
- If **epiglottitis** is suspected, it may be prudent to perform bronchoscopy in the **surgical suite**, with the surgical team available for **emergency tracheostomy** in case of failure.
- When performing bronchoscopic intubation in suspected upper-airway obstruction, the **nasotracheal approach** may be preferable because the turbinates offer stabilization and a more controlled approach to the area of acute airway obstruction. Flexible bronchoscopic intubation in upper-airway obstruction may be performed in the **sitting position** with **decreased posterior displacement of the epiglottis** over the compromised upper airway as compared with laryngoscopic examination in the supine position.
- If **foreign-body obstruction** is known or suspected as the cause of the upper-airway obstruction, rigid (not flexible) bronchoscopy may be preferable.
- Central airway obstruction may be from primary lung cancer or metastatic **malignancies**. Treatment for malignant airway obstruction from endoluminal tumor has typically consisted of **Nd:YAG laser photoresection** and metal or silicone **stent** placement, although endobronchial electrocautery or argon plasma coagulation has more recently been used in lieu of the Nd:YAG laser.
- Benign causes of obstruction occur most commonly from previous intubation or tracheostomy tube placement, leading to **cicatricial stenosis** with or without **granulation tissue**. Patients with an indwelling tracheostomy tube may also develop a fibrous stenosis or granulation tissue just beyond the tip of the tracheostomy tube, thereby causing airway obstruction. The granulation tissue may be resected with laser electrocautery therapy. The stenosis may be dilated with a rigid bronchoscope or balloon dilatation catheters.

Inhalation Injury

- Patients with singed nasal hairs, facial burns around the nose or mouth, oral/nasopharyngeal burns, carbonaceous sputum,

or hoarseness should be suspected of having an upper-airway injury.

- **Stridor, wheezing**, or other manifestations of upper airway symptomatology may imply **impending ventilatory failure**.
- Flexible bronchoscopy should be performed **early** by an experienced bronchoscopist to identify evidence of thermal airway injury with direct examination of the **supraglottic and infraglottic** areas. The need for intubation should be anticipated and an ET placed over the bronchoscope before examining the airways.
- **Serial examinations** may be necessary in patients with apparent minimal thermal airway injury on initial evaluation.
- Signs indicating impending airway obstruction include **inflammation, edema, ulceration, or hemorrhage** of the upper-airway mucosa.
- In the intubated patient, repeat airway examination by bronchoscopy may be necessary before **extubation** to ensure airway patency and resolution of the supraglottic or laryngeal edema. The endotracheal tube can be withdrawn over the bronchoscope while inspecting the airway mucosa and replaced if the airway is compromised.

COMPLICATIONS

- The incidence rate of major complications ranges from 0.08% to 0.15%, and the mortality rate ranges from 0.01% to 0.04%.
- The characteristics of high-risk patients are summarized in Table 15.3.
- Life-threatening complications including hypoxemia, hypercapnia, barotrauma, cardiac arrhythmias, myocardial ischemia, intracranial hypertension, local anesthetic toxicity, and pulmonary hemorrhage.
- In critically ill patients, the decrement in PaO₂ can exceed 30 to 60 mm Hg and hypoxemia may occur as much as 20% of the time. The greater the amount of normal saline instilled for lavage during bronchoscopy, the more frequent the hypoxemia—seen in as many as 23% of patients—and the longer its duration, up to 8 hours.
- Complications associated with the administration of sedation, analgesia, and topical anesthesia include hypotension and allergic reactions, and hypoventilation and hypoxemia from over-sedation and respiratory depression.
- The overzealous use of local anesthetic agents within the airways has potential for toxicity with the rapid uptake of these agents into the systemic circulation from the bronchial mucosa. Lidocaine in excessive doses can cause sinus arrest

TABLE 15.3

CHARACTERISTICS OF INCREASED-RISK PATIENTS FOR BRONCHOSCOPY ON MECHANICAL VENTILATION

Pulmonary

PaO₂ <70 mm Hg with FiO₂ >0.70

PEEP >10 cm H₂O

Auto-PEEP >15 cm H₂O

Active bronchospasm

Cardiac

Recent myocardial infarction (<48 h)

Unstable dysrhythmia

Mean arterial pressure <65 mm Hg on vasopressor therapy

Coagulopathy

Platelet count <20,000 cells/ μ L

Increase of prothrombin time or partial thromboplastin time
2.0 times control

Central nervous system

Increased intracranial pressure

FiO₂, fraction of inspired oxygen; PEEP, positive end-expiratory pressure.

and atrial ventricular block, especially in patients with underlying heart disease. Other potential adverse reactions include respiratory arrest, seizures, laryngospasm and, rarely, hypersensitivity reactions. Although not as commonly used for topical anesthesia, benzocaine has been associated with the development of methemoglobinemia.

- The incidence rate of bronchoscopy-related hemorrhage in normal hosts approaches 1.4%. In immunocompromised hosts, the rate of hemorrhage ranges from 25% to 29%, whereas hemorrhage occurs in as many as 45% of uremic patients.
- Postbronchoscopy fever occurs in as many as 16% of patients.
- Bronchoscopy-related pneumonia is rare, occurring in fewer than 5%, and bacteremia is exceedingly rare. In general, endocarditis prophylaxis is not required with flexible bronchoscopy.
- Neurosurgical patients are at risk for intracranial hypertension as a result of bronchoscopy-induced elevation of intrathoracic pressure, arterial hypertension, and hypercapnia. Bronchoscopy-associated cough or retching must therefore be avoided. Deep sedation with or without neuromuscular blockade may be utilized if bronchoscopy is deemed necessary.

CHAPTER 16 ■ OTHER IMPORTANT INTENSIVE CARE PROCEDURES

Invasive procedures are performed at the bedside of critically ill patients with increasing frequency. With the development of safety systems and new techniques, the morbidity of these bedside procedures is not higher than the morbidity of similar procedures performed in the operating room, emergency department, or angiography suite.

TUBE THORACOSTOMY

- Fluid or air that remains undrained into the pleural cavity may cause infection, lung collapse, or entrapment and should be drained.
- A **pneumothorax** is usually drained if it exceeds 15% to 20% of the hemithoracic volume or causes hemodynamic instability.
- A **hemothorax** after blunt trauma is drained if more than 200 mL of blood is in the thoracic cavity as found by blunting of the costodiaphragmatic angle on erect chest radiograph or estimated on computed tomographic (CT) imaging.
- After trauma, a **thoracotomy** may be indicated if the chest tube output is more than 1,500 mL at placement or if output of more than 200 mL/hour persists over 4 to 6 hours after placement. A hemodynamically unstable patient who is bleeding in the chest should be taken to the operating room even with lower than the preceding chest tube outputs.

Percutaneous Technique

- The **percutaneous technique** is safe for patients who do not have risk factors for intrathoracic adhesions (e.g., previous thoracic operation, empyema, clotted hemothorax). A No. 28 Fr or No. 32 Fr chest tube is adequate according to the size of the patient and does not cause excessive pain. For the drainage of simple pneumothorax, smaller tubes (No. 18 Fr or No. 22 Fr) may be used.
- The most common site is at the intercostal space above the nipple (usually the **fourth intercostal space**) and at the **midaxillary line**. The diaphragm can elevate up to the nipple in expiration and, for this reason, lower placement of chest tubes is not safe and may risk injury to the diaphragm and intra-abdominal organs.
- **Adequate local analgesia** is key because tube thoracostomy is a painful procedure. The entire tract should be infiltrated including the **muscles and the rib periosteum and the superior border of the rib**, not just the subcutaneous tissue.
- A needle covered by a plastic sheath and connected to a fluid-filled syringe is inserted through the skin with the intent to hit the underlying rib. Once the rib is felt, the needle is slightly

withdrawn and then redirected immediately **over the rib** to avoid injury to the **neurovascular intercostals bundle** that travels under each rib. Under continuous suction, the syringe and needle are slowly advanced until bubbles of air are aspirated. This indicates that the needle has entered into the pleural space. The needle and syringe are withdrawn and the plastic sheath left in place. A **guidewire** is inserted into the sheath (Fig. 16.1). If there is any resistance during advancement of the guidewire, the procedure should be repeated from the beginning. With the guidewire in place, the plastic sheath is removed. A 2-cm skin incision is made, and **sequential dilatation** with three consecutive dilators is done over the guidewire. After this, the chest tube, loaded on a plastic guide, is placed over the guidewire into the chest. The plastic guide and guidewire are withdrawn, and the chest tube is left in place.

- **Securing the chest tube** is a very important part of the procedure. The tube is tied to the skin with a 0 nonabsorbable suture. A separate suture should be placed as a purse-string around the tube and left untied. This suture will serve to close the incision once the chest tube is removed. The tube should also be **taped** to the skin. Extra precautions should be taken to have the chest tube and its connection to the drainage bottles **secured** to avoid inadvertent partial or complete removal.

FIGURE 16.1. A guidewire is inserted through the sheath into the pleural space, guiding sequential enlargement of the tract by tapered dilators.

- Usually, 20 cm H₂O negative suction is applied at least for the first 48 hours although there is no evidence that this shortens the period of placement or decreases the rate of residual pneumothorax compared to water seal.

Open Thoracostomy Technique

- The open thoracostomy technique is similar to the percutaneous thoracostomy except the skin incision made parallel to the ribs is slightly larger (3–4 cm). Blunt dissection using a sturdy clamp (some use Mayo scissors) is done through the subcutaneous tissue and muscle. It is then opened wide to **spread the muscles and enlarge the tract**. This is an **important step**, as the novice tends to make the skin incision large but the intermuscular tract too small, resulting in difficulty with tube insertion.
- The clamp is finally inserted into the pleural space in a controlled way over the rib underlying the skin incision and spread wide to admit the chest tube (Fig. 16.2). There is no reason to “tunnel” the track to the rib above the skin incision. Tunneling causes more pain, makes the procedure more difficult, and offers no benefit.
- A **finger** is inserted to explore for the presence of adhesions at the site of insertion (Fig. 16.3). Then, the chest tube is guided by a clamp into the opening and toward the superior and posterior hemithorax (Fig. 16.4). The tube is secured as discussed earlier.

Pitfalls and Complications

- A **misplaced chest tube** may not drain adequately.
- Do not assume that air or fluid will be drained because a chest tube is in place.

FIGURE 16.2. A sturdy clamp is necessary to spread the muscles wide to allow easy insertion of the chest tube.

FIGURE 16.3. A finger is inserted into the tract prior to tube insertion to ensure a clear pleural space and absence of adhesions.

- Confirm correct placement with a chest radiograph, and have a low threshold to **replace or add a chest tube**, if the symptoms are not relieved, hemodynamic instability persists, or drain seizes abruptly.
- Injury to the intercostal vessels or lung may cause significant **bleeding**. The chest tube should then be removed and on rare occasions the bleeding site explored if the hemorrhage continues
- **Intraparenchymal placement** may cause a persistent air leak. It is usually diagnosed by CT. The tube should be removed, and the leak usually seals.
- The chest tubes should be **securely tied and taped** to the skin and checked daily. Accidental removal of a tube equals a sloppy technique.

FIGURE 16.4. The final position of the chest tube.

- **Infection** is the most common related complication. Poor aseptic technique, long duration of the tube in the chest, and no antibiotic prophylaxis (one dose before tube placement) are associated with this complication.
- Significant **undrained hemothorax** (estimated at more than 400 mL) should be managed by thoracoscopic evacuation or intrathoracic thrombolysis.

Removal of Chest Tubes

- Removal takes place when there is no air leak and fluid output is <2 mL/kg per 24 hours. The patient is asked to inspire maximally and hold the breath. Warn the patient that the tube must be **pulled quickly** to prevent air entry into the chest. With one hand against the chest wall, the physician pulls abruptly the chest tube with the other hand and immediately ties the purse string to seal the insertion site. The site is dressed. If a purse-string suture is absent, it is important to apply occlusive dressing to prevent air entry into the chest.

DIAGNOSTIC PERITONEAL ASPIRATION AND LAVAGE

The most common reason for a diagnostic peritoneal aspiration and lavage is the diagnosis of **intra-abdominal injury**. Portable ultrasonography and the liberal use of helical CT have limited the usefulness of diagnostic peritoneal aspiration and lavage. Occasionally, aspiration or paracentesis of the abdomen is also performed to diagnose and treat **ascites**.

- Currently, diagnostic peritoneal aspiration (DPA) and diagnostic peritoneal lavage (DPL) are used only on rare occasions due to lack of appropriate technologic resources or due to major physiologic **instability** that precludes patient transport to CT.
- Another indication for DPL may be to detect **bowel injury**, as CT scan may miss intestinal infarction and perforation.
- Once the peritoneal cavity is accessed, **aspiration** is performed first (DPA) and is considered positive if **10 mL** of gross blood is aspirated. If the DPA is negative, 1 L of normal saline is infused (DPL), and the abdomen is gently shaken or “laved.” By lowering the normal saline bag below the level of the body, the lavage fluid returns into the bag, but not all is retrieved, usually less than half; the fluid is sent for analysis.
- A count of more than **100,000 red blood cells/mm³** indicates bleeding. More than **500 white blood cells/mm³** or the presence of bile, enteric content, or high-amylase in the effluent of the lavage may indicate bowel injury. However, the red cell criteria are oversensitive and frequently lead to unnecessary operations. These cell counts are valid for **blunt** but not for penetrating trauma.

Percutaneous Insertion of Peritoneal Catheter

- Patient must have a Foley catheter placed to **decompress the bladder** to avoid injury to a distended bladder.
- A 0.5-cm skin incision is placed under the umbilicus (or over it in the presence of pregnancy, pelvic hematoma, or a lower

FIGURE 16.5. A peritoneal lavage catheter is placed over the guidewire.

midline operative scar). A sheathed needle is introduced in the direction of the pelvis. The needle is connected to a fluid-filled syringe and advanced slowly. When the flow of fluid becomes unobstructed, the needle is in the peritoneal cavity. Needle and syringe are withdrawn, and the plastic sheath is left in place. A guidewire is introduced through the sheath, which is then removed. A dilator is placed over the guidewire and withdrawn. Then, the DPL catheter is introduced, and the guidewire is removed (Fig. 16.5).

- A simpler DPL system includes only a catheter fed over a trocar. After the skin incision, the **trocar and catheter** are introduced in a controlled and slow fashion into the abdomen in the direction of the pelvis. **Two points of resistance** are felt as the trocar passes through the anterior fascia and the peritoneum. As soon as the tip of the trocar passes the second point of resistance—and is presumably into the abdomen—the catheter is fed over it toward the pelvis, and the trocar is removed. Experience is needed to perform this technique to prevent trocar injury of abdominal contents.

Open Technique for Peritoneal Catheter Insertion

- A 2- to 4-cm skin incision is performed under or over the umbilicus. The **fascia is visualized** and retracted. The fascia is then incised and the peritoneal cavity entered (Fig. 16.6). Under direct observation, a DPL catheter is introduced toward the pelvis (Fig. 16.7). Sometimes, sutures are placed in the fascia to close the perforation.

Pitfalls and Complications

- The introduction of needles and catheters in the abdominal cavity carries the (very low) risk of **injuring the bowel or vessels**. The procedure needs to be performed by physicians experienced with the procedure, which is becoming uncommon as the procedure is not frequently performed.
- Once-useful cell counts need to be viewed with caution, as the indications for surgical exploration after abdominal trauma have changed, and many injuries are managed nonoperatively.

FIGURE 16.6. Open technique for peritoneal lavage catheter insertion with direct visualization and incision of the abdominal fascia.

- Infusing the lavage fluid but being unable to retrieve it is not uncommon. Slight repositioning of the catheter may help.

CRICOTHYROIDOTOMY

Indications

Cricothyroidotomy is a real emergency and reserved for those patients who cannot be intubated orally or nasally or have lost

FIGURE 16.7. Insertion of the peritoneal lavage catheter under direct vision.

FIGURE 16.8. Digital identification of the cricothyroid space.

a pre-existing oral airway and are desaturating. It would be a mistake to attempt a tracheostomy in such patients, as this consumes considerably more time. Because the cricothyroid space is superficial in relationship to the skin, it should be selected as the easiest point—even if suboptimal—for insertion of a life-saving airway.

Open Cricothyroidotomy

- A **vertical incision** is placed above the cricothyroid space. Compared to a horizontal incision, this incision decreases the likelihood of bleeding from injury to the anterior jugular veins
- After sharp incision of any soft tissue between the skin and cricoid cartilage, the cricothyroid space is identified by **palpation** (Fig. 16.8). Any bleeding at this point is ignored, as the sheer goal is to establish an airway as soon as possible.
- A pointed clamp is introduced through the cricothyroid membrane and opened to dilate the space (Fig. 16.9). Experienced surgeons can use the scalpel to incise the membrane, although the risk exists for injuring the cartilage or posterior wall. The thyroid cartilage is immobilized and pulled upward and anteriorly with a **tracheostomy hook**. The **tracheostomy hook** is essential for this procedure. A No. 4 tracheostomy tube is introduced. If the space is wide, a No. 6 tube is preferable. The bleeding is controlled by sutures, electrocoagulation, or pressure.

Percutaneous Cricothyroidotomy

- A vertical incision is made. A hollow needle is introduced through the cricothyroid space and a guidewire is introduced through the needle (Figs. 16.10 through 16.12), which is then removed.
- Dilation of the trachea takes place over the guidewire by introducing a dilator (Fig. 16.13). Finally, a No. 4 tracheostomy tube is placed over a guiding dilator and the guidewire. The dilator and guidewire are removed, and the tube is left in place and secured to the skin.

FIGURE 16.9. Dilatation of the cricothyroid membrane and insertion of the tracheostomy tube.

Pitfalls and Complications

- Cricothyroidotomy can become a **challenging procedure**, as the pressure to establish an airway in a dying patient is great. Blood can obscure the field and create additional difficulty.
- **Incorrect identification of the cricothyroid space** and placement of the incision above the thyroid cartilage are possible.
- **Inadequate opening** of the cricothyroid membrane and loss of valuable minutes while trying to insert the tracheostomy tube through a very narrow opening is not uncommon.

FIGURE 16.10. Access site for cricothyroidotomy (lateral view). (From Cook Medical, Inc., with permission.)

FIGURE 16.11. Localization of the cricothyroid space and placement of catheter (lateral view). (From Cook Medical, Inc., with permission.)

- **Injury** of the thyroid and cricoid cartilage, vocal cords, or posterior tracheal wall and esophagus are additional intra-operative complications.
- There is controversy about the need to **convert** the cricothyroidotomy to a tracheostomy at a later stage. Previous standard teaching recommended that a tracheostomy should be performed because cricothyroidotomy is associated with a higher degree of tracheal stenosis if left in place for a long time, but studies vary in results.

PERCUTANEOUS TRACHEOSTOMY

- The neck is **hyperextended** by placing a pillow under the patient's shoulder (except in patients with spinal precautions).
- After preparation of the neck, the site of incision is selected to be in the middle between the cricoid cartilage and sternal notch, which corresponds to the **second or third tracheal cartilage**.

FIGURE 16.12. Insertion of guidewire through the hollow catheter (lateral view). (From Cook Medical, Inc., with permission.)

FIGURE 16.13. Dilation of tract (figure A, lateral view). Figure B shows the tracheostomy in place. (From Cook Medical, Inc., with permission.)

- The procedure is performed under **bronchoscopic guidance**. The bronchoscope is introduced through the orotracheal tube, and the tube is pulled to the level immediately below the vocal cords (usually at approximately 16 cm at the lip). A common error is not withdrawing the tube far enough, leading to impalement of the orotracheal tube by the introductory needle.
- A 2- to 3-cm **vertical incision** is placed, and the subcutaneous tissue and pretracheal muscles are bluntly dissected until the trachea is palpated.
- A sheathed needle connected to a fluid-filled syringe is introduced. **Aspiration of bubbles into the syringe** indicates entry into the trachea, also confirmed by the bronchoscope. The needle is pushed in 2 mm farther, as the sheath is shorter than the needle. The needle and syringe are removed, and the sheath remains in place. The syringe is placed back on the sheath and **air reaspirated** to confirm that the sheath remains in the airway and has not dislodged during removal of the needle (a **crucial step**).
- A J-tipped **guidewire** is introduced through the sheath into the trachea, and the sheath is then removed (Fig. 16.14). The tract is dilated by a short firm dilator. A thin **guiding tube** is threaded over the guidewire, then a **large curved dilator** is fed over a guiding tube and the guidewire (Fig. 16.15). The large curved dilator has a **mark** to guide how deep it should be inserted into the airway.
- Now the trachea is adequately dilated to accommodate the tracheostomy tube. The large curved dilator is removed, and the tracheostomy tube (usually a Shiley No. 8) is fed over a No. 28 Fr dilator, guided by the guidewire/guiding tube complex into the trachea (Fig. 16.16).
- The kit contains several sizes of dilators to accommodate different-caliber tracheostomy tubes. A **single cannula tracheostomy tube** will have the same internal diameter as a double cannula tube but a smaller external diameter, making it easier for insertion.

- All these steps are visualized through the bronchoscope although during insertion of the main dilator, the force required to push the dilator may temporarily collapse the trachea for several seconds with poor visualization through the bronchoscope.
- Finally, the guidewire, guiding tube, and curved dilator are removed, and the tracheostomy tube is left in place. The bronchoscope is withdrawn from the endotracheal tube (which remains in place) and inserted into the newly placed tracheostomy tube to **confirm correct placement by visualizing the carina**. The cuff of the tracheostomy tube is inflated, and the tube is connected to the ventilatory circuit.

FIGURE 16.14. Insertion of guidewire and guiding catheter.

FIGURE 16.15. Dilation with the large progressive curved dilator.

Pitfalls and Complications

- **Loss of airway** is the most important concern. It can occur by unrecognized pretracheal or paratracheal placement of the dilators, which dilate the soft tissues instead of the trachea,

FIGURE 16.16. Insertion of the tracheostomy tube over a guiding dilator.

leading to placement of the tracheostomy tube outside of the trachea (usually the mediastinum).

- **Posterior tear** to the trachea and even the **esophagus** can occur. **Bronchoscopic guidance** is key to avoid placement of the tube in non-tracheal sites.
- **Bleeding** is usually not a problem. On occasion, however, injury to an anterior vessel or the thyroid may cause bleeding through the wound. In most cases, one needs to complete the procedure rapidly to prevent blood from draining into the airway and achieve hemostasis by compression of the tracheostomy tube against the track. It is very rare that bleeding will persist. Anterior veins may easily be suture ligated as well.
- A common error is not withdrawing the endotracheal tube far enough, leading to impalement of the tube/cuff (or even the bronchoscope) with the finder needle (see preceding).

PERCUTANEOUS GASTROSTOMY

A gastrostomy is required for patients who cannot be fed through the mouth because of inability to swallow, prolonged intubation, obstructing lesions of the pharynx or esophagus, or extensive neck operations.

- The procedure starts with an esophagogastroscope and insufflation of the stomach, so that it opposes the anterior abdominal wall. An appropriate site of placement is selected by applying digital pressure on the skin, which is seen through the gastroscope as an indentation to the stomach. **Transillumination through the abdominal wall** should also be possible at the selected site of placement. This area is infiltrated with local anesthesia.
- A long needle covered by a plastic sheath is introduced through the skin and abdominal muscles into the stomach (Fig. 16.17). The needle is withdrawn and the plastic sheath left in place. A snare is introduced through the appropriate port of the gastroscope. A guidewire is placed in the stomach

FIGURE 16.17. Insertion of needle into the stomach under endoscopic guidance.

FIGURE 16.18. Guidewire snared and pulled with gastroscope through mouth.

through the plastic sheath and grasped by the snare (Fig. 16.18). The gastroscopist, snare, and guidewire are withdrawn out of the mouth.

- The guidewire at the oral end is tied to the tip of a percutaneous gastrostomy tube. A 2-cm incision is made on the skin of the abdomen at the site of guidewire entry, and the guidewire is pulled from the abdominal side. In this way, the gastrostomy tube is pulled back into the mouth and, through the esophagus and stomach, out through the abdominal wall (Fig. 16.19). The gastroscopist is reintroduced into the stomach and confirms correct placement of the tube. The tube

FIGURE 16.19. Gastrostomy tube pulled through stomach.

is secured by placing a flange and suturing it to the skin. It can be used within 6 hours for medication and 12 hours for feeds.

Pitfalls and Complications

- It is necessary to confirm that there are no vessels and no intervening hollow viscera (such as the colon) **between the stomach and anterior abdominal wall**. The indentation created by digital pressure should be clearly evident by the gastroscopist, and transillumination at that site should be clear.
- **Infection of the wound** should be recognized early and can be avoided with strict sterile technique. Usually, the tube does not need to be removed. The infection is treated by opening the wound and administering antibiotics.
- **Tube dislodgement** may occur either if the stomach is under tension (e.g., on a patient with hiatal hernia or with adhesions) or because the tube was not secured adequately and was inadvertently pulled. Both complications are usually preventable and should be avoided by recognizing that the anatomy is not favorable for a gastrostomy or suturing the gastrostomy tube adequately to the skin. Early tube dislodgement may lead to extravasation of gastric contents and **peritonitis**.

ABDOMINAL PRESSURE MONITORING

Abdominal hypertension, the elevation of pressure in the abdominal cavity due to bleeding or visceral swelling, leads to compromise of cardiac output, tissue perfusion, and ventilation, all eventually resulting in death if untreated. Intra-abdominal pressures below 10 cm H₂O are considered normal, 10 to 15 acceptable for postoperative patients, 15 to 20 worrisome and possibly in need of action, and more than 20 is cause for decompression in most cases. Bladder pressures are widely used to reflect intra-abdominal pressures, as intraperitoneal pressure is transmitted on the bladder wall.

- Patients must have a Foley catheter decompressing the bladder. With the patient lying flat and under aseptic technique, a three-way stopcock is connected to a syringe and pressure monitor. Fifty to 100 mL of saline are injected into the bladder, and the stopcock is opened toward the pressure monitor. It is important to level the monitor in advance, so that the 0 mark corresponds to the level of the pubic symphysis.
- An easy and simple technique that does not require any instruments is the U-tube technique. The Foley catheter is elevated while allowing a U-loop to form. If there is not enough urine in the tube, saline needs to be injected. The column of urine or injected fluid that forms is measured between the pubic symphysis and meniscus (Fig. 16.20).
- There are several systems on the market that allow continuous measurement of pressures without interrupting the continuity of the Foley circuit and therefore decreasing the risk of urinary infection.

Pitfalls and Complications

- The most dangerous pitfall is the exclusive reliance on bladder pressure measurements. **Clinical examination** should always

FIGURE 16.20. Measurement of intra-abdominal pressure using column of urine/water in the Foley catheter tubing.

be the principal reason for continued observation or immediate decompression. Bladder pressure measurements should support only the clinical diagnosis.

PERICARDIOCENTESIS

The pericardial space can accommodate large volumes of fluid if accumulation occurs over a long period of time, whereas **cardiac tamponade** develops with even small quantities of fluid if occurring abruptly. Pericardiocentesis is indicated to treat tamponade or diagnose the nature of chronic fluid. The latter is performed under ultrasonographic guidance. The former will be described later, although pericardiocentesis for traumatic tamponade is **rarely useful**. Unless the patient is in a remote area with difficult access to a trauma center, pericardiocentesis is not indicated; rapid **sternotomy** and control of the bleeding is the treatment of choice.

- With the patient supine, a standard pericardiocentesis kit or, in true emergencies, a central line kit can be used. A hollow needle is inserted approximately **1 cm below the costal margin** and slightly to the left of the midline. The direction is **toward the left shoulder**. The needle is advanced slowly under the rib (Fig. 16.21). Electrocardiographic monitoring

is possible by attaching an alligator clip to the needle. **ST-segment elevations** indicate contact of the needle with the epicardium. Aspiration of fluid or blood obviously indicates that the needle is in the pericardial sac. Aspiration of blood relieves the pericardial tamponade, and a guidewire is inserted through the needle. Using a Seldinger technique, a catheter is inserted and used to withdraw further fluid or blood over time, if needed. With wide availability of portable **ultrasound machines**, emergent tapping of pericardial space may be safer than the “blind” technique previously used.

Pitfalls and Complications

- Pericardiocentesis is a potentially **dangerous** technique if performed blindly. When performed under emergency situations for presumed cardiac tamponade, there is risk of **injuring the heart**, particularly if the clinical diagnosis of tamponade is not correct and the space between the pericardium and epicardium is very narrow. Additionally, misplacement of the needle—most typically under the heart—is not unusual. As mentioned previously, blind pericardiocentesis for traumatic injury purposes has been nearly abandoned in urban hospital settings.
- When performed using radiologic guidance for stable conditions, little risk is involved.

PERCUTANEOUS INFERIOR VENA CAVA FILTER PLACEMENT

- **Absolute indications** for filter placement are recurrent pulmonary embolism despite anticoagulation, contraindications to anticoagulation in the presence of pulmonary embolism or proximal deep venous thrombosis, and complications of anticoagulation prompting its cessation.
- **Relative indications** include polytrauma patients at high risk for venous thromboembolism, critically ill patients with

FIGURE 16.21. Technique of pericardiocentesis.

tenuous respiratory status in whom even a small pulmonary embolism may prove detrimental, and large free-floating venous clot.

- Multiple types of permanent filters exist, although **removable filters** are used with increasing frequency. All devices are **magnetic resonance imaging-compatible**. Two techniques are dominant in performing filter insertion at the bedside and will be described further: the fluoroscopy-guided and the endovascular ultrasound-guided techniques.

Fluoroscopy Guided

- After a screening duplex ultrasound is performed to examine for femoral venous clots, portable fluoroscopy is used to define the **L2–4 lumbar** region. The site of venous access is selected—typically the left or right **femoral vein**—and venous cannulation is performed using a Seldinger technique. A No. 4 or No. 5 Fr angiographic catheter is advanced over a guidewire into the inferior vena cava and up to the second lumbar vertebra.
- **Contrast material is injected**, and the cava is imaged to delineate its anatomy and size. In particular, **the renal veins** are defined as the landmark for which the filter should be placed **below**.
- The pigtail catheter is exchanged for the **sheath**, which is inserted over a dilator. The sheath is positioned **caudad to the renal veins**, and the filter carrier system is advanced into the sheath. The filter is then deployed, completion venography is performed, and the sheath is withdrawn

Intravascular Ultrasound Guided

- Insertion is usually performed through a **right femoral vein** approach. A micropuncture is made in the vein using a No. 4 Fr catheter, and a 0.035 wire is introduced.
- A No. 8 Fr sheath is inserted into the inferior vena cava, and the intravascular ultrasonographic (In-Vision Gold, Volcano Corp, Rancho Cordova, CA) is advanced over the wire through the iliac venous system up to the level of the **right**

atrium. Then, it is slowly withdrawn to evaluate the inferior vena cava in a retrograde fashion. The **right renal artery and bilateral veins** are visualized, and the maximum diameter of the vena cava is measured.

- After a **second puncture** in the right common femoral vein, the delivery sheath for a vena cava filter (VCF) is introduced over a 0.035 guidewire. The sheath and then the VCF are advanced to the level of the renal veins. Deployment is performed under **direct** intravascular ultrasonographic **visualization**. Confirmation of correct placement below the renal and above the iliac veins is established ultrasonographically.
- A postinsertion plain radiograph is routinely performed to verify correct placement at the L2–4 level. This technique is valuable in patients at risk for renal failure due to avoidance of radiocontrast dye.

Pitfalls and Complications

- Complications of venous access include bleeding, hematoma, arteriovenous fistula, hemopneumothorax, and cardiac dysrhythmias.
- Misplacement outside the inferior vena cava (IVC) at an incorrect location has been reported to be as high as 4.6%. Locations for filter misplacement include renal veins, gonadal veins, or unintended suprarenal placement.
- Insertion-site venous thrombosis and vena cava occlusion are potential complications of filters. Access via the internal jugular or subclavian vein results in a lower incidence of thrombosis when compared to femoral access. Caval thrombosis rates do not appear to vary significantly among the available filters.
- Pulmonary embolism in the presence of an IVC filter has been reported in 3% to 7% of patients after filter placement.
- Guidewire entrapment may occur during placement of central venous and pulmonary artery catheters and during catheter exchanges. Attempts at removal of an entrapped item can lead to filter displacement and vessel damage when excessive force is applied. Straight guidewires should be used for all new central venous catheters in patients with indwelling IVC filters.

CHAPTER 17 ■ FLUIDS AND ELECTROLYTES

GENERAL COMMENTS

- In an average person without extremes of weight, approximately **60% of total body weight is water**. Of this total body water, two-thirds (40% of total body weight) is in the **intracellular fluid (ICF) space**, and one-third (20% of total body weight) is outside the cells (i.e., **extracellular fluid space [ECF]**).
- Extracellular volume is divided into **intravascular space and interstitial fluid (5% and 15% of total body weight, respectively)**. The intravascular space contains **plasma volume** that is the most mobile fluid compartment and the first to be released to areas of injury and the first to be repleted through intravenous infusion. Also in the intravascular space are **red cells**. **Red cell volume plus plasma volume comprise the blood volume (BV)**, which is estimated to be 7% of the total body weight. In a 70-kg person, total body water is 42 L (60% × 70 kg), circulating BV is 4.9 L (7% × 70 kg), ICF is 28 L (40% × 70 kg), and ECF is 14 L (20% × 70 kg). The percentage of weight used will vary depending on deviation from ideal body weight and gender.
- Maintaining BV or “**effective circulating BV**” is an important part of resuscitation, as BV consists of red cells (carrying O₂) and plasma (carrying glucose), which supply fuel and oxygen to the cells to synthesize adenosine triphosphate (ATP).
- Water is **freely permeable** between body compartments and migrates to areas of higher solutes, but this **takes time**. Therefore, **chronic hypotonic losses** with ability to “borrow” from ICF (approximately 28L in a 70-kg person) are better tolerated than **acute isotonic losses**, which have only the ECF (approximately 14 L in a 70-kg person) to borrow from.
- **Osmolality** (tonicity) defined as number of particles in solution is normally 280 to 300 mOsm/L in the serum.
- The **ICF concentration of solutes** is vastly **different from** that of the ECF, and approximately 80% of ATP generated is used to maintain this gradient. Some of the ECF cations (in mEq/L) are as follows: sodium (Na⁺), 142; potassium (K⁺), 4; calcium (Ca⁺⁺), 5; and magnesium (Mg⁺⁺), 3. The ICF cations (in mEq/L) are: K⁺, 150; Mg⁺⁺, 40; and Na⁺, 10. Some of the ECF anions (in mEq/L) are chloride (Cl⁻), 103; and bicarbonate (HCO₃⁻), 27. The major ICF anions (in mEq/L) are phosphates, 107; proteins, 40; and sulfates, 43.
- This difference in ICF and ECF electrolyte composition explains the clinical observations regarding electrolyte **shifts between ECF and ICF**. This explains why large amounts of certain electrolytes are needed to replete small deficiencies in the serum (ECF) if the ICF stores are depleted. One of our limitations is the inability to assess ICF electrolyte composition easily at the bedside.

- Because water is freely permeable, the osmolality of all body compartments should be the same but, in reality, the protein concentration in the plasma to interstitial fluid is 16:1, generating an **oncotic pressure difference** between the two compartments.
- **Starling forces** describe **net fluid flux** between intravascular space and the interstitium:

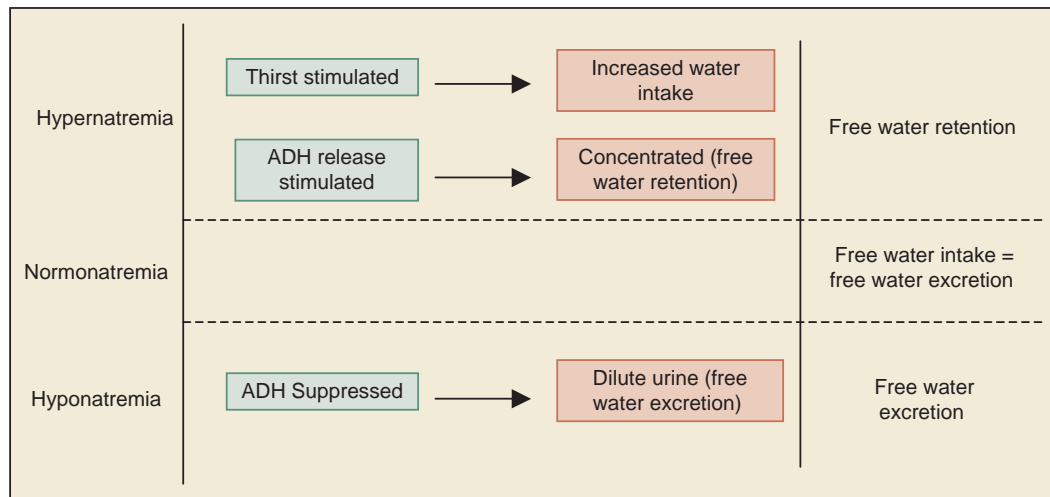

$$Q = Kf\{(P_c - P_i) - \sigma(\pi_c - \pi_i)\},$$

where Q is the net fluid flux (mL/min), (P_c – P_t) is hydrostatic pressure difference between capillary (c) and interstitium (i), and (π_c – π_i) is the oncotic pressure difference between the capillary and interstitium. K_f is the filtration coefficient for that membrane (mL/min/mm Hg), and is the product of capillary surface area and capillary hydraulic conductance, and σ is the permeability factor (i.e. reflection coefficient), with “one” being impermeable and “zero” being completely permeable.

- The **permeability factor** explains why, in times of capillary leak as in shock states, colloids cannot maintain an oncotic pressure difference and tend to leak out into the interstitium.
- The general principle of **fluid resuscitation** is that intravascular hypovolemia should be replaced with **isotonic fluid**, which tends to distribute in the ECF (3:1 intravascular:interstitium). Hypotonic fluid will distribute between all body compartments with only a small amount remaining in the intravascular space (as water is freely permeable).
- Frequently used **isotonic solutions** are **0.9% normal saline**, which contains 154 mEq/L of Na⁺ and Cl⁻ each, and **lactated Ringer** solution that contains 130 mEq/L Na⁺, 109 mEq/L Cl⁻, 4 mEq/L K⁺, 3 mEq/L Ca²⁺, 28 mEq/L lactate.
- The **end point of fluid resuscitation** continues to be an area of great debate, as direct measurement of intravascular (plasma) volume is not the norm. Surrogate markers are used to assess adequate fluid resuscitation: blood pressure, heart rate, urine output, and parameters of perfusion and cardiac function. Although every clinician wants to treat patients to “**euvolemia**,” there are only a few centers measuring intravascular volume using **radioisotope studies** and **measuring plasma volume**. Debates will continue on how much fluid to give until an easy method of measuring intravascular volume is available.

REGULATION OF WATER BALANCE

- ECF **tonicity** is generally reflected in the concentration of **sodium** in the serum. The serum sodium (Na_{pl}) is proportional to the total body exchangeable sodium (Na_e) plus the total body exchangeable potassium (K_e): {(Na_e + K_e)/(total body water)} ∝ Na_{pl}.

ADH = anti-diuretic hormone

FIGURE 17.1. Water intake and excretion regulation. ADH, antidiuretic hormone.

- This equation illustrates the **relationship between total body solutes and total body water**. Decreases in potassium often accompany hyponatremia, and replacement of intracellular solute losses can also be an important part of treating hyponatremia.
- As water intake and excretion are tightly regulated to maintain near-constant plasma osmolality (Fig. 17.1), disturbances in serum sodium indicate **disorders in water balance, not gains or loss of sodium**. This is a **crucial point in understanding dysnatremias**.
- The actions of **antidiuretic hormone (ADH)**, also called arginine vasopressin, on the kidney tightly regulates water excretion. To maintain water balance, an **intact thirst mechanism** and the ability of the kidneys to **vary urinary concentration** are required.

RENAL WATER HANDLING

- In the absence of ADH activity (as in **diabetes insipidus**), **urine concentration** will remain very low (50–80 mOsm/kg). When

TABLE 17.1

STATES OF IMPAIRED WATER EXCRETION IN THE INTENSIVE CARE UNIT RESULTING IN HYPONATREMIA

Volume-depleted states
Volume depletion

Pain
Postoperative state
Nausea
Hypothyroidism
Volume-expanded states
Congestive heart failure
Renal failure
Cirrhosis

ADH activity is maximal, urinary concentration can be as high as **1,200 mOsm/kg**. This ability to excrete very dilute or a very concentrated urine allows the body to achieve water balance across a very wide range of water intake (between approximately **0.8 L/day** and **15 L/day**).

- Administration of water to a patient with **impaired water excretion** (Table 17.1) can lead to hyponatremia.

Electrolyte Free Water

- **Electrolyte free water** is a conceptual volume of a body fluid (usually urine) that represents the volume of that fluid that would be required to dilute the electrolytes contained within total volume of the fluid to the same tonicity as plasma electrolytes.
- The remainder of the volume (total volume minus electrolyte free water) can be thought of as containing the **nonelectrolyte osmoles**. This nonelectrolyte water excretion is the amount of water excreted above the excretion of electrolyte solutes, and thus, if it is not replaced, will have an effect on the plasma sodium concentration. In other words, the osmolality of a solution is not important in determining whether it contains “free water”; rather, it is the **concentration of electrolytes that is important**.
- An important concept is **urine electrolytes and not the urine osmolality** determine the **degree of free water excretion** in the urine. If the concentration of electrolytes in the urine is greater than the concentration of electrolytes in the plasma, free water is not being excreted in the urine. If the concentration of electrolytes in the urine is less than that in the plasma, the patient is excreting free water in the urine. This relationship is illustrated in Figure 17.2.

SODIUM

Hyponatremia

- Hyponatremia commonly occurs in hospital settings. Often the condition is asymptomatic, but **hyponatremic**

FIGURE 17.2. Relationship of electrolyte concentration in urine and plasma to the amount of free water excreted.

- encephalopathy** (brain dysfunction due to cerebral edema) can result in a life-threatening emergency.
- Risk factors for life-threatening hyponatremia are **female gender of premenopausal age, children, and hypoxia**.
 - Hyponatremia is defined as **serum sodium of <135 mEq/L**. The ability of the kidney to dilute the urine and thus excrete free water is the body's primary defense against the development of hyponatremia.
 - **Excess ingestion of water** as the sole cause of hyponatremia is **rare**, as the typical adult with normal renal function can excrete a massive free water load (15 L of free water per day).
 - The combination of factors necessary for the development of hyponatremia are **free water intake** in the setting of an underlying condition that impairs free water excretion (see Table 17.1).
 - The states that impair water excretion are usually states where **ADH release** is a physiologic response to a stimulus such as **volume depletion, pain, nausea, postoperative state, or congestive heart failure** (due to decreased circulating blood volume). Pathologic release of ADH occurs in syndrome of inappropriate ADH release (syndrome of inappropriate antidiuretic hormone [SIADH]) and with certain medications such as **thiazide diuretics and anticonvulsants**.

Clinical Manifestations of Hyponatremia

- **Hyponatremic encephalopathy** is the clinical term for symptomatic cerebral edema secondary to hyponatremia, and this condition can have a fulminant presentation. Early signs are usually nonspecific—**nausea, vomiting, headaches**—often go unrecognized, and are thought to be due to cerebral edema. When pressure is exerted on the skull by the brain, **seizures** may occur and, if uncorrected, **brainstem herniation** with respiratory failure and death will follow.

Risk Factors for Hyponatremic Encephalopathy

- The **time to development** of hyponatremia (i.e., acute versus chronic) has been presumed to be an important risk factor in determining severity of symptoms, but there is disparity in patient outcomes even when the time to development of hyponatremia is similar.
- There are **three major risk factors** for poor outcomes after hyponatremic encephalopathy: **female of premenopausal age, hypoxia** at disease presentation, **younger age**, and **children** (high brain-to-cranial vault ratio).

Approach to a Hyponatremic Patient

- The first step in working up the *hyponatremic* patient is to exclude hyperosmolar hyponatremia (Fig. 17.3). An osmot-

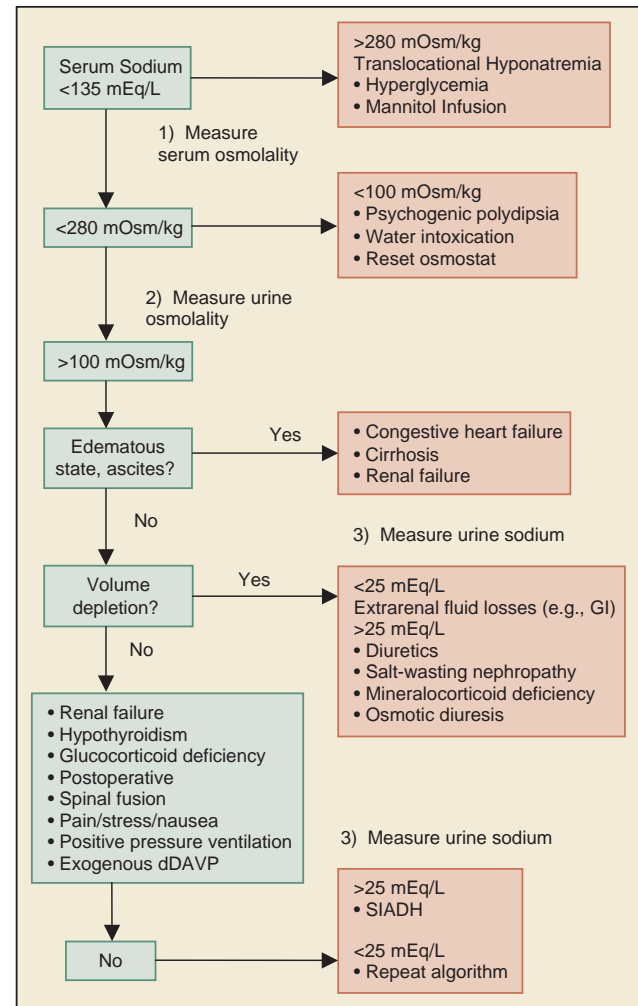

FIGURE 17.3. Diagnostic approach to hyponatremia. DDAVP, desmopressin; GI, gastrointestinal; SIADH, syndrome of inappropriate antidiuretic hormone.

ically active substance that is confined to the extracellular fluid (usually glucose or mannitol) will remove water from the intracellular space and will dilute the serum sodium concentration (**translocational hyponatremia**).

- To correct for hyperglycemia, 1.6 mEq of Na^+/L is added for every 100 mg/dL increase of the serum glucose above 100 mg/dL.
- **Pseudohyponatremia** may occur due to hyperproteinemia and hyperlipidemia when samples are diluted prior to measurement of the serum sodium. If a **potentiometric method** is used, this is not a concern. In pseudohyponatremia, the measured serum osmolality will be normal.
- After assessment of osmolality, the remainder of the diagnostic approach is based on the **history, urinary electrolytes, and clinical assessment** of the patient's **intravascular volume status**.
- Physical examination can be **unreliable** in the clinical assessment of volume status and thus should be interpreted with caution (see Fig. 17.3). A difficult group of patients to assess are those with **total body fluid excess** (with edema, weight gain) due to shock and loss of fluid into the interstitial space but who are **intravascular volume-depleted**. Despite edema, they would be categorized as the “volume depletion” group,

and the intravascular volume may best be assessed and treatment guided by BV measurements.

Treatment of Hyponatremic Encephalopathy

- **Early recognition** of the problem and prompt therapy are the most important factors associated with successful intervention and good neurologic outcomes.
- Fluid restriction alone is never appropriate to manage a patient with hyponatremic encephalopathy, **especially in intravascular hypovolemic states**.
- Use of **hypertonic saline** to correct hyponatremia is reserved for patients with signs of encephalopathy and is not appropriate in asymptomatic patients regardless of serum sodium. **Serum osmolality** should be measured prior to beginning therapy.
 - The rationale for treatment with **hypertonic saline** is (a) for severe manifestations of cerebral edema, (b) correct serum sodium to a mildly hyponatremic level, and (c) maintain this level of serum sodium to allow for the brain to adapt to the change in serum osmolality (Table 17.2).
- In patients with severe manifestations (**active seizures or respiratory failure**), a **bolus** of 100 mL 3% saline (given over 10 minutes) can be given to promptly change the serum osmolality. The goal is to raise the serum sodium by about 2 to 4 mEq/L. If symptoms persist, the bolus may be **repeated** followed by an infusion of hypertonic saline.
- Goal is to raise the serum sodium to mildly hyponatremic levels. However, the total change in serum sodium should not exceed **15 to 20 mEq/L over 48 hours**.
- **Cerebral demyelination** is a rare, serious complication associated with the correction of severe hyponatremia. It is usually

a **delayed phenomenon** occurring days to weeks after correction of hyponatremia and can manifest as a **pseudocoma** with a locked-in stare. This condition can also be asymptomatic and **magnetic resonance imaging** (which is sensitive for the detection of demyelinating lesions) may be necessary for the diagnosis.

- The rate of correction of serum sodium alone does not predict the development of cerebral demyelination. What is important is the **absolute change in serum sodium over 48 hours exceeding 15 to 20 mEq/L** and overly aggressive correction to **normonatremic** levels. **Liver disease** and **hypoxia** increase the risk of demyelination, and care must be exercised in these groups.
- The serum sodium should never be corrected to **normonatremic** levels for a **few days** after hyponatremic encephalopathy. This allows the patient to adjust to the new plasma tonicity.
- In patients with **impaired cardiac output** in whom pulmonary edema may develop with vigorous volume expansion, intravenous **furosemide** should be given in addition to hypertonic saline to prevent volume overload.

Hypernatremia

- Hypernatremia, a serum sodium **>145 mEq/L** is commonly encountered. **Thirst** is a powerful protective mechanism and, therefore, **restricted access to water** is nearly always necessary for the development of hypernatremia.
- In critically ill patients, usually there is a combination of **impaired access to water** and **ongoing free water losses** (Fig. 17.4).
- A detailed history focusing on **fluid intake and losses** and an estimate of the patients intravascular volume is the first step in the evaluation. Sources of water losses are in the **urine**, from the **gastrointestinal tract** (diarrhea and nasogastric suction), and **insensible losses** (fever, sepsis, massive diaphoresis, burns).
- The urine osmolality alone cannot be used to determine whether there is free water loss in the urine. This is because water is excreted with **nonelectrolyte osmoles** (which under physiologic conditions is typically **urea**) and with electrolyte osmoles. Both contribute to the osmolality of the urine but have differential effects on water balance. Water that is excreted with nonelectrolyte osmoles is water that is lost in excess of electrolyte loss. Therefore, **loss of water with the nonelectrolyte osmoles will raise the serum sodium**. Water that is excreted with electrolyte osmoles will not affect the serum sodium (as long as the concentration of electrolytes in the urine and serum are similar).
- Failure to concentrate the urine in the face of hypernatremia should raise suspicion of a **urinary concentrating defect**. Renal failure, loop diuretics, tubulointerstitial renal disease, and diabetes insipidus are the main causes of urinary concentrating defects.
- During hypernatremic states, the brain is subject to osmolar stress that favors the movement of water out of the brain and can lead to significant **brain damage**.

Central Diabetes Insipidus

- **Central diabetes insipidus** (CDI) is most commonly in the setting of head injury, pituitary surgery, and cerebral

TABLE 17.2

TREATMENT OF HYPONATREMIA

High-risk groups for poor outcomes

Menstruant females
Children
Hypoxic patients

Hyponatremic encephalopathy with evidence of severe cerebral edema (active seizures, respiratory arrest)

- Bolus, 100 mL of 3% NaCl over 10 min
- Can repeat bolus 1–2 times with the goal of increasing serum sodium 2–4 mEq/L or until clinical improvement
- Begin infusion as for hyponatremic encephalopathy

Hyponatremic encephalopathy (seizures, decreased mental status, headache, nausea, vomiting)

- Infuse 3% NaCl at a rate of 1 mL/kg/h. ICU setting using infusion pump
- Check serum sodium every 2 hours until symptom-free
- Stop hypertonic saline when patient is symptom-free or serum sodium has increased by 15–20 mEq/L *in the initial 48 hours of therapy*

Asymptomatic hyponatremia

- Fluid restriction unless hypovolemia is suspected
- Demeclocycline
- Vasopressin V₂ receptor antagonists

From Ayus JC, Krothapalli RK, Arief AI. Treatment of symptomatic hyponatremia and its relation to brain damage. A prospective study. *N Engl J Med*. 1987;317(19):1190–1195.

Lack of water intake	Increased water losses
Decreased thirst (dementia, neurologic impairment) Mechanical ventilation Bowel rest/nasogastric suction	Solute diuresis (hyperglycemia, urea loading from tube feeds or hyperalimentation) Loop diuretics Gastrointestinal water losses Diabetes insipidus

FIGURE 17.4. Common causes of hypernatremia in the intensive care unit.

hemorrhages. Urine is not concentrated in the setting of hypernatremia. In general, the plasma osmolality exceeds the urine osmolality.

- A simple and reliable clinical test that can be used to distinguish **CDI** from **nephrogenic diabetes insipidus** is to administer a V_2 receptor agonist, such as DDAVP. A 50% increase in **urine osmolality** after DDAVP administration strongly suggests CDI. Once the diagnosis is established, DDAVP can be given either subcutaneously or intranasally with close monitoring of water intake to avoid hyponatremia, and monitoring of electrolytes.

Treatment of Hypernatremia

- The goal of treatment is to achieve **normal circulatory volume** as patients typically have circulatory volume depletion, and then to correct the serum sodium with free water replacement (Table 17.3). **Oral hydration** is preferable to parenteral and should be used in patients with functional gastrointestinal tract.
- It is also possible to be **hypernatremic** and **hypervolemic**, in which case sodium should be withheld and patient allowed to be in negative fluid balance.
- In hypernatremic states, **insulin resistance** has also been observed leading to severe hyperglycemia and potential worsening of hyperosmolality.
- In patients without evidence of hypernatremic encephalopathy, the serum sodium should not be corrected more quickly than **15 mEq/24 hours**. In severe cases (>170 mEq/L), sodium

should not be corrected to below 150 mEq/L in the first 48 to 72 hours to prevent cerebral edema.

POTASSIUM

- Potassium is present mainly in the **intracellular space** (approximately 4,000 mEq of total body stores) and is sequestered in the intracellular space through the action of the Na^+/K^+ ATPase pump.
- The serum potassium level is **tightly regulated** so that the potential differences across membranes, especially cardiac, are not affected by alterations in potassium level.
- The major influences that favor potassium movement **into cells** are **insulin** and **β_2 -adrenergic stimulation**.
- Metabolic **acidosis** favors potassium movement **out of cells** as H^+ is exchanged for K^+ when H^+ moves intracellularly. However, this may have less importance in settings where an organic anion is generated as a result of the acidosis (such as lactic acidosis) as the organic ions may also move intracellularly and thus negate the electrogenic stimulus for potassium to move out of the cell.
- There are two main determinants of **potassium excretion** of clinical significance: **flow of tubular filtrate** into the distal nephron and **secretion** of potassium into the electronegative filtrate through epithelial potassium channels.
- The effect of **aldosterone** with sodium retention is the most important influence increasing the action of ENaC and therefore **stimulates potassium excretion**.
- Medications such as **amiloride**, **triamterene**, and **trimethoprim** block ENaC and lead to decreased K^+ secretion and can lead to clinically important hyperkalemia.
- **Decrease in the rate of tubular flow** into the distal nephron **stimulates the renin angiotensin system**, which in turn stimulates release of aldosterone with increased **potassium excretion**.

Hyperkalemia

- Hyperkalemia occurs through several mechanisms: **shifting** of potassium from intracellular compartment to the extracellular fluid compartment or through total body excess (either **too much intake** or **too little excretion** from renal failure) (Table 17.4). Other causes for impaired renal excretion are adrenal insufficiency, type IV renal tubular acidosis (usually seen in diabetics).
- Chronic renal failure alone typically does not lead to hyperkalemia until the glomerular filtration rate (GFR) falls below approximately **15 mL/minute**.
- Medications are a very important risk factor for the development of hyperkalemia (Table 17.5).

TABLE 17.3

TREATMENT OF HYPERNATREMIA

1. Replete intravascular volume with colloid solution, isotonic saline, or plasma
2. Estimate water deficit. Deficit should be replaced over 48–72 hours, aiming for a correction of 1 mOsm/L/hour. In severe hypernatremia (>170 mEq/L), serum sodium should not be corrected to below 150 mEq/L in the first 48–72 hours. Replacement of ongoing water losses are given in addition to the deficit
3. Hypotonic fluid should be used. Usual replacement fluid is 77 mEq/L (0.45 N saline). A lower sodium concentration may be needed if there is a renal concentrating defect or sodium overload. Glucose-containing solutions should be avoided, and an oral route of administration should be used
4. Monitor plasma; electrolytes should be monitored every 2 hours until patient is neurologically stable

Reproduced from Medical Knowledge Self-assessment Program (MKSAF) 2006.

TABLE 17.4**CAUSES OF HYPERKALEMIA**

Assess for increased potassium intake
Low-sodium salt substitutes and potassium supplements
 Assess for shift of potassium intracellular fluid to extracellular fluid
 Metabolic acidosis
 Tissue necrosis (rhabdomyolysis, bowel infarction, tumor lysis) or depolarization
 Insulin deficiency
 β_2 -Blockade

Assess for reduced potassium excretion in urine
 Renal failure
 Low aldosterone action (Think drugs: especially heparin, cyclosporine, tacrolimus, ARB, ACE-I)
 Decreased distal nephron flow rate

ARB, angiotensin receptor blockers; ACE-I, angiotensin-converting enzyme inhibitor.
 From Medical Knowledge Self-assessment Program (MKSAP) 2006.

Management of Hyperkalemia

- The first step is to differentiate **life-threatening hyperkalemia** from less urgent cases and then to identify the diagnosis.
- The absolute levels of the potassium cannot be reliably used to determine if a life-threatening condition exists, and the effect of elevated potassium on the cardiac membrane must be determined through an **electrocardiogram**.
- The management of emergent hyperkalemia is detailed in Table 17.6. As a temporizing measure, **shifting of potassium intracellularly** with insulin or beta-agonists can be used until definitive removal therapy is instituted. If normal renal function is present, diuretics and intravenous saline can be used to remove potassium. Cation exchange resins can be used as an adjunctive therapy.
- In patients with renal failure, especially with oliguria, **emergency dialysis** is often necessary.
- Hyperkalemia not associated with electrocardiographic changes can sometimes be managed with discontinuation of

TABLE 17.5**MEDICATIONS THAT CAUSE HYPERKALEMIA**

Drugs that interfere with potassium excretion
 Interfere with renin–angiotensin–aldosterone axis:
 ACE-I, ARB, aldosterone blockers, heparin (decrease aldosterone synthesis), beta-blockers (decrease renin release)
 Interfere with tubular potassium handling
 Potassium-sparing diuretics (amiloride, triamterene), trimethoprim, calcineurin inhibitors (cyclosporine, tacrolimus)

Drugs that shift potassium from intracellular fluid to extracellular
 β_2 -blockers, depolarizing paralytics (e.g., succinylcholine), digitalis

ACE-I, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blockers.
 From Medical Knowledge Self-assessment Program (MKSAP) 2006.

TABLE 17.6**TREATMENT OF HYPERKALEMIA****Immediate actions**

Electrocardiogram: Look for peaked T waves, loss of p waves, widened QRS. Loss of p wave and widened QRS suggest impending ventricular fibrillation
 Send repeat serum potassium to confirm diagnosis (do not wait for confirmatory test to initiate emergency therapy)

Hyperkalemia with electrocardiographic (ECG) changes**Stabilize cardiac membrane**

- Intravenous (IV) calcium gluconate or chloride to stabilize cardiac membrane, may repeat in 5 min if ECG changes persist
- Place patient on cardiac monitoring
- Shift potassium into cells
- IV insulin (with IV dextrose if necessary to prevent hypoglycemia)
- Albuterol, 10–20 mg by nebulization (caution in heart disease)
- IV NaHCO_3 may be of benefit

Potassium removal

- Dialysis
- Diuretics (with IV saline if patient is not volume overloaded) if renal function is normal
- Cation exchange resins (caution with decreased gastrointestinal motility as bowel necrosis can occur)

Hyperkalemia without electrocardiographic changes

- Remove offending agents
- Otherwise follow same therapy as above with dialysis, diuretics, and/or cation exchange resins.

the offending agent. Some medications causing hyperkalemia such as spironolactone can have a long half-life, and the effect can last for up to 1 to 2 weeks.

Hypokalemia

- Hypokalemia can occur either through **shifting** from ECF to ICF or through total body potassium **depletion** via gastrointestinal losses (distal to the stomach) or urinary losses (Table 17.7). It should be noted that gastric secretion contains only 10 mEq/L of K^+ , but hypovolemia associated with vomiting/nasogastric (NG) suction stimulates aldosterone with sodium retention and potassium excretion.
- **Shifting of K^+ into the intracellular compartment** is a normal physiologic process in response to **insulin** secretion after a meal. This avoids a dangerously high K^+ level as the total amount of K^+ contained within the extracellular space is quite low. **β_2 -adrenergic stimulation** is another avenue for cellular uptake of potassium. This is clinically significant as β_2 agonists can be used to transiently treat hyperkalemia and possibly lead to hypokalemia in certain clinical settings.

Clinical Manifestations of Hypokalemia

- The effects of hypokalemia are related to the effect on **neuromuscular transmission and conduction in the heart**. A

TABLE 17.7**COMMON CAUSES OF HYPOKALEMIA**

Potassium shift into cells
 Alkalosis, recovery from diabetic ketoacidosis, β_2 -agonists, insulin
 Gastrointestinal potassium losses
 Vomiting, nasogastric suction, diarrhea
 Renal potassium losses
 Diuretics, hypomagnesemia, hyperaldosteronism, drugs (amphotericin B, cisplatin), proximal (type II) and distal (type I) renal tubular acidosis (RTA), Bartter and Gitelman syndromes
 Decreased potassium intake
 Intestinal secretion contains 30–60 mEq/L of potassium
 Gastric secretion contains only 10 mEq/L of potassium, and hypokalemia may be a result of hypovolemia with stimulation of aldosterone. Aldosterone will lead to sodium retention and potassium excretion in the kidneys

From Medical Knowledge Self-assessment Program (MKSAP), 2006.

decrease in extracellular potassium makes the **membrane less excitable** and muscle weakness results.

- Hypokalemia can lead to **arrhythmias** (especially in patients on **digitalis** or with heart disease). Other effects include **ileus**, **muscular cramps**, **augmented ammonia production in the kidney** (which can potentiate hepatic encephalopathy), and **rhabdomyolysis**.
- Hypokalemia is often associated with **hypomagnesemia**, and serum magnesium status should be assessed in all patients with hypokalemia.

Management of Hypokalemia

- As K^+ is a major intracellular cation, serum levels may not reflect the severity of deficiency. Total body potassium deficits are typically large (200–300 mmol for serum potassium of 3.0 mEq/L; i.e., for each 1 mEq below normal), and repeated replacements may be needed with serial measurements.
- For severe hypokalemia, potassium chloride should be given intravenously (IV) at a rate of **10 to 20 mEq/hour**.
- **Hypomagnesemia** should also be corrected if present.

PHOSPHORUS**Phosphate Homeostasis**

- The need for phosphate for proper **cellular energy metabolism** through high-energy phosphate compounds (ATP) is among the most important. Phosphate is obtained in the diet primarily through protein intake.
- The typical Western diet contains sufficient phosphate to meet metabolic demands; however, in patients with **poor nutritional** status, often seen in alcoholics, hypophosphatemia may develop.
- The **phosphate excretion in the kidney** is regulated by several factors that favor tubular phosphate **reabsorption** (such as **insulin**, **prostaglandin E₂**, and **thyroid hormone**) and factors that **inhibit phosphate reabsorption** (such as **parathyroid hormone** and the newly characterized phosphat

uric hormone FGF-23 that plays a role in hereditary and acquired **phosphate-wasting disorders**). Phosphate reabsorption is handled principally in the **proximal tubule** through the **NPT2 sodium phosphate cotransporter**. Therefore, disorders of the proximal tubule, such as Fanconi syndrome, may lead to renal phosphate wasting.

Hypophosphatemia

- There are three major mechanisms of hypophosphatemia: decreased absorption, increased loss, and ECF to ICF shifts (Table 17.8).
- Phosphate, like potassium and magnesium, is mainly an **intracellular ion**, and low serum phosphate usually represents significant total body phosphate depletion.
- Hypophosphatemia commonly occurs in alcoholics and in hospitalized patients with nasogastric suction, malnutrition, extensive bowel resection, malignancy, low sun exposure, and diuretic use.
- If the cause is in doubt, **renal phosphate losses** can be assessed by calculating the fractional excretion of phosphorus at a time when serum phosphorus is low:

$$\text{Fractional excretion of phosphorus} = (P_u \times Cr_{pl}) / (P_{pl} \times Cr_u)$$

where P is phosphorus level, u is urine, pl is plasma, and Cr is creatinine level.

If the value is **below 5%**, the kidney is appropriately conserving phosphate and, therefore, the **losses are extrarenal**.

TABLE 17.8**CAUSES OF HYPOPHOSPHATEMIA****Decreased phosphate absorption, GI phosphate losses**

- Alcoholism/poor nutrition
- Diarrhea
- GI tract surgery
- Ingestion of phosphate-binding medications or antacids
- TPN preparations with inadequate phosphorus
- Vitamin D deficiency
- Use of corticosteroids

Shifting of phosphate from extracellular space

- Refeeding syndrome
- Respiratory alkalosis
- Hungry bone syndrome
- High-grade lymphoma, acute leukemia
- Administration of glucagon, epinephrine

Increased renal losses of phosphate

- Hyperparathyroidism
- Fanconi syndrome (proximal tubular dysfunction seen in several diseases especially multiple myeloma)
- Diuretics, especially carbonic anhydrase inhibitors
- Acute volume expansion
- Amphotericin B
- Oncogenic osteomalacia
- Hypophosphatemic rickets (X-linked and AD)

GI, gastrointestinal; TPN, total parenteral nutrition; AD, autosomal dominant.

From Medical Knowledge Self-assessment Program (MKSAP), 2006.

Clinical Manifestations of Hypophosphatemia

- The most life-threatening events are failure of two important muscles leading to cardiac and ventilatory failure.
- In severe depletion, muscular weakness (especially large muscle groups, proximal extremity weakness), arrhythmias, rhabdomyolysis, hypotension, hypoventilation, seizures, coma, and hemolytic anemia may occur.
- Other undesirable effects of hypophosphatemia are the following: shift of oxygen dissociation curve to the left from deficiency of 2,3-DPG; depressed immune function (chemotaxis, phagocytosis, bacteriocidal activity); platelet dysfunction (adhesion and aggregation); metabolic acidosis (impaired bicarbonate resorption and ammonia production); and abnormal glucose metabolism from decreased entry into the cell to make high-energy phosphates.

Treatment of Hypophosphatemia

- Parenteral phosphorus administration should be undertaken in symptomatic patients or in patients with severe depletion (<1.0 mg/dL) or when the oral route is not appropriate. Parenteral phosphate preparations are generally ordered in millimoles. **One millimole (mmol) of phosphate equals 31 mg of phosphorus.**
- As phosphate is administered as either a sodium salt or a potassium salt, intolerance to either of these should be considered in settings such as renal failure or congestive heart failure.
- Phosphorus replacement in asymptomatic patients should be oral and can be given as a potassium or sodium salt.
- Be careful of the **refeeding syndrome** in total body depleted patients as phosphorus is a major intracellular anion, and sudden decreases in ECF may lead to cardiovascular and respiratory failure.

Hyperphosphatemia

- Occurs primarily in the setting of **impaired renal function**
- Significant **phosphate loading** can occur due to exogenous phosphate administration or as part of the **tumor lysis syndrome**; however, renal insufficiency also commonly complicates this condition. Occult sources of phosphate loading include **sodium phosphate solutions** (either orally or as an **enema**), which can produce significant and, in some rare cases, fatal outcomes.
- In renal failure, elevated serum phosphorus is associated with cardiovascular disease and cardiovascular mortality.

Clinical Manifestations of Hyperphosphatemia

- There are few overt symptoms of hyperphosphatemia, and the syndrome may be insidious. Nephrocalcinosis can complicate hyperphosphatemia and manifest as renal insufficiency.
- On rare occasions, **acute dialysis** may be indicated to treat hyperphosphatemia. Extended dialysis session (>4 hours) may be necessary as phosphorus mobilization is time dependent and phosphorus removal in short dialysis sessions is limited.
- Patients may exhibit **signs of hypocalcemia**, hypotension, and impending cardiovascular collapse that can occur with acute hyperphosphatemia.

CALCIUM

Calcium Homeostasis

- Calcium concentration in plasma is tightly regulated by processes that promote **calcium influx** into the extracellular fluid (mainly intestinal calcium absorption and release of calcium from bone demineralization), and **remove calcium** from the extracellular fluid (urinary calcium excretion and bone formation).
- Intracellular calcium levels are very low, whereas the total body calcium stores in the bone are abundant.
- The hormonal influences that regulate these processes are complex but involve the actions of two principal hormones: **parathyroid hormone and calcitriol**.
- Calcium exists in the plasma as **protein-bound calcium** and **ionized calcium**, usually measured in mmol/L.
- Measurement of the total serum calcium reflects the aggregate amount of these two pools of plasma calcium. **Ionized calcium** is the **active component** and the more important physiologically.
- Albumin is the predominant calcium-binding protein in the circulation. A reduction in plasma **albumin** of 1 g/L will decrease the serum total **calcium** by 0.8 mg/dL. The **validity** of this correction in critical illness has been **questioned**, possibly due to other factors that affect binding of calcium to albumin.
- Therefore, measurement of **ionized calcium** levels in critically ill patients is a good practice, and results may be available within minutes of using point-of-care testing.

Hypocalcemia

- The causes of hypocalcemia can be divided into either efflux of calcium **out of the extracellular space** or by **decreased entry** of calcium into the extracellular space (Table 17.9).
- Normally, homeostatic mechanisms can maintain serum calcium levels despite low intake by increasing mobilization from the bone.
- Hypocalcemia can result from **decreased calcium absorption and mobilization** from bone stores in **hypoparathyroidism** and **vitamin D deficiency**.

TABLE 17.9

CAUSES OF HYPOCALCEMIA

Hypoparathyroidism/pseudohypoparathyroidism

Hyperphosphatemia

Hypomagnesemia

Vitamin D deficiency

- Dietary deficit

- Reduced sun exposure

- Decreased 25-hydroxylation of vitamin D (liver disease, alcoholism)

- Decreased vitamin D–sensitive rickets type 1 (1- α -hydroxylase deficiency) and type 2 (receptor deficiency)

Renal failure (reduced 1-hydroxylation of vitamin D)

Osteoblastic metastases (prostate, breast)

Saponification in severe pancreatitis

Citrate load (blood transfusion)

From Medical Knowledge Self-assessment Program (MKSAP), 2006.

- Increased calcium removal from the serum occurs in severe pancreatitis through **saponification** of fats and in **osteoblastic metastatic** disease.
- **Ionized calcium** is impacted by conditions that alter **protein binding** of calcium. **Alkalemia** will increase the affinity of albumin for calcium (through altering the net charge of the protein) and will lower the ionized calcium. Acute increases in total albumin may lower ionized calcium.
- **Risk factors** for hypocalcemia include the following: neck irradiation, parathyroid surgery, renal transplantation in patients with tertiary hyperparathyroidism, malignancy, alcoholism, low sun exposure, and malnutrition.

Clinical Manifestations of Hypocalcemia

- Altered **mental status** and **tetany** (Chvostek and Trousseau signs)
- In sepsis, hypocalcemia may be associated with parathyroid hormone (PTH) insufficiency, altered vitamin D metabolism, hypomagnesemia, chelation of calcium by lactate, and calcitonin precursors.
- The association between **hypocalcemia** and **sepsis** is not well understood although it is now recognized that elevated intracellular calcium levels are a common mechanism for cell death, and low calcium levels may not reflect intracellular concentration of calcium.

Treatment of Hypocalcemia

- The first questions should be to what degree is the ionized calcium altered and why? If the ionized calcium is decreased due to chelation from hyperphosphatemia, treatment of the hypocalcemia can be dangerous, as it can precipitate vascular calcification.
- In **sepsis**, hypocalcemia is common, and treatment is not usually necessary unless cardiovascular collapse with ionized calcium levels of <0.8 mmol/L is present. Data from animal models suggest that it may be harmful to treat hypocalcemia in the setting of sepsis. There are no randomized clinical studies to guide treatment of hypocalcemia in sepsis, and treatment should be reserved for those with symptomatic hypocalcemia such as hemodynamic instability.
- For acute symptomatic hypocalcemia, administer intravenous **calcium chloride** or **calcium gluconate**. Calcium gluconate is advantageous because it is less caustic to veins. Calcium should not be infused more rapidly than **2.5 to 5 mmol in 20 minutes** because of the risk of cardiac abnormalities and asystole. Intravenous calcium will transiently normalize the calcium level, and an infusion should be started after the bolus, especially in settings where there is an ongoing process such as the hungry-bone syndrome after parathyroidectomy.
- **Magnesium deficiency**, by inducing resistance to the actions of parathyroid hormone, can be an important cause of hypocalcemia. If magnesium deficiency is the cause, calcium levels should return to normal once magnesium is replaced.

Hypercalcemia

- Hypercalcemia is caused by entrance of calcium into the intravascular space in excess of renal excretion and calcium incorporation into bone. Two sources of **calcium influx** into the intravascular space are **intestinal absorption** and **bone**

TABLE 17.10

CAUSES OF HYPERCALCEMIA

Excess calcium influx into vascular space
–Primary hyperparathyroidism (usually adenoma, gland hyperplasia; parathyroid malignancy is rare)
–Malignancy (multiple myeloma, carcinomas through production of PTH-related peptide, osteosarcomas)
–Immobilization
–Granulomatous disease (increased vitamin D production?)
–Sarcoidosis
–Tuberculosis
–Paget disease
–Milk-alkali syndrome
–Vitamin D intoxication
–Hyperparathyroidism (stimulation of osteoclasts)
Decreased calcium excretion
–Primary hyperparathyroidism
–Thiazide diuretics
–Familial hypocalciuric hypercalcemia

PTH, parathyroid hormone.

reabsorption. Decreased renal excretion occurs in primary hyperparathyroidism and with thiazide diuretics.

- Causes are listed in Table 17.10, with the most common causes being primary hyperparathyroidism, malignancy, and granulomatous diseases.
- Total calcium must be corrected for serum albumin because of protein binding, and **ionized calcium** should be measured in hypercalcemic patients.

Clinical Manifestations of Hypercalcemia

- There is a decrease in neuromuscular excitability and decreased muscular tone. Other manifestations include **lethargy**, **confusion**, **coma**, **nausea**, **constipation**, **polyuria**, and **hypertension**. Hypercalcemia can lead to **volume depletion**, **nephrolithiasis**, and **nephrogenic diabetes insipidus**.

Approach to Diagnosis

- First step is to measure PTH level.
- Failure to suppress PTH secretion in the face of hypercalcemia denotes hyperparathyroidism. Primary hyperparathyroidism typically does not result in severe, symptomatic hypercalcemia.
- In hypercalcemia of malignancy, PTH is usually suppressed (this is the normal response of the parathyroid gland). PTH-related peptide should also be ordered if malignancy is suspected, as many cancers express this protein product that stimulates PTH receptors.
- 1,25-hydroxyvitamin D and 25-hydroxyvitamin D levels can be helpful if abnormal vitamin D metabolism is suspected. Certain granulomatous conditions lead to increased 1,25 vitamin D, and in cases of vitamin D intoxication, high levels of 25-OH vitamin D may be seen.

Management of Hypercalcemia

- In most patients with symptomatic hypercalcemia, **volume depletion** occurs, and one of the first steps is volume repletion with intravenous **saline** (0.9% saline is the treatment of choice). This replacement of the extracellular volume will

increase calcium excretion in the urine. Caution is advised in infusing large amounts of saline to an oliguric patient.

- After fluid resuscitation, normal saline should be continued, and **furosemide** can also be given to **increase urinary calcium excretion**. Diuretics should not be given until the patient is completely volume-resuscitated. The action of loop diuretics is distinct from that of thiazide diuretics. Loop diuretics act in the ascending limb of Henle and will promote calcium excretion in the urine. Thiazide diuretics act more distally in the nephron and will decrease calcium excretion.
- **Bisphosphonates** are a good long-term treatment for hypercalcemia of malignancy by **impairing bone reabsorption**, but these agents must be used with caution in patients with renal insufficiency. **Calcitonin** is usually effective in the short term, but tachyphylaxis develops. It is best used early in the management while waiting for diuresis to remove calcium from the body.
- In patients with renal failure, **dialysis** is usually necessary to treat symptomatic hypercalcemia.

MAGNESIUM

Hypomagnesemia

- Magnesium depletion occurs in many conditions (Table 17.11) and is common in critical illness through urinary or gastrointestinal losses with inadequate intake in malnourished patients.
- It is important to identify low magnesium levels, especially in those with known (or at risk for) **cardiac arrhythmias** due to membrane-stabilizing effects on myocardium.
- Magnesium depletion has effects on the homeostasis of other ions and often occurs with **hypokalemia** and **hypocalcemia**. Low magnesium causes a potassium-wasting state, and patients with hypokalemia should be assessed for magnesium depletion. Hypomagnesemia induces a state of **reduced PTH secretion** and **PTH resistance**.
- Tissue magnesium depletion can be present in the absence of decreased serum magnesium levels (as more magnesium is in the **intracellular space**).
- Decreased total serum magnesium levels are often due to a decrease in serum albumin, which is the principal binding

protein of magnesium, and many of these patients do not have decreased ionized magnesium levels. The correlation of ionized hypomagnesemia and mortality in ICU patients is controversial. Magnesium is not actively mobilized from a body pool (unlike calcium) and, therefore, serum levels are very dependent on intake. If magnesium intake is exceeded by magnesium loss (e.g., urinary losses), the serum magnesium levels will be decreased.

Clinical Manifestations of Hypomagnesemia

- The most serious consequences of hypomagnesemia are its **cardiovascular effects**; it is associated with poor outcomes in acute myocardial infarction and may predispose to arrhythmias. Magnesium treatment may decrease **arrhythmias** after myocardial infarction. Magnesium depletion increases the risk of **torsades des pointes**, a form of polymorphic ventricular tachycardia. Intravenous magnesium is regarded as a treatment for torsades des pointes and refractory ventricular tachycardia, even in the absence of documented hypomagnesemia. Hypomagnesemia may contribute to **atrial arrhythmias** after cardiopulmonary bypass.
- Other manifestations include **altered mental status**, **seizures**, and **muscular weakness**.
- Magnesium is an important cofactor for multiple enzyme function (including **ATPase**).

Treatment of Hypomagnesemia

- For acutely symptomatic patients, parenteral administration should be undertaken; **8 to 16 mEq** should be administered intravenously in 5 to 10 minutes followed by 48 mEq over the next 24 hours.
- In asymptomatic patients, the oral route should be used although absorption is variable. Parenterally administered magnesium inhibits magnesium reabsorption in the ascending limb of Henle, and much of a parenterally administered dose may be wasted in the urine.

Hypermagnesemia

- Hypermagnesemia is not a common condition, and it is often **iatrogenic**. Magnesium is readily excreted by the kidney unless overwhelmed by large ingestions (Epsom salt and magnesium-containing cathartics).
- In the presence of peptic ulcer disease, **magnesium absorption** can be enhanced, and magnesium-containing antacids in this setting can lead to toxic hypermagnesemia.
- Patients with **renal failure** are at highest risk for developing hypermagnesemia, and the administration of magnesium-containing cathartics to these patients can be fatal.
- **Clinical manifestations** of hypermagnesemia include **hypotension**, **bradycardia**, **respiratory depression**, **decreased mental status**, and **ECG abnormalities**.

Treatment of Hypermagnesemia

- **Removal of the offending agent** may be sufficient in mild cases with normal renal function.
- In symptomatic hypermagnesemia, the neuromuscular membrane can be stabilized by administration of **1 g of calcium chloride** intravenously over 5 to 10 minutes. **Dialysis** is usually necessary in the setting of renal insufficiency or severe toxicity.

TABLE 17.11

CAUSES OF HYPOMAGNESEMIA

Gastrointestinal losses

- Diarrhea
- Nasogastric suction
- Malabsorption
- Steatorrhea
- Extensive bowel resection
- Acute pancreatitis
- Intestinal fistula

Urinary losses

- Diuretics, aminoglycosides, cisplatin, alcohol
- Pentamidine, foscarnet, cyclosporine, amphotericin B
- Phosphorus depletion
- Metabolic acidosis

From Medical Knowledge Self-assessment Program (MKSAP), 2006.

CHAPTER 18 ■ BLOOD GAS ANALYSIS AND ACID-BASE DISORDERS

Acid-base physiology is among the most complex topics in clinical medicine. Disturbances of this system are common in the critically ill, and important clinical decisions based on measured acid-base parameters occur on a daily, even hourly basis. The purpose of this chapter is to provide a conceptual introduction to the current approach to acid-base physiology, while de-emphasizing calculations and formulas.

MAINTENANCE OF THE ARTERIAL pH AND ACID-BASE BALANCE: BUFFERING AND ACID EXCRETION

- Buffering of acids is the first line of defense against perturbations in systemic pH.
- pH is a logarithmic scale that is a function of the concentration of H_3O^+ species in solution (H^+ will be used interchangeably with H_3O^+ in this chapter).
- A **buffer** can be thought of as a substance that, when present in solution, **takes up $[\text{H}^+]$ and therefore resists change in pH when $[\text{H}^+]$ is added.**
- The overall **buffering system** of the body is complex and includes several components. These are listed in Table 18.1.
- The most important system is the **carbon dioxide–bicarbonate system**, which is the principal buffer in the extracellular fluid. It is the only buffering system where the **two components (acid and conjugate base) are readily measurable** in the extracellular fluid.
- Buffers work by **binding the free H^+ as the conjugate base**, which is a weak acid.
- Buffering capacity will be depleted if acid is continually added. In humans, the net fixed acid production is approximately 70 to 100 mmol/day. The excretion of the daily acid load occurs through two distinct mechanisms: (a) the **renal excretion of fixed acid** and (b) the **respiratory excretion of volatile acid** (i.e., carbon dioxide).
- Through the interconversion of **bicarbonate, carbonic acid, and carbon dioxide**, fixed and volatile acids can be buffered

TABLE 18.1
BLOOD AND EXTRACELLULAR FLUID BUFFERS

Acid	Conjugate base
H_2CO_3	HCO_3^-
Albumin-H	Albumin ⁻
H_2PO_4	HPO_4^-
Hgb-H	Hgb ⁻

until they can be excreted through the urine or respiration (Fig. 18.1).

- In the lung, CO_2 is released, which ultimately leads to more H^+ reacting with HCO_3^- to generate water and more CO_2 .

URINARY EXCRETION OF FIXED ACIDS

- In the kidneys, the **entire filtered load of bicarbonate** is—to avoid losing base—**reabsorbed**. When the kidney excretes one H^+ in the urine, one “new” HCO_3^- is generated.
- Most **bicarbonate reabsorption** occurs in the **proximal tubule**, the renal secretion of H^+ is ten times greater in the proximal tubule—approximately 4,000 mmol/day—as compared with the distal tubule—approximately 400 mmol/day. However, in the **distal tubule**, there is a much **higher luminal–intracellular H^+ gradient** than that seen in the proximal tubule—a ratio of approximately 500:1, due to **active secretion of H^+ into the tubule**.
- In the absence of buffers, the ability to excrete acid in the urine would be limited. Through the use of **buffers in the urine** with modestly acidic pH (approximately 5.5 under maximal conditions), the excretion of H^+ in the urine occurs with different conjugate bases, which are grouped as **titratable acids—mostly phosphates**, and **nontitratable acids—ammonium**.
- The excretion of **titratable acid** has a **limit**, as it is dependent on the filtered load of phosphate and makes up a relatively small proportion of the acid excreted.
- However, the kidney can generate its **own buffer—ammonia** in substantial amounts, which can be up-regulated in the face of systemic acidosis. Ammonia is produced in the kidney, traverses the plasma membrane, and is “trapped” in the tubular

FIGURE 18.1. Normal acid-base homeostasis.

lumen because the low pH drives the following reaction to the right, as the plasma membrane is much less permeable to the charged species ammonium.

Therefore, **ammonia–ammonium** acts as a urinary buffer system, allowing the elimination of one H^+ for nearly every ammonia produced.

- Through **active secretion of H^+** in the distal tubule, the H^+ concentration gradient can be maintained approximately 100:1 between the urine and the intracellular space of the tubular epithelial cells. This corresponds to the maximally acidic urine of approximately pH 5.
- In the presence of systemic acidosis, the kidney will compensate by increasing the excretion of fixed acids, mainly in the non-titratable form (i.e., ammonium), which exists in the NH_4^+ form at a pH of 7 or below.
- This manifests as a change in the **urine anion gap** where ammonium is the **unmeasured cation**. The urinary anion gap is a useful clinical test that can be used to answer the question, “Are the kidneys excreting the acid load appropriately, or are the kidneys part of the acid-base problem?”

$$\text{Urinary anion gap} = [\text{Na}^+] + [\text{K}^+] - [\text{Cl}^-]$$

- Because ammonium is not a measured cation, the presence of significant amounts of ammonium causes an abundance of chloride relative to the measured cationic constituents of the urine (sodium and potassium).
- If there is a high level of ammonium in the urine, the **urine anion gap** will be **negative**, suggesting nonrenal causes of metabolic acidosis. If the **urinary anion gap is zero or positive**, this suggests **inability of the kidney to excrete acid**.
- A caveat that is often clinically important is that the presence of unmeasured anions in the urine (such as β -hydroxybutyrate) may falsely depress the urinary anion gap, and therefore this test does have some limitations, such as during ketonuria.

RELATIONSHIP BETWEEN SYSTEMIC pH AND BUFFER CONCENTRATIONS: AN EVOLVING CONCEPT

Traditional Paradigm

- One of the earliest observations by Hendersen was that the concentration of H^+ in the blood was dependent upon the concentration of CO_2 , H_2CO_3 , and HCO_3^- . The **Henderson–Hasselbalch equation** was later derived by using the **Sorenson** convention of expressing $[\text{H}^+]$ as pH. This relationship is usually expressed as follows:

$$\text{pH} = 6.1 + \log[\text{HCO}_3^-]/[\text{H}_2\text{CO}_3]$$

As the $[\text{H}_2\text{CO}_3]$ in plasma is related to the partial pressure of CO_2 , this relationship can be rewritten as follows:

$$\text{pH} = 6.1 + \log([\text{HCO}_3^-]/0.03 \times \text{PCO}_2)$$

This relationship became very meaningful clinically as the methodologies to measure the key variables pH, HCO_3^- , and PCO_2 were developed.

- However, the relationship between pH, HCO_3^- , and PCO_2 failed to completely describe the **relative contributions of fixed acids and volatile acids** (the respiratory component) to acidosis. This is because PCO_2 and HCO_3^- are not truly independent of each other, as changes in one will lead to changes in the other, as seen in this relationship: $\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}_2\text{CO}_3 \rightleftharpoons \text{H}^+ + \text{HCO}_3^-$
- Additionally, no single value accurately **quantifies** the degree of fixed acids present during metabolic acidosis or alkalosis. The degree of acidemia could be considered as simply the pH, as the **pH is ultimately a composite of the net respiratory and metabolic components of the acid-base disturbance**.
- Historically, several theoretical frameworks have been developed in an attempt to overcome this lack of exactitude in the concepts of **quantification** and etiology. The first is that the **HCO_3^- system was not the only quantitatively important buffering system** to be considered. The erythrocyte membrane is permeable to H^+ , and, therefore, H^+ can diffuse inside the cell, and **hemoglobin** can act as an intracellular buffer. Other buffering systems, such as **phosphate** and **circulating proteins**, can act as clinically relevant buffers as well (see Table 18.1).
- By quantitative chemistry, the **pH** of a system is dependent on the relative concentrations of the acids and conjugate bases of **all of the buffering systems** present. Clinically, we measure accurately the concentration of the acid (CO_2) and conjugate base (HCO_3^-) of **only one buffering system** while perturbations in the other buffering systems are not accounted for.
- Another major complicating factor is the fact that the human body is **not a closed system**. CO_2 is both continually being generated in the tissues and continually excreted through the respiratory system. Changes in CO_2 can occur very rapidly in humans as the respiratory rate increases or decreases. Additionally, the kidney can modulate the production of HCO_3^- to adjust the HCO_3^- concentration and the pH, albeit at a much slower pace than respiratory effects
- This means that the **concentration of the measured parameters** (HCO_3^- and PCO_2) are not just dependent on the **inciting insult**—the disease process—that caused them to change but on the body’s response to that change (i.e., **compensation**).

Base Excess and Standard Base Excess

- The change in pH of a system is dependent on both the amount of acid (or base) added to the system and the buffering capacity present in the system. As acid is added to a buffered solution, for every H^+ that is buffered, one molecule of conjugate base of the buffer is consumed.
- Therefore, assessing **changes in concentrations of the conjugate base** is more helpful than the degree of change in the pH in **quantifying** the degree of fixed acids present.
- The difficulty in describing the buffering system of a patient is the **inaccessibility** for measurement of a fair proportion of the buffers (see Table 18.1), especially **intracellular buffers**.
- **Base excess** has been proposed to quantify the degree of acid loading based on the change in body buffers. Siggaard–Andersen defined the **base excess** of blood as the **number of mEq of acid (or base) needed to titrate 1 L of blood to a pH of 7.4 at 37°C with a PCO_2 of 40 mm Hg**.
- The **standard base excess** is the base excess corrected for changes in hemoglobin, recalling that hemoglobin is an important intracellular buffer. The base excess can be

considered as a **measurement of the “metabolic portion” of an acid-base disturbance** as the concentration of CO_2 is being held constant at a normal level.

The Anion Gap

- The anion gap is calculated by taking the difference between the concentrations of the measured cations and the measured anion; it takes on a value of approximately **8 to 12 mEq/L** in healthy individuals.
- The anion gap is an indirect estimation of the amount of “**extra anions**” in the circulation. The anion gap reflects the serum albumin (negatively charged), phosphates, and other minor anions. The gain of acid is usually associated with the presence of an unmeasured anion. The **extra base** present leads to a greater difference between the measured anions and cations and, therefore, a **greater anion gap**.
- The anion gap is calculated using the following formula:

$$[\text{Na}^+] - ([\text{Cl}^-] + [\text{HCO}_3^-])$$

- There is a wide range for the normal anion gap. When interpreting the anion gap, caution must be exercised, as it can be influenced by many conditions other than metabolic acidosis.
- **Hypoalbuminemia** is the most common condition that affects the normal anion gap, as albumin normally contributes to the net negative charge of the blood. For every **1 mg/dL** fall in the plasma albumin concentration, the anion gap should decrease by approximately **3 mEq/L**.
- In plasma cell dyscrasias, such as **multiple myeloma**, the presence of cationic proteins (immunoglobulins) in the serum is a cause for falsely depressing the anion gap.
- Other conditions that decrease anion gap are **hypercalcemia** and **hyponatremia**.
- Conditions that have been noted to **increase the anion gap** in the absence of metabolic acidosis are renal failure, volume depletion, metabolic alkalosis, and some penicillins.
- Because of the wide variation in the anion gap and the variety of conditions that can affect it, it is best to **directly measure** “unmeasured anions” such as lactate or ketones whenever feasible.
- Metabolic acidosis is subdivided into **anion gap** and **non-anion gap** metabolic acidosis based on the value of the anion gap and to guide with the differential diagnosis.

Newer Models of Acid-base Quantification: Stewart Approach

- In the traditional model, acids behave as Brønsted/Lowry acids (i.e., proton donors), which causes a decrease in buffers. This is best approximated by the decrease in serum bicarbonate, but other unmeasured buffers, such as Hgb-H, are also decreased during acidosis.
- A nontraditional approach is the **Stewart model** that defines acids and bases differently. An acid is defined as any substance that **raises the $[\text{H}^+]$** of a solution, not necessarily limited to an H^+ -donating species.
- The most strikingly different concept of the Stewart model is that the serum bicarbonate is not used as the measure of

buffering capacity. This model uses the **strong ion difference** as a fundamental **measure of the presence of buffers**.

The Strong Ion Difference

- Strong ions (SIDs) are the ions in the blood that can be considered as **completely dissociated** in solution. The **SID is analogous to the buffer base of a solution**. The SID is calculated as follows:

$$[\text{SID}] = \{[\text{Na}^+] + [\text{K}^+]\} - \{[\text{Cl}^-] - [\text{lactate}]\}$$

- The remaining anions in solution are the buffers, which can be thought of as the bicarbonate plus the nonbicarbonate buffers, denoted $[\text{A}^-]$. $[\text{A}^-]$ is the sum of negative charge (buffering capacity) of albumin and phosphate.

$$[\text{SID}] = [\text{HCO}_3^-] + [\text{A}^-]$$

- The SID is considered more reflective of the concentrations of buffers and not only the serum bicarbonate.
- The Stewart equation describes the pH in terms of three independent variables: The SID, $[\text{A}_{\text{tot}}]$, and PCO_2 , where A_{tot} is the concentration of weak acids (see later). This is in contrast to the Henderson–Hasselbalch equation, which relates pH to $[\text{HCO}_3^-]$ and PCO_2 .
- The SID under normal conditions can be thought of as the sum of the buffer anions (bicarbonate and nonbicarbonate buffer anions) and should be about 40 mEq/L.
- A high SID denotes metabolic alkalosis, and a low SID denotes metabolic acidosis.
- The expected SID (SID_e) is the SID that would be predicted based on the pH, PCO_2 , and A_{tot} (in this case, A_{tot} is approximated based on the albumin and phosphate). This relationship is given below.

$$[\text{SID}_e] = (1,000 \times 2.46 \times 10^{-11} \times \text{PCO}_2 / 10^{-\text{pH}}) + [\text{albumin}] \times (0.123 \times \text{pH} - 0.631) + [\text{phosphate}] \times (0.309 \times \text{pH} - 0.469)$$

- The **apparent SID (SID_a)** is the strong ion difference that is normally present in the serum: Na^+ , K^+ , and Cl^- .

$$[\text{SID}_a] = \{[\text{Na}^+] + [\text{K}^+]\} - [\text{Cl}^-]$$

- When the SID_a and SID differ, there is a strong anion gap, which is described next.

Strong Ion Gap

- The strong ion gap (SIG) is as an evaluation of **unmeasured anions**, analogous to the traditional anion gap. The strong anion gap is **normally zero** and is defined as follows:

$$\text{SIG} = \text{anion gap} - [\text{A}^-]$$

where A^- is the composite of nonbicarbonate buffers in the blood. $[\text{A}^-] = 2.8$ (albumin in g/dL) + 0.6 (phosphate in mg/dL) at a pH of 7.4

$$\text{SIG} = [\text{SID}_e] - [\text{SID}_a]$$

- **SIG exceeding zero (high SIG)** signifies presence of **unmeasured anions**. This is analogous to the traditional anion gap,

with a correction factor for the presence of hypoalbuminemia. The traditional anion gap is rarely corrected for disturbances in phosphate although the contribution of deviations in phosphate is much smaller than that of albumin (see previous equation).

- A **low SID** is consistent with **metabolic acidosis**. The metabolic acidosis are **further subdivided** based on a **high SIG** (analogous in many ways to a high anion gap) and a **low SIG** (analogous to a low or normal anion gap). In this regard, the two approaches approximate each other. The use of the SIG may be advantageous over the use of the standard anion gap, given that the anion gap can have a wide range of values and is thus somewhat imprecise. This is especially true in settings where nonbicarbonate buffers deviate from normal—for example, the patient with acidosis, sepsis, and acute renal failure with serum albumin of 1.9, phosphorus of 7.0, and hemoglobin of 7.2 mg/dL. Clearly, in this extreme, the assumption that only changes in serum bicarbonate species reflect the metabolic component of the acidosis may not hold true.

Stewart versus Traditional Approach

- The advantage of the Stewart approach is that nonbicarbonate buffers are considered in quantifying acid-base disturbances.
- However, accurate quantification of acid-base status is only part of managing acid-base disturbances. Correctly diagnosing acid-base disorders and **treating** them appropriately is the **ultimate goal**; in this regard, we do not find considerable advantage of the Stewart approach over more traditional methodologies. It is important that the clinician understand the limitation of any of the acid-base models.

Volatile Acidity

- Volatile acidity plays a very important role in determining the systemic pH both in **primary respiratory disturbances** and in **compensation** to metabolic disturbances, as will be discussed
- Carbon dioxide is soluble in water and, in solution, reacts with water molecules to form carbonic acid, which can then further react as follows:

- **H₂CO₃** is the **acid portion** of the bicarbonate buffer; however, its concentration is **proportional to the partial pressure of CO₂**, and, therefore, its direct measurement of H₂CO₃ is not necessary. By the previous equilibrium expressions, a high PCO₂ will increase the concentration of H₂CO₃, and a low PCO₂ will decrease the concentration of H₂CO₃.
- The PCO₂ in the circulation is the sum of its production and excretion. The production of CO₂ is not frequently altered; however, the excretion of CO₂—occurring only through respiration—is variable based upon the minute ventilation.

Mechanisms of Compensation

- The buffering systems and respiratory compensation are very rapid, whereas renal compensation may take days.

- In response to systemic changes in pH, compensatory mechanisms act to counteract the primary disturbance (Fig. 18.2A and B) gives an overview of the compensatory responses to the primary acid-base disturbances.
- In response to **metabolic acidosis**, there is increased ventilation to decrease PCO₂; the kidney responds by increasing the excretion of H⁺, thereby generating more HCO₃[−] (see Fig. 18.2A). The opposite response occurs during **metabolic alkalosis**, except that the kidneys are usually not able to respond to the increase in HCO₃[−] appropriately, as failure of the kidney to respond to elevated HCO₃[−] is necessary for the development of metabolic alkalosis (this is described later).
- The response to **elevated PCO₂** (**respiratory acidosis**) is to increase the renal excretion of H⁺, which leads to increased HCO₃[−] production (see Fig. 18.2B)
- In response to **decreased PCO₂** (**respiratory alkalosis**), the excretion of H⁺ decreases, and less bicarbonate is produced, thereby decreasing serum bicarbonate. Only the chronic phase is depicted in Figure 18.2B.
- An important point is that a **compensatory response will never normalize the pH** or lead to a recovery of the pH past neutrality. If this has occurred, there must be another acid-base disturbance present.

Determining which Acid-base Disturbances Are Present

- The approach to acid-base disorders is summarized in Figures 18.3 and 18.4. A key is to identify **the primary disturbance**.
- Once the primary disturbance is identified, the next step is to **assess the adequacy of compensation**. Table 18.2 gives the expected values of PCO₂ and HCO₃[−] after compensations for primary disturbances.
- In the setting of **respiratory disorders**, **acute compensation occurs over hours**, whereas the **chronic compensation occurs over days**.
- If there is only **one disturbance**, the **compensation is adequate**.
- If the compensation is inappropriate (patient has a derangement that is not all explained by compensation), a **second disorder is present**.
- Recall that a compensation will never normalize the pH or “compensate” past the point of neutrality. In these cases, a mixed acid-base disorder is present.
- An additional clue that a mixed acid-base disorder is present is an elevated anion gap when a metabolic acidosis is not suspected. For this reason, it is good practice to **calculate the anion gap** in all critically ill patients.

METABOLIC ACIDOSIS

Causes of Anion Gap Acidosis

- The common etiologies of elevated anion gap metabolic acidosis are listed in Table 18.3.

Diabetic Ketoacidosis

- Diabetic ketoacidosis occurs when a deficit of insulin activity leads to altered cellular metabolism and glucose utilization

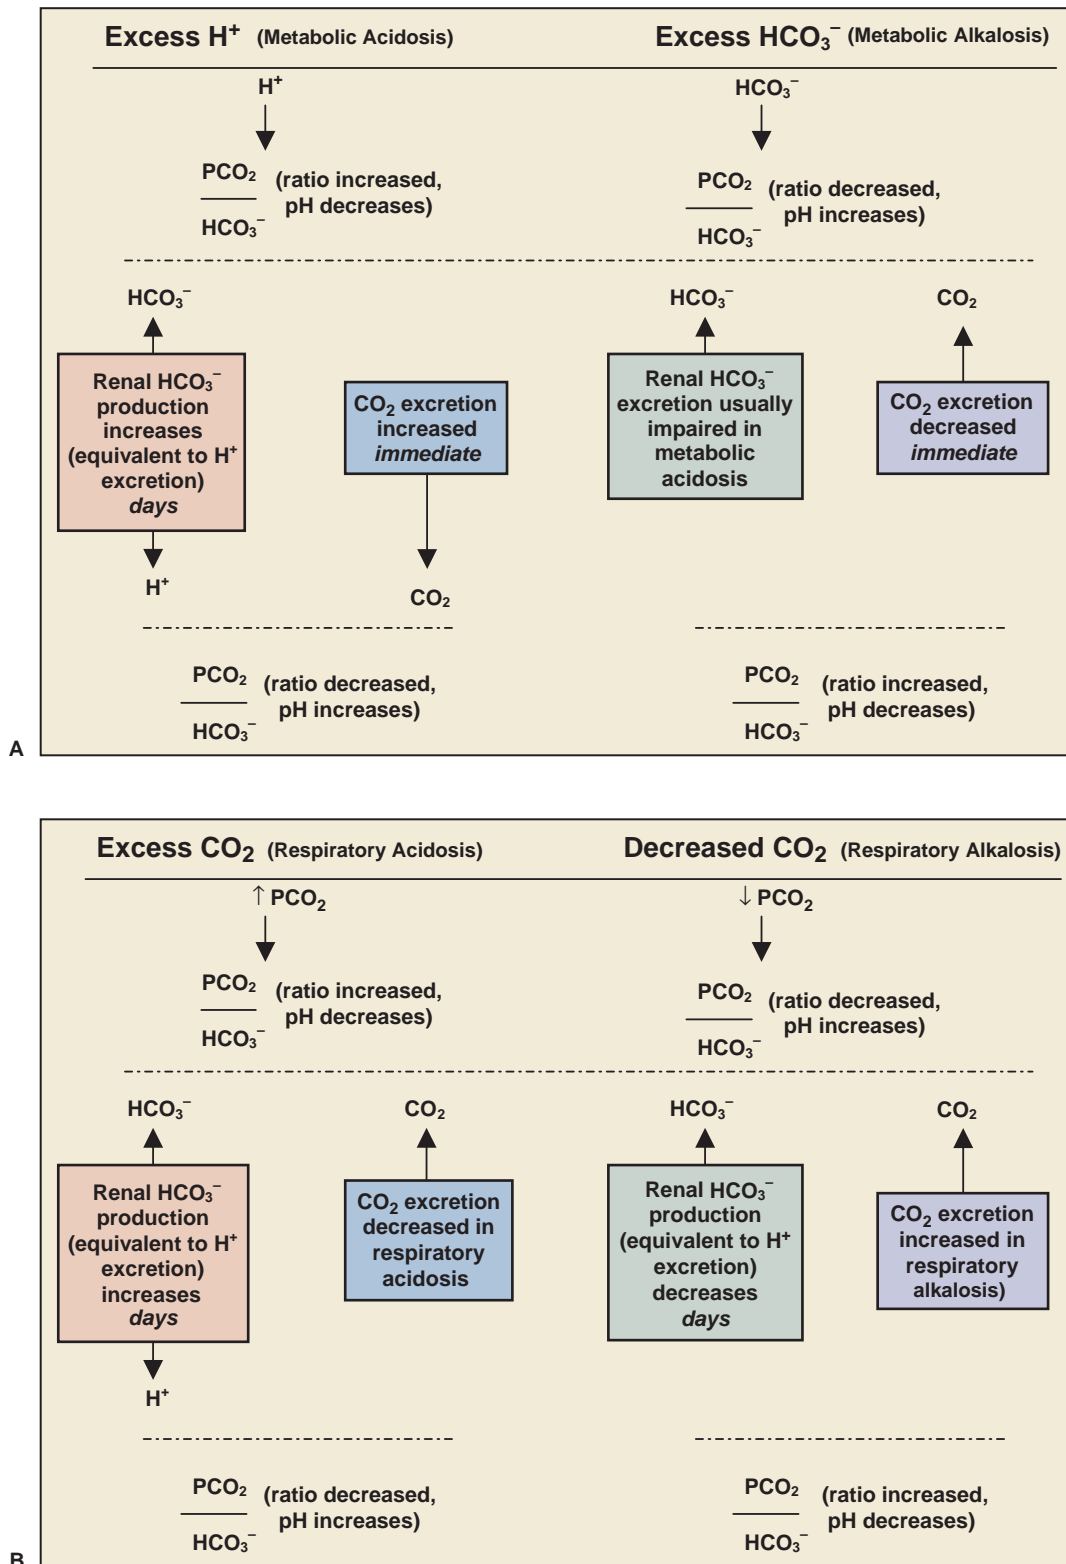

FIGURE 18.2. A: Primary metabolic acid-base disturbances and compensatory mechanisms. B: Primary respiratory acid-base disturbances and compensatory mechanisms.

Approach to the Critically Ill Patient with an Acid-base Disorder

The first step is to determine which acid-base disorder(s) are present, the cause of each disorder, and the degree of compensation. There are four important variables to look at when determining the acid-base status of a patient and these should be evaluated in all critically ill patients:

- Arterial pH: This is always the starting point. Avoid making judgments in the absence of a measured arterial pH. The pH is the negative logarithm of the concentration of H^+ and the physiologic range for this value is 7.38 to 7.44
- Arterial PCO_2 : Indicates the amount of volatile acidity. The PCO_2 generally reflects the respiratory response or contribution to the acid-base disorder.
- Serum bicarbonate: Indicative of the degree of fixed acids present (lower means more fixed acids present). Normal value is 24 mEq/L.
- Serum anion gap ($= [Na^+] - ([Cl^-] + [HCO_3^-])$): A measure of conjugate bases (anions) present above what is expected under "normal" conditions. Has a wide variability, normal is usually between 8 and 12 mEq/L.

FIGURE 18.3. Approach to the critically ill patient with an acid-base disorder.

is impaired. The deficiency of insulin causes the **liberation of fatty acids** and pathophysiologic **keto acid** production.

- A decrease in circulatory volume, deficits in free water, with concurrent hypokalemia and hypophosphatemia may occur. Even though total body **potassium stores are decreased**, the **serum potassium** concentration is frequently **elevated** on presentation owing to the effects of insulin deficiency, hyperglycemia, and acidosis on potassium distribution.
- Treatment of diabetic ketoacidosis includes re-expansion of the extracellular **fluid volume**, administration of insulin to halt acid production, and correction of **potassium** and **phosphorus** deficits, with close monitoring of plasma electrolytes.
- Too-rapid correction of blood glucose may lead to cerebral edema.

Lactic Acidosis

- There are two types of lactic acidosis:
 - **Type A lactic acidosis** is due to **tissue hypoxia** and the formation of excess lactic acid, a by-product of anaerobic

cellular metabolism. This is frequently seen in sepsis, profound anemia, shock, hypotension, and bowel and limb ischemia. Carbon monoxide poisoning can present with nonspecific symptoms and lead to lactic acidosis by inhibiting oxygen utilization in the tissues.

- Type A lactic acidosis is often associated with **poor outcomes** if the cause is not quickly reversed.
- **Type B lactic acidosis** occurs when there is insufficient liver metabolism of lactate. The normal metabolism of lactate leads to the generation of bicarbonate, which is compromised in severe liver disease. Several commonly used **medications** have been associated with lactic acidosis including propofol, metformin, the nonnucleotide reverse transcriptase inhibitors, stavudine, didanosine, and zidovudine.

Toxic Ingestions Associated with Elevated Anion Gap Acidosis

- Ingestions are important causes of acidosis in the critical care setting and are listed in Table 18.3

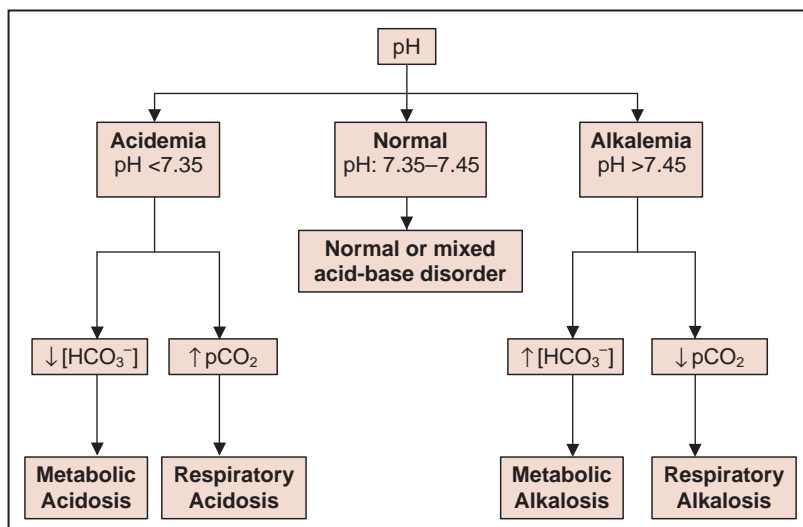

FIGURE 18.4. General approach to acid-base disorders. (From Ayus JC. MKSAP 14, 2006, Nephrology Section. Medical Knowledge Self Assessment Program. American College of Physicians; 2006. Copyrighted by the American College of Physicians.)

TABLE 18.2

COMPENSATIONS FOR ACID-BASE DISORDERS

Metabolic acidosis	<ul style="list-style-type: none"> For every 1 mmol/L decrease in $\text{HCO}_3^- \rightarrow$ 1 mm Hg decrease in PCO_2 Expected $\text{PCO}_2 = 1.5 (\text{HCO}_3^-) + 8 \pm 2$ PCO_2 should approach last two digits of pH
Metabolic alkalosis	<ul style="list-style-type: none"> For every 1 mmol/L increase in $\text{HCO}_3^- \rightarrow$ 0.7 mm Hg increase in PCO_2
Respiratory acidosis	<ul style="list-style-type: none"> Acute: For 10 mm Hg increase in $\text{PCO}_2 \rightarrow$ 1 mmol/L increase in HCO_3^- Chronic: For 10 mm Hg increase in $\text{PCO}_2 \rightarrow$ 4 mmol/L increase in HCO_3^-
Respiratory alkalosis	<ul style="list-style-type: none"> Acute: For every 10 mm Hg decrease in $\text{PCO}_2 \rightarrow$ 2 mmol/L decrease in HCO_3^- Chronic: For every 10 mm Hg decrease in $\text{PCO}_2 \rightarrow$ 4 mmol/L decrease in HCO_3^-

- The presence of ingested alcohols or other solvents can be inferred by measurement of the **osmolal gap** calculated as follows:

(Measured serum osmolality) – (Calculated serum osmolality)

where the calculated serum osmolality is obtained as follows:

$$2 \times [\text{Na}^+](\text{mEq/L}) + \text{Urea nitrogen (mg/dL)}/2.8 \\ + \text{Glucose (mg/dL)}/18$$

- The osmolal gap is normally approximately **10 mOsm/kg H_2O** . The normal osmolal gap is a reflection of substances normally present in the serum that exert oncotic forces. These are plasma proteins and ions found in smaller quantities, such as calcium and magnesium.
- An **elevated osmolal gap** is an indication that an **unmeasured osmole** is present and can be used to quantify the level of ethylene glycol or methanol, although direct measurement of these toxins is indicated if their presence is suspected. Therapy should not be delayed while waiting for results.

Renal Failure

- Renal failure can run the spectrum of causing either anion gap or non-anion gap acidosis.
- Usually associated with mixed type of metabolic acidosis, and glomerular filtration rate of <20 mL/minute, anion gap is caused by elevation in organic acids.

TABLE 18.3

COMMON CAUSES OF ELEVATED ANION GAP METABOLIC ACIDOSIS

--

Causes of Non-anion Gap Acidosis

- There is a primary **decrease in the serum bicarbonate** and an associated **increase in the serum chloride** (Table 18.4).

Gastrointestinal Loss below the Stomach

- Diarrhea:** There is **loss of bicarbonate** via the intestinal tract, and is typically associated with volume depletion and hypokalemia. In very severe cases, circulatory collapse can occur, and an anion gap (lactic) acidosis may supervene upon the non-anion gap acidosis.
- Pancreatic or biliary fistula:** These disorders can lead to the loss of bicarbonate-rich solutions and, if correction of the underlying fistula is not possible, treatment with alkali salts may be needed.

Ureterointestinal Diversions

- In a ureterointestinal diversion, urine in the intestine leads to reabsorption of chloride and water. Consequently, the absorption of chloride can induce secretion of bicarbonate into the intestine. Additionally, urease-positive bacteria in the intestine metabolizes the urea in the urine to form ammonium that, when absorbed, liberates excess acid after it is metabolized in the liver. Also, chronic pyelonephritis is common in the diverted kidney, and a superimposed distal renal tubular acidosis (RTA) may occur.

Renal Causes

- One of the key etiologic questions is whether the kidney is appropriately responding to the acidosis by excreting the acid load or whether the cause of the acidosis is improper acid excretion by the kidney. This allows one to differentiate **renal from nonrenal** causes of the acidosis. The **urine anion gap** is a convenient method to assess urinary acid excretion.
- $[\text{Na}^+] + [\text{K}^+] - [\text{Cl}^-] = \text{urinary anion gap}$.
- If the **urine anion gap is positive or close to zero**, this suggests that (a) there is very little ammonium in the urine and the **kidney is not appropriately excreting acids**. If the **urine anion gap is highly negative**, this suggests that (b) there is a large amount of ammonium in the urine and the **kidney is excreting acids** appropriately.

Renal Tubular Acidosis

- Renal tubular acidosis (RTA) is a heterogeneous mix of disorders that is characterized by defects in urinary acid excretion in the setting of intact renal function. **Proximal (type 2)** RTA is caused by a decrease in proximal bicarbonate

TABLE 18.4

ETIOLOGIES OF NON-ANION GAP METABOLIC ACIDOSIS

Extrarenal source	Renal source
Gastrointestinal disorders <ul style="list-style-type: none"> Diarrhea Pancreatic and biliary fistulas Laxatives, cholestyramine Ureterointestinal diversions (ileal conduit) 	<ul style="list-style-type: none"> Renal tubular acidosis Renal failure Hypoaldosteronism

reabsorption. **Distal (type 1) RTA** is caused by impairment of distal acidification.

- **RTA often presents with profound acidosis and hypokalemia.** It is important to treat the hypokalemia first with potassium chloride before correcting the acidosis, as administration of bicarbonate in the setting of severe potassium depletion can lead to fatal hypokalemia as potassium is taken up by cells when H^+ exits the cells.
- **Type 4 RTA** is a clinical syndrome of hyperkalemia and hyperchloremic metabolic acidosis caused by a **lack of aldosterone effect** on the kidney and is seen most commonly in the following settings: diabetes, advanced age, acquired immunodeficiency syndrome, interstitial nephritis, obstructive uropathy, postrenal transplant status, use of angiotensin-converting enzyme inhibitors and heparin (both of which impair aldosterone production), and use of cyclosporine.
- RTA should be suspected if the renal response to systemic acidemia is impaired as evidenced by a **positive urine anion gap**.
- The next step is to **determine the type**. The most practical starting point is to differentiate a **proximal from a distal RTA**. Proximal RTA demonstrates lack of bicarbonate reabsorption with wasting of bicarbonate in the urine until a steady state is reached in which the serum bicarbonate drops to a level at which the reabsorptive capacity of the proximal tubule is no longer overwhelmed. At this point, there is **no longer any bicarbonate in the urine**. For this reason, in a patient with proximal RTA, the **serum bicarbonate will be low**; however, the **urine pH will be low**—this is because the distal acidification mechanisms are functional. If such a patient is given an alkali load, serum bicarbonate is temporarily increased, and bicarbonate “spills” into the urine because the filtered load of bicarbonate exceeds the reabsorptive threshold, which leads to an **increase in the urine pH**. Once the alkali load is stopped, serum bicarbonate drops, bicarbonate no longer appears in the urine, and the urine pH can now drop to its maximally acidic level of approximately 5.5. This is the basis for the **provocative testing** to demonstrate a **proximal RTA**, and also explains why these patients often require a tremendous amount of alkali to achieve normal serum pH.
- **Hypoaldosteronism:** Similar to type 4 RTA acidosis, hypoaldosteronism can lead to excretion of sodium and absorption of K^+ and H^+ , leading to metabolic acidosis.
- **Renal failure:** The kidneys have the capacity to excrete acids until kidney function deteriorates to below a glomerular filtration rate of approximately 20 mL/minute. The resulting acidosis is of a mixed type, and it is generally associated with an elevated anion gap. Chronic metabolic acidosis should be treated to prevent bone demineralization, which may occur with time. The goal of treatment is to maintain normal acid-base status.

Treatment of Metabolic Acidosis

Treatment of Anion Gap Metabolic Acidosis

- The treatment is focused on reversing the pathogenesis of the endogenous acid production and eliminating excess acid.
- Treatment with **bicarbonate** replacement therapy remains **controversial**, especially in lactic acidosis. The approach of using alkali therapy assumes that there is a detriment to a low pH (or serum bicarbonate) above and beyond the harm

caused by the underlying condition. Bicarbonate may lead to the generation of CO_2 during buffering and, as CO_2 readily diffuses across cell membranes, intracellular acidosis has been shown to worsen.

Treatment of Non-anion Gap Metabolic Acidosis

- Bicarbonate therapy is generally indicated in non-anion gap acidosis as the primary disturbance is a decrease in bicarbonate. This is contrasted to anion gap acidosis where correction of the underlying cause is the primary concern. Oral bicarbonate or oral citrate solutions are agents for chronic therapy for non-anion gap acidosis. For acute presentations, especially in patients who may not be able to tolerate prolonged hyperventilation, intravenous bicarbonate therapy may be used.

Medications and Metabolic Acidosis

- **Lactic acidosis** has been reported with all **nonnucleoside reverse transcriptase inhibitors** used to treat human immunodeficiency virus; this effect is related to the drug's inhibition of mitochondrial function, with resultant anaerobic metabolism. The newer-generation anticonvulsant **topiramate** and antiglycemic agent **metformin** may cause a metabolic acidosis. The propofol infusion syndrome is a dangerous complication sometimes seen with the use of this drug and associated with head injury, use of propofol for more than 48 hours, use in children, and concomitant use of catecholamines and steroids.

METABOLIC ALKALOSIS

- **Metabolic alkalosis occurs when there is an excess of buffers present, raising the systemic pH** and serum bicarbonate. Without an impairment of the renal capacity to excrete bicarbonate, the kidneys would simply excrete the bicarbonate load. The most common reason for **impairment of renal excretion of bicarbonate** is **chloride deficiency and renal failure**.
- In general, metabolic alkaloses are generated by either **bicarbonate intake** in excess of loss or by the primary loss of H^+ .

“Chloride-sensitive or Responsive” Metabolic Alkalosis

- The **hallmark** is **spot urine $Cl^- < 20$ mEq/L**.
- The key factors are **hypovolemia** (also called **contraction alkalosis**) and/or **Cl^- deficiency** resulting in **active sodium-bicarbonate absorption and excretion of H^+** by the kidneys from the effects of secondary hyperaldosteronism.
- **Nasogastric suction, vomiting, and diuretics** are very frequent causes of metabolic alkalosis. Volume depletion stimulates **aldosterone** secretion enhancing sodium reabsorption in the distal tubule, which is coupled with secretion of potassium and H^+ . Therefore, a urine that is paradoxically acidic is generated despite alkalemia.
- Hypokalemia develops in the setting of vomiting or nasogastric suction not due to gastrointestinal losses (as the stomach contents are not rich in potassium) but through **renal losses** due to potassium bicarbonate excretion and secondary hyperaldosteronism. In these settings, renal losses of sodium and potassium are obligatory to excrete bicarbonate. In this situation, the **urinary chloride** (not the urinary sodium) better reflects the **effective blood volume** of the patient.

"Chloride-insensitive or Unresponsive" Metabolic Alkalosis

- The **hallmark** is spot urine chloride >40 mEq/L.
- A common etiology is the use of **loop diuretics** (furosemide) that inhibits the sodium-potassium-chloride cotransporter in the thick ascending limb. This increases distal tubular sodium concentration and stimulates the aldosterone-sensitive sodium pump to increase sodium resorption in exchange for K^+ and H^+ . Loss of H^+ and K^+ will result in metabolic alkalosis. Excessive use of diuretics may result in hypovolemia and contraction alkalosis (i.e., chloride-sensitive metabolic alkalosis).
- Other causes of chloride-insensitive metabolic alkalosis are **hyperaldosteronism**—both primary and secondary—such as might be seen with renovascular disease and **mineralocorticoid (steroid)** use. Rare causes of chloride-insensitive metabolic alkalosis are Bartter and Gitelman syndromes.

Renal and Extrarenal Compensation

- Respiratory compensation for a metabolic alkalosis involves respiratory suppression and an increase in the PCO_2 (see Fig. 18.2A and Table 18.2).
- Respiratory compensation for severe metabolic alkalosis has practical limits, as respirations can be suppressed only to a certain degree.

Treatment of Metabolic Alkalosis (Table 18.5)

- In patients with chloride-sensitive metabolic alkalosis, treatment usually consists of **replacing volume and chloride**—usually with **normal saline**.
- **Potassium chloride** is almost always indicated when hypokalemia is also present, although potassium concentrations may increase as the alkalosis is corrected.
- **Carbonic anhydrase inhibitors** may be used if one is confident that patient is not hypovolemic, K^+ has been replaced, has adequate renal function, and does not have a sulfa allergy.
- In severe, symptomatic metabolic alkalosis—a $pH >7.6$ **hemodialysis**—may be indicated and can be used to correct alkalemia, especially when associated with renal failure. The use of **acidic solutions** is rarely indicated.

TABLE 18.5

TREATMENT OF METABOLIC ALKALOSIS

Chloride resistant	<ul style="list-style-type: none"> • Remove offending agent • Replace potassium if deficient
Extreme alkalosis	<ul style="list-style-type: none"> • Hemodialysis • NH_4Cl or HCl can also be used

RESPIRATORY ACID-BASE DISORDERS

- Approximately 15,000 mmol/day of CO_2 is produced.
- Carbon dioxide enters the plasma and forms carbonic acid, which subsequently dissociates to **bicarbonate and H^+** . The bulk of this CO_2 generated is transported to the lungs in the **form of bicarbonate**. The H^+ produced in the process is exchanged across the erythrocyte cell membrane and is buffered intracellularly.
- In the alveoli, this process is reversed, and the **bicarbonate combines with H^+ , liberating CO_2** , which is then excreted through respiration.
- Carbon dioxide is the **main stimulus for respiration**, which is activated by small elevations in the PCO_2 .
- Hypoxia is a minor stimulus for respiration and is typically effective when the PO_2 is in the range of 50 to 55 mm Hg.
- Derangements in respiratory CO_2 excretion lead to alterations in the ratio of PCO_2 to bicarbonate in the serum and, therefore, alter systemic pH (Henderson–Hasselbalch relationship).

Respiratory Acidosis

- Respiratory acidosis results from the primary retention of carbon dioxide (in relationship to CO_2 production).
- The common etiologies of respiratory acidosis are listed in Table 18.6.

TABLE 18.6

CAUSES OF RESPIRATORY ACIDOSIS

Airway obstruction	<ul style="list-style-type: none"> • Foreign body, aspiration • Obstructive sleep apnea • Laryngospasm or bronchospasm

Chronic	<ul style="list-style-type: none"> • Morbid obesity (aka Pickwickian syndrome) • Central sleep apnea
Central respiratory depression	<ul style="list-style-type: none"> • Drugs (opiates, sedatives), anesthetics • Oxygen administration in acute hypercapnia • Brain trauma or stroke
Respirator disorders	
Acute	<ul style="list-style-type: none"> • Severe pulmonary edema • Asthma or pneumonia • Acute respiratory distress syndrome
Chronic	<ul style="list-style-type: none"> • Chronic obstructive pulmonary disorder • Pulmonary fibrosis • Chronic pneumonitis

- In respiratory acidosis, the extracellular buffering capacity is severely limited because bicarbonate cannot buffer carbonic acid. Intracellular buffers—**hemoglobin and other intracellular proteins**—serve as the protection against acute rises in PCO_2 , and buffering occurs within 10 to 15 minutes.
- **Renal compensation** occurs and stimulates secretion of protons in the distal nephron-enhanced reabsorption of bicarbonate. Full compensation may take 3 to 4 days (see Table 18.2).
- An increase in **alveolar ventilation** is ultimately required to eliminate excess CO_2 and therefore to re-establish equilibrium
- After sustained hypercapnia that has elicited an appropriate renal response (i.e., a compensatory increase in serum bicarbonate), bicarbonaturia accompanies the return of the PCO_2 to normal. **Chloride intake** must be sufficient to replenish the deficit that developed during the renal compensation to the chronic respiratory acidosis, which induces a negative chloride balance. If chloride is deficient, the serum bicarbonate will remain persistently elevated, a phenomenon termed **posthypercapnic metabolic alkalosis**.
- **Clinical presentation:** Acute respiratory acidosis can produce headaches, confusion, irritability, anxiety, and insomnia, although the symptoms are difficult to separate from concomitant hypoxemia. Symptoms may progress to asterixis, delirium, and somnolence. The severity of the clinical presentation correlates more closely with the **rapidity** of the development of the disturbance rather than the absolute PCO_2 level.

Treatment

- An increase in **effective alveolar ventilation** is necessary through either reversal of the underlying cause or, if necessary, mechanical ventilation.
- The administration of bicarbonate in respiratory acidosis when a coexisting metabolic acidosis is not present is potentially harmful.
- During chronic respiratory acidosis, renal compensation leads to a near-normalization of the arterial pH. The objective is to ensure adequate oxygenation and, if possible, to increase alveolar ventilation. The administration of excessive oxygen and use of sedatives should be avoided because these treatments can depress the respiratory drive.
- Mechanical ventilation may be indicated when there is an acute exacerbation of chronic hypercapnia. If mechanical ventilation is used, the PCO_2 should be **decreased gradually**, avoiding precipitous drops, as rapid correction may cause severe alkalemia. Also, this may increase the cerebrospinal fluid pH, because carbon dioxide rapidly equilibrates across the blood-cerebrospinal fluid barrier. This complication can lead to serious neurologic problems, including seizures and death.
- **Permissive hypercapnia:** It has been shown that ventilator strategies to reduce tidal volume and decrease stretch trauma will reduce ventilator-associated lung injury and improve outcomes. Further studies will be needed to delineate the specific role of respiratory acidosis with or without buffering in the management of acute lung injury, cardiac function, and outcomes.

Respiratory Alkalosis

- Respiratory alkalosis is due to a primary increase in ventilation or decrease in CO_2 production.

- The lowered PCO_2 in turn reduces carbonic acid levels, which decreases systemic pH. Proteins, phosphates, and hemoglobin liberate H^+ . These liberated protons subsequently react with bicarbonate to form carbonic acid. At the level of the erythrocyte, a shift of chloride to the extracellular compartment ensues, as bicarbonate and cations enter in exchange for protons.
- The net effect results in a **2-mEq/L decrease** in the serum bicarbonate for every **10 mm Hg decrease** in the PCO_2 that occurs in the **acute** setting (see Table 18.2).
- Persistent respiratory alkalemia elicits a renal response, which leads to a net decrease in the secretion of H^+ . The kidneys decrease proximal reabsorption of bicarbonate and a decrease in the excretion of titratable acids and of ammonium. This compensatory response reaches peak in 3 to 4 days.
- **Clinical presentation:** Respiratory alkalosis may lead to a wide range of clinical manifestations ranging from alteration in consciousness, perioral paresthesias, muscle spasms, coronary and cerebral vasoconstriction, cardiac arrhythmias, and bronchoconstriction.
- In addition, alkalemia also can affect metabolism of divalent ions. By stimulating **glycolysis**, alkalemia causes phosphate to shift from the extracellular space into the intracellular compartment as glucose-6-phosphate is formed. **Ionized calcium** may decrease due to increased binding of calcium to albumin.
- Shifting of the O_2 dissociation curve to the left may impair unloading of O_2 to the tissues.

Treatment

- The underlying cause for respiratory alkalosis should be sought in order to tailor the treatment (Table 18.7).
- **Cirrhosis** can lead to respiratory alkalosis through impaired clearance from the circulation of progesterones and estrogens, similar to pregnancy.
- In **psychogenic hyperventilation**, rebreathing air using a bag increases the systemic PCO_2 and can treat alkalemia. Specific therapy, other than treatment of the underlying cause, is typically not necessary.

TABLE 18.7

CAUSES OF RESPIRATORY ALKALOSIS

Hypoxia	<ul style="list-style-type: none"> • High altitude • Congestive heart failure • Severe V/Q mismatch
Lung diseases	<ul style="list-style-type: none"> • Pulmonary fibrosis • Pulmonary edema • Pneumonia • Pulmonary embolism
Drugs	<ul style="list-style-type: none"> • Salicylates • Progesterone • Nicotine

APPROACH TO ACID-BASE DISORDERS

- There is no simple algorithm to use in the approach to an acid-base disorder. Complex acid-base problems should be suspected when the values cannot be explained by a **single disorder and its compensation**. An example of this might be a patient with lactic acidosis and an alkaline pH.
- Start with the pH value to determine the primary disturbance.
- Assess the compensatory response using clinical judgment whether this is “acute” or “chronic.”
- A mixed acid-base disorder should always be suspected if the pH is normal or the “compensation” has surpassed the normal pH.
- Mixed metabolic and respiratory acidosis occurs when the respiratory compensation is insufficient for the degree of decrease in bicarbonate.
- The presence of an increased anion gap despite normal serum bicarbonate levels should raise suspicion for mixed metabolic acidosis and metabolic alkalosis.
- Non-anion gap metabolic acidosis and anion gap metabolic acidosis can coexist.
- After the differential diagnosis of each disturbance, ask whether the disturbance needs to be treated.
- Administer treatment with close observation of electrolytes, fluid status, and acid-base status.

SECTION V ■ MODULATING THE RESPONSE TO INJURY

CHAPTER 19 ■ THE HOST RESPONSE TO INJURY AND CRITICAL ILLNESS

INITIAL THOUGHTS

- The stress response
 - Biphasic physiologic response
 - When uninterrupted by complications, has predictable characteristics
 - Lasts 7 to 10 days (Fig. 19.1)
 - Initiated by a global depression of energy expenditure and metabolism.
 - A 24-hour phase immediately following injury
 - Followed by a period of hypermetabolism that persists 5 to 7 days
 - Driving force lies with the need to mount an immune or inflammatory response to combat infection and facilitate repair
 - Most markers for ongoing inflammation/metabolism peak post injury day 2 and return to baseline around day 7.
 - These events must take place or the organism will not survive.
 - Normal stress response may be altered by coexisting disease or interrupted by adverse events.
 - Recurrent bleeding
 - Systemic inflammatory response syndrome (SIRS)
 - Progression of SIRS to sepsis
 - Organism may then enter a state of persistent hypermetabolism.
 - Continued inflammation postulated to lead to organ dysfunction and immune incompetence (Fig. 19.2)
 - Onset of immune incompetence marks transition from hyperfunctional to hypofunctional state: most ICU deaths result from this.

FIGURE 19.1. The stress response. (Reprinted with permission from Kohl BA, Deutschman CS. The inflammatory response to surgery and trauma. *Curr Opin Crit Care*. 2006;12(4):325–332.)

- Patients at higher risk for nosocomial infections.
- Demonstrates pervasive endocrinopathy (Fig. 19.3)

THE NORMAL STRESS RESPONSE

- Prolonged immobilization post injury
 - Urinary excretion of sulfur, nitrogen, phosphorus, and calcium elevated
 - Body temperature follows characteristic pattern (Fig. 19.1).
 - First 24 hours following injury, temperature decreases
 - The temperature then rises, peaking post injury day 3 and returning to baseline by post injury day 7
 - Temperature change correlates with alterations in O₂ consumption and CO₂ production.
 - Paradigm by which the body responds to injury
 - Not immediate fatal damage
 - Compensatory reaction—vasoconstriction shunts blood away from periphery and to central organs, notably heart and brain.
 - Promotes short-term survival
 - Hypothermia and oliguria associated with global decrease in oxygen consumption and energy expenditure
 - Termed the “ebb” phase of traumatic shock
 - When clear death not imminent, a second aspect of response emerges
 - Attempt to repair tissue damage
 - Accomplished by the activity of WBCs
 - Neutrophils react first, followed by macrophages
 - Characterized by phagocytosis and lysis of bacterial, viral, or fungal invaders and removal of cellular debris

FIGURE 19.2. Continued inflammation, which has been postulated to lead to organ dysfunction and immune incompetence. SIRS, systemic inflammatory response syndrome; MODS, multiple organ dysfunction syndrome.

FIGURE 19.3. The onset of immune incompetence marks a transition from a hyperfunctional to a hypofunctional state in which patients are at higher risks for nosocomial infections and demonstrate a pervasive endocrinopathy. SIRS, systemic inflammatory response syndrome; MODS, multiple organ dysfunction syndrome.

- Cytokines—secreted by macrophages, lymphocytes, and antigen-presenting cells (APCs)
- Growth factors that facilitate repair of damaged tissue
- Process requires enormous amounts of energy, with a 2- to 20-fold increase in O_2 consumption and resting energy expenditure (REE)
- Body temperature rises, O_2 consumption and CO_2 production increase
- Associated increase in glucose requirements
- After first 24 hours, hepatic glycogen stores get depleted
 - Glucose is further generated by hepatic gluconeogenesis—breaking down protein
- Due to thrombosis in damaged tissue, most injured areas are avascular.
 - Substrate delivery to these regions
 - Requires capillary tight junctions to separate
 - This allows fluid and substrate to “leak” from the vasculature
 - Increased vascular permeability
 - Results in redistribution of extracellular fluid and plasma proteins to form edema and exudate
 - Causes glucose/other nutrients to
 - Move down concentration gradients across the extracellular matrix to areas of damage
 - This part of the response is the “flow” phase
- Initiation of the flow phase is partly hormonally modulated
 - Results in initial dramatic release of endogenous catecholamines
 - Supplemented by alterations in growth hormone and insulin-like growth factor
 - Causes suppression of thyroid and gonadal axes
 - ACTH secretion heightened
 - Increased corticotropin-releasing hormone
 - Arginine vasopressin (AVP)
 - Catecholamines
 - Angiotensin II
 - Serotonin
 - Some inflammatory cytokines (interleukin [IL]-1, IL-2, IL-6, and tumor necrosis factor [TNF])

- ACTH stimulates adrenal production of glucocorticoids and mineralocorticoids
 - Glucocorticoids/glucagon promote gluconeogenesis, glycogenolysis, and induce peripheral insulin resistance
 - Leads to increased glucose production
 - In turn, increases insulin secretion, producing an “insulin-resistant” state
- Tissue repair initiated by these activities
 - Fibroblasts at edge of wound divide, migrate toward center, and produce collagen,
 - Surviving capillaries bud, and new capillaries also migrate toward center.
 - Wound edges fuse and consist of vascularized granulation tissue.
 - Mediated by increased fibroblast growth factors, epidermal growth factor, platelet-derived growth factor, and vascular endothelial growth factor

DEVIATION FROM THE NORMAL STRESS RESPONSE

- Aspects of the process may become excessive or unbalanced.
 - Converts adaptive response to pathologic one
 - Risk factors that predispose to the development of an abnormal response include:
 - Inadequate or delayed resuscitation
 - Persistent inflammatory or infectious sources
 - Baseline organ dysfunction
 - Age more than 65 years
 - Immunosuppression
 - Alcohol abuse
 - Malnutrition
 - Invasive instrumentation
- Two common occurrences in surgical/trauma population
 - Hemorrhage, uncorrected fluid loss, or under-resuscitation
 - Results in recurrence of shock, vasoconstriction, decreased perfusion and cardiac output, and impaired tissue substrate delivery
 - Treatment
 - Identification and treatment of underlying cause and correction of fluid imbalance
 - Prolonged hypermetabolism
 - Persistence of a hyperdynamic circulation and secretion of immunologic markers
 - Elevation of serum potassium, magnesium, phosphate, and marginal urine output
 - Indicate prolonged/renewed stress response and warn of a new or recurrent abnormality
 - Commonly referred to as SIRS
 - If SIRS suspected to be from infectious cause
 - Condition referred to as *sepsis* or *sepsis syndrome*
 - Initially, normal stress response, SIRS, and sepsis may mimic each other
 - Differentiation lies in time course and etiology of metabolic perturbations (Table 19.1)
- Sepsis
 - Most common cause of death in noncardiac intensive care units
 - Increasing use of broad-spectrum antibiotics, immunosuppression, and invasive technology may be responsible

TABLE 19.1**DIAGNOSTIC CRITERIA FOR SEPSIS IN ADULTS****Suspected or documented infection****General variables**Fever ($T > 38.3^{\circ}\text{C}$)Hypothermia ($T < 36^{\circ}\text{C}$)Heart rate (> 90 bpm or > 2 SDs above normal for age)

From Levy MM, Fink MP, Marshall JC, et al. 2001 SCCM/ESICM/ACCP/ATS/SIS international sepsis definitions conference. *Crit Care Med.* 2003;31(4):1250–1256.

- Incidence of sepsis in United States estimated as 240 to 300 cases of severe sepsis per 100,000 people
 - Increased from 74 cases per 100,000 people in 1979
- Mortality rate:
 - Is 17.9% for sepsis
 - Is 28.6% for severe sepsis
 - Up to 50% in those with septic shock and comorbid conditions
- Etiology of sepsis has changed over time
 - In 1970s and 1980s, gram-negative bacteria were predominant.
 - Gram-positive organisms are now the leading pathogens
 - Fungal organisms are also on the rise.
- Likely predisposes to organ dysfunction
 - When overt, process is referred to as *multiple organ dysfunction syndrome (MODS)*.

- Abnormalities in MODS seem confined to cellular and organ dysfunction as histology and infrastructure are preserved.
- Most proximal defect identified to date in SIRS/sepsis/MODS is abnormality of oxygen utilization at subcellular level.
- Two theories to explain this advanced
 - First, impairment of microcirculatory autoregulation
 - Second, adequate perfusion but an alteration in cellular metabolism with an inability to extract and use oxygen
 - Supported by studies demonstrating defect in mitochondrial function
 - In either case, the result is a block in cellular metabolism with inability of cells and organs to respond to external stimuli.
 - Progressive loss of hormonal responsiveness
 - Liver becomes unresponsive to insulin and glucagons.
 - Cardiovascular system becomes less responsive to catecholamines
- Thus, the hyperfunctional state cannot be maintained.
 - Acute lung injury progresses to acute respiratory distress syndrome.
 - Hypotension from vasoplegia is compounded by cardiac dysfunction that requires vasopressors and inotropic and chronotropic support.
 - Renal function decreases to a point that renal replacement therapy must be considered.
 - Hepatic dysfunction results in severe ascites and coagulopathy, and potentially profound encephalopathy.
 - Immune incompetence coupled with a pervasive endocrinopathy places patient at higher risk for nosocomial infections.
 - In this state, most deaths from sepsis occur.
- Major contributor to development of complications is the presence of comorbidities
 - Chronic comorbid conditions present in over 50% of septic patients.
 - Associated with increased mortality
 - Comorbid conditions reported to increase risk of normal stress response
 - Diabetes mellitus (DM)
 - Human immunodeficiency virus (HIV)
 - Chronic liver disease
 - Cancer
- Other factors increasing likelihood of sepsis include:
 - Men more likely than women
 - African-Americans more likely than Caucasians
 - Septic non-Caucasians are more likely to have concomitant DM, HIV, chronic renal failure, and alcohol abuse.
 - Septic Caucasians had higher incidences of cancer and chronic obstructive pulmonary disease (COPD)
 - Presence of one comorbidity increased the risk of developing at least one organ system failure by 30%.
 - The risk of developing organ failure increased by 39% for two comorbidities.
 - Three or more comorbidities presented a 45% chance of developing acute organ failure.

TREATMENT OR PREVENTION

- Treatment of pre-existing disorders/comorbidities will alter the stress response.

- Perhaps the reason why perioperative β -blockade, in appropriate patients, improves outcome
- Attempts to alter the course of prolonged state constituting SIRS, sepsis, MODS, and chronic critical illness are more problematic.
- Most approaches have failed in patients.
- Some successes
 - In the pediatric burn population, REE decreased and net muscle protein balance increased with administration of propranolol.
 - Several murine experiments in septic or hemorrhagic shock increased mortality from immunosuppression after β -blockade.
 - Adequate analgesia
 - Epidural and intravenous
- Opiates, α -blockers, NSAIDs, and local anesthetics
- Shown to both decrease inflammation and improve immune function
- Early goal-directed resuscitation was shown to improve outcome in a single-center trial.
- Protocol using insulin infusion to maintain serum glucose levels between 80 and 110 mg/dL was shown to reduce mortality and complications in a surgical ICU in a single institution.
 - Similar results not observed in medical ICU
 - Benefit of insulin confined to patients in the MICU for more than 3 to 5 days
- Likely “optimal” goal for glucose control has moved to a range of 100 to 140 mg/dL.
 - Data need to be confirmed.

CHAPTER 20 ■ MULTIPLE ORGAN DYSFUNCTION SYNDROME

IMMEDIATE CONCERNS

- Multiple organ dysfunction syndrome (MODS)
 - A leading cause of death in critically ill and injured patients
 - MODS is a disease of medical progress.
 - Broader use of intensive care unit (ICU) resources
 - Improvements in single organ-directed therapy
 - Mechanical ventilation and renal replacement therapy
 - Has reduced early mortality after major physiologic insults
 - The result is longer ICU stay after severe sepsis and trauma.
 - Inflammation and tissue injury may result in MODS.
 - MODS represents a systemic disorder.
 - Immunoregulation
 - Endothelial dysfunction
 - Hypermetabolism
 - Varying manifestations in individual organs
 - Mortality of MODS
 - Increases as the number of failing organs increases
 - Suggests that changes in function of all organs of equal significance in outcome
 - Organs differ in host defense functions and sensitivity to host-derived inflammatory mediators or reductions in oxygen delivery ($\dot{V}O_2$).
 - Thus, diagnosis and therapy focus on prevention.
 - Changes in cellular oxygen (O_2) supply and metabolism may cause and complicate MODS
 - Consequences can include the following:
 - Direct hypoxic organ damage
 - Secondary ischemia/reperfusion (I/R) injury mediated by neutrophils and reactive O_2 species

- Enhanced injury by activation of cytokines, including tumor necrosis factor- α
- Initial and subsequent therapy follows a two-tiered approach.
 - Targeting systemic factors contributing to ongoing inflammation and single organ-related problems
 - Stabilizing $\dot{V}O_2$
 - Addressing life-threatening derangements in acid-base balance and gas exchange
 - Prompt correction of hemodynamic instability to defined end points that correlate with resolution of tissue O_2 debt minimizes ischemia-related organ damage.
 - Element of time is a critical factor.
 - Delays in completing initial resuscitation, eliminating foci of infection or devitalized tissue, or treating *de novo* organ-specific problems, (i.e., oliguria) worsen outcome.
 - Late-phase (e.g., >72 h) problems involve acquired immunosuppression, predisposition to secondary infection, and hypermetabolism, which impairs wound healing and host defense.

INITIAL ESSENTIAL DIAGNOSTIC TESTS AND PROCEDURES

Hemodynamic and Metabolic Monitoring

- Assess adequacy of initial resuscitation efforts by noninvasive measures including the following:
 - Skin color and temperature

- Arterial blood pressure and pulse rate
- Respiratory rate
- Mental status
- Urine output
- Determine whether metabolic acidosis is present from arterial blood gas and plasma bicarbonate determinations.
 - If acidosis present, establish whether the anion gap and plasma lactate concentrations increased.
- Consider invasive hemodynamic monitoring by arterial and central vascular catheterization.
 - Central venous pressure estimates right heart filling.
 - May not accurately gauge left ventricular preload with tricuspid insufficiency, pre-existing heart disease, pulmonary hypertension, or adult respiratory distress syndrome (ARDS)
 - Exclude myocardial infarction as cause of hemodynamic instability.
 - Electrocardiography, creatine kinase isoenzyme, and troponin I levels
- Targeted hemodynamic management:
 - Accomplished by invasive or noninvasive means
 - Pulmonary artery catheterization
 - Arterial pulse contour analysis
 - Esophageal Doppler
 - Mixed/central venous O₂ saturation and lactate concentrations—if the latter are initially elevated
 - Monitored to determine the adequacy of resuscitation and assist in titration of therapy
- Hemodynamic instability despite adequate fluid resuscitation in severe sepsis
 - Treated with inotropes as indicated
 - Hemoglobin level should be raised to 10 mg/dL in early stages of resuscitation.

Evaluation for Infection

- Suspected sepsis upon ICU admission before antibiotic initiation
 - Immediate blood cultures—including fungal where appropriate
 - Gram stains and cultures of urine
 - Adequate sputum specimen
 - “Adequate is defined by 25 or more leukocytes per low-power field” or tracheobronchial washings.
 - Wound discharges
 - Suspicious skin lesions—culture by aspiration and biopsy
 - Fluid collections should be studied
 - Perform thoracentesis and paracentesis within 12 hours or less.
 - Determine pH.
 - Perform Gram stain, culture, cell count, cytologic studies, glucose level, and other chemistries as needed.
 - Evaluate patient for all infectious/potential noninfectious etiologies of MODS.
- Suspected nosocomial sepsis
 - Reculture blood, urine, and sputum.
 - Evaluate all sites of vascular cannulation and remove catheters, if possible.
 - Consider fiberoptic bronchoscopy to obtain protected brush specimen or bronchoalveolar lavage samples in patients with pneumonia.
 - Exclude infective endocarditis or endovascular infection by echocardiography and scintigraphic scanning for high-grade or recurrent bacteremia.
 - Serially monitor renal, pancreatic, and hepatic function:
 - Exclude acalculous cholecystitis or pancreatitis by abdominal ultrasound.
 - Perform computed tomography of the sinuses, chest, abdomen, and pelvis when appropriate to define fluid collections.
 - Maintain high index of suspicion for opportunistic fungal infection.
 - For example, *Candida* spp. despite negative blood culture results

Initial Therapy

- Resuscitation of hemodynamic instability should be rapidly initiated.
 - Crystalloid or colloid infusions
 - Followed by replenishment of the red cell mass
- Vasopressors
 - Dopamine, norepinephrine, vasopressin
 - Titrated to systolic blood pressure of 90 to 100 mm Hg or mean pressure of 70 mm Hg or higher
- With septic shock and hypotension despite “adequate” fluid resuscitation
 - Is patient resuscitated?
 - Evaluate for evidence of adrenal insufficiency.
 - Random cortisol level <12 µg/dL
 - Artificial adrenocorticotrophic hormone (ACTH) stimulation study
 - Initiate therapy with low-dose corticosteroids if indicated.
 - 50 mg every 6 hours or 10 mg/hour continuous infusion
 - Our preference is the latter.
 - Begin wean about 48 hours after hemodynamic stability obtained.
- If response to catecholamine therapy is inadequate
 - Evaluate and treat ionized hypocalcemia and severe metabolic acidosis.
- If shock persists despite rapid and aggressive fluid resuscitation
 - Consider endotracheal intubation and mechanical ventilation, irrespective of arterial blood gas values.
 - Achieve proper titration of ventilatory therapy, which averts respiratory muscle fatigue and arrest by reducing shock-related increases in the O₂ cost of breathing.
- Evaluate and treat oliguria.
 - Differentiate prerenal causes by obtaining serum and urine Na⁺, creatinine, and urea nitrogen to calculate fractional excretion of sodium (FeNa) or urea nitrogen.
- Stabilize long-bone fractures early.
- Initiate broad-spectrum antimicrobial therapy.
 - Coverage against methicillin-resistant *Staphylococcus aureus*, *Staphylococcus epidermidis*, and *Pseudomonas aeruginosa*
 - Add coverage for suspected anaerobic intra-abdominal sepsis.
- Begin antifungal therapy when high risk for fungal sepsis present.
 - Despite negative results on blood culture

TABLE 20.1**COMPARISON OF THE PHYSIOLOGIC AND BIOCHEMICAL PARAMETERS USED BY FOUR SCORING SYSTEMS FOR ORGAN DYSFUNCTION AND FAILURE**

Organ system	Sequential organ failure assessment (SOFA)	Multiple organ dysfunction score (MOD)	Logistic organ dysfunction (LOD)	Brussels
Cardiovascular	Blood pressure and vasopressor use	Blood pressure and adjusted heart rate	Blood pressure and heart rate	Blood pressure, fluid responsiveness, and acidosis
Pulmonary	PaO ₂ /FiO ₂ and mechanical ventilation	PaO ₂ /FiO ₂	PaO ₂ /FiO ₂ and mechanical ventilation	PaO ₂ /FiO ₂
Hepatic	Bilirubin	Bilirubin	Bilirubin and prothrombin time	Bilirubin
Hematologic	Platelets	Platelets	Platelets and white blood cell count	Platelets
Renal	Creatinine and urine output	Creatinine	Creatinine, blood urea nitrogen, or urine output	Creatinine
Central nervous system	Glasgow coma score (GCS)	GCS	GCS	GCS

Reprinted from Bernard GR. Quantification of organ dysfunction: seeking standardization. *Crit Care Med.* 1998;26:1767–1768, with permission.

- When clinical findings suggestive
 - Extensive colonization by *Candida*
 - Nonintertriginous skin rash
 - Myositis
 - Retinitis
- Prompt re-exploration for suspected intra-abdominal sepsis and abscess formation

EPIDEMIOLOGY OF MULTIPLE ORGAN DYSFUNCTION SYNDROME

- MODS is leading cause of death for patients in the ICU.
- Death rate remains high for patients who survive ICU admission.
- Financial costs are significant.
 - More than 60% of ICU resources consumed by these patients.
- Individual organ dysfunction may result from a direct insult, pulmonary aspiration of gastric contents (primary MODS), or associated with a systemic process, shock, or pancreatitis (secondary MODS).
- Alterations in organ function a continuum rather than a discrete, dichotomous event indicating the failure of an organ
 - Several organ dysfunction scores have been developed to predict the clinical outcome of these patients (Table 20.1).

- Changes in the **sequential organ failure assessment (SOFA)** score are a good indicator of prognosis.
 - In a study of 352 consecutive patients, increased SOFA score during first 48 hours of intensive care predicted a mortality rate of at least 50%.
- The overall rate of MODS, defined as severe acquired dysfunction in two or more organ systems
 - 43% for patients without a diagnosis of sepsis
 - 73% of those with a diagnosis of severe sepsis
- There is a direct relationship between number of organs failing and ICU mortality (Fig. 20.1).
 - Single-organ failure has ICU mortality rate of 6%.
 - Four or more failing organs has mortality rate of 65%.
 - Organ failure in patients with severe sepsis generally carried a higher mortality than in those patients without a diagnosis of severe sepsis.
 - For individual organ systems in the group of patients with severe sepsis
 - Failure of the coagulation system has highest mortality—52.9%
 - Hepatic system—45.1%
 - Central nervous system—43.9%
 - Cardiovascular system—42.3%
 - Renal system—41.2%
 - Respiratory failure—34.5%

FIGURE 20.1. Relationship between the number of failed organs on admission and intensive care unit mortality. (Reproduced from Vincent J-L, Sakr Y, Sprung CL, et al. Sepsis in European intensive care units: results of the SOAP study. *Crit Care Med.* 2006;34:344–353, with permission.)

- Certain subsets of ICU patients at greater risk of MODS:
 - Patients older than 65 years (older than 55 years in trauma patients)
 - Increased severity of illness as assessed by APACHE II scores (20 or more)
 - Those carrying the diagnosis of sepsis or acute lung injury (ALI) on admission

Pathophysiology

- MODS usually occurs in patients with signs of a generalized inflammatory response (systemic inflammatory response syndrome).

Derangements in Oxygen Delivery and Consumption

- Usually, oxygen consumption (VO_2) is determined by metabolic demand and is independent of $\dot{\text{V}}\text{O}_2$.
 - When $\dot{\text{V}}\text{O}_2$ is reduced, VO_2 is maintained by increased oxygen extraction by the tissues.
 - If $\dot{\text{V}}\text{O}_2$ is reduced to the point where the metabolic need cannot be met, VO_2 becomes “supply dependent.”
 - Point at which VO_2 decreases is called the critical $\dot{\text{V}}\text{O}_2$.
- More recent recognition that supply dependency may be occurring locally in patients.
 - Increasing appreciation that the regional circulation and microcirculation—arterioles, capillary bed, and postcapillary venules—play a crucial role in the pathogenesis of organ dysfunction in shock
 - Heterogeneous microcirculatory abnormalities occur due to changes in the activation state and shape of endothelial cells, alterations in vascular smooth muscle tone, activation of the clotting system, and changes in red and white blood cell deformability.
 - The surface receptors and mediators associated with these changes are now being identified, and include oxidants, lectins, proteases, vasoactive products of inducible nitric oxide synthase, and altered adrenergic receptor sensitivity.
 - Alterations in microvascular circulation have been demonstrated in congestive heart failure, cardiogenic shock, hemorrhage, and sepsis.
 - Tissue (skeletal muscle) oxygen saturation in septic patients is no different than that observed in healthy controls or postsurgical patients.
 - Microvascular compliance and skeletal muscle oxygen consumption is reduced, and postischemic reperfusion time is increased compared to controls.
 - Orthogonal polarization spectral imaging—a technique by which perfusion of small and large vessels in the microcirculation of mucosal surfaces can be seen and quantified—has been utilized to show the fraction of perfused small vessels in patients with severe heart failure, cardiogenic shock, or sepsis is significantly lower than in those critically ill patients without those conditions.
 - Functional cellular hypoxia—“cytopathic hypoxia”—or metabolic failure is a condition where the cell is incapable of utilizing oxygen to produce despite adequate oxygen delivery.
 - In patients with sepsis and in animal models of sepsis, oxygen tension in the intestine, bladder, and skeletal muscle is elevated, suggesting that the problem is not one of inadequate $\dot{\text{V}}\text{O}_2$ but one of oxygen utilization.
 - The defect in oxygen utilization likely resides in the mitochondrion.
 - Mechanism by which cytopathic hypoxia or metabolic failure occurs has not been fully elucidated.
 - However, nitric oxide and its metabolite, peroxynitrite, are mediators that are released during sepsis and are inhibitors of the mitochondrial electron transport chain.

Role of Inflammatory and Vasoactive Mediators

- Early clinical series emphasized the implication of uncontrolled infection in the development of MODS.
 - Clear now that MODS can occur either with extensive tissue injury such as that seen with trauma, pancreatitis, or sepsis
 - Large amount of evidence available that implicates the release of inflammatory mediators in the pathogenesis of MODS (Table 20.2)
- The coagulation system
 - Lipopolysaccharide (LPS) and many proinflammatory mediators will activate the coagulation system.

TABLE 20.2

INFLAMMATORY MEDIATORS IMPORTANT IN THE PATHOGENESIS OF SEPSIS AND THE MULTIPLE ORGAN DYSFUNCTION SYNDROME

Complement (C3a, C5a)
 Neutrophil products
 Proteases
 Neutral proteases
 Elastase
 Cathepsin G
 Collagenase
 Acid hydrolase
 Cathepsins B and D
 β -glucuronidase
 Glucosaminase
 Oxygen radicals
 Superoxide anion
 Hydroxyl radical
 Hydrogen peroxide
 Peroxynitrite
 Bradykinin
 Lipid mediators
 Prostaglandins
 Thromboxane A_2
 Prostaglandin I_2
 Prostaglandin E_2
 Leukotrienes (LTB_4 , LTC_4 , LTD_4 , LTE_4)
 Platelet-activating factor (PAF)
 Cytokines
 Tumor necrosis factor- α (TNF- α)
 Interleukins (IL-1, IL-6, IL-8)
 High-mobility group 1 (HMG-1)
 Macrophage migration inhibition factor (MIF)
 Nitric oxide

Reprinted from Heard SO, Fink MP. Multiple-organ dysfunction syndrome. In: Murray MJ, Coursin DB, Pearl RG, et al., eds. *Critical Care Medicine. Perioperative Management*. Philadelphia: Lippincott Williams & Wilkins; 2002, with permission.

- Coagulation in sepsis or inflammatory states is initiated primarily by the extrinsic tissue factor–dependent pathway.
- Same mediators activate the fibrinolytic system, but subsequent increases in plasminogen activator inhibitor-1 and thrombin-activatable fibrinolysis inhibitor effectively suppress fibrinolysis.
- Important inhibitors of coagulation such as antithrombin, tissue factor pathway inhibitor, protein C, protein S, and endothelial-bound modulators—heparan sulfate and thrombomodulin—may be down-regulated.
- Consequently, there is a net *procoagulant tendency* with the potential for the development of disseminated intravascular coagulation.
- Recombinant human activated protein C has been shown to reduce the relative risk of death in patients with severe sepsis by more than 19%, at least in part by its inhibition of the coagulation cascade.

Prevention and Treatment of Multiple Organ Dysfunction Syndrome

- (Table 20.3) lists suggested strategies for the prevention of multiple organ dysfunction syndrome.

Resuscitation

- An episode of circulatory shock is probably the most common event that occurs before the development of MODS.
- Timely restoration of intravascular volume and oxygen delivery is important in preventing or abrogating MODS in high-risk patients.
- Controversy continues regarding the correct fluid for resuscitation and the optimal circulating hemoglobin concentration.
 - Crystalloid solutions are efficacious and cheaper than colloid solutions—there is no overall difference in outcome—death, length of stay, or organ dysfunction—when the two groups were compared.
 - Subgroup analysis demonstrated an increased relative risk of death for trauma patients who received albumin, whereas the relative risk of death for severe sepsis patients was higher if saline was used.
- Assessing the adequacy of tissue oxygenation can often be difficult.
 - Clinical parameters used most often, including arterial blood pressure, skin color, temperature, urine flow, mixed venous oxygen saturation, and blood-lactate concentrations, may be unreliable.
 - Use of the pulmonary artery catheter to guide therapy has not been shown to be of benefit in a large number of studies.
 - Pulmonary capillary wedge pressure does not accurately reflect ventricular volume, even in normal volunteers.
 - Less invasive and probably safer monitors have been developed for monitoring cardiac output that compare favorably with the accuracy of the thermodilution method—systolic blood pressure variation, pulse pressure variation, stroke volume variation, or left ventricular end-diastolic area (as assessed by transesophageal echocardiography).

TABLE 20.3

SUGGESTED STRATEGIES FOR THE PREVENTION OF MULTIPLE ORGAN DYSFUNCTION SYNDROME

- 1. Prevention of hospital-acquired infection**
 - a. Prevention of catheter-related bloodstream infections
 - Implementation of educational initiatives
 - Use of chlorhexidine solution for skin preparation
 - Use of maximum barrier precautions
 - Avoidance of the femoral insertion site
 - Removal of catheter as soon as possible when no longer needed
 - b. Strict infection control measures and hand hygiene
- 2. Metabolic control and support**
 - a. Strict glucose control
 - b. Early enteral nutrition
- 3. Early and appropriate treatment of infection and trauma**
 - a. Early goal-directed therapy for severe sepsis
 - b. Early and aggressive resuscitation of trauma victims
 - c. Prompt eradication of documented sources/foci of infection
 - d. Early fracture stabilization in multiple trauma
 - e. Appropriate empiric antibiotic therapy according to consensus guidelines where available, with earliest possible de-escalation of therapy according to culture results
- 4. Prevention of acute lung injury (ALI), acute respiratory distress syndrome (ARDS), and ventilator-associated and aspiration pneumonia**
 - a. Elevation of the head of bed to 30 degrees in all patients without spine precautions
 - b. Stress gastritis prophylaxis according to consensus guidelines
 - c. Lung protective ventilation strategies in patients with ALI/ARDS
 - d. Implementation of weaning protocols
 - e. Daily sedation holidays
 - f. Chlorhexidine oral rinse
 - g. Selective decontamination of the digestive tract
- 5. Prevention of acute renal failure**
 - a. Normal saline administration to prevent contrast-induced nephropathy, with the addition of sodium bicarbonate or N-acetylcysteine as indicated
 - b. Discontinuation of nephrotoxic drugs whenever possible; consider once-daily dosing regimens for aminoglycoside antibiotics

- Aggressive resuscitation in the ICU may be too late. Early (i.e., in the emergency department before hospital admission), goal-directed therapy can reduce mortality and organ dysfunction in patients with severe sepsis and septic shock.

Mechanical Ventilation

- The method by which patients are mechanically ventilated can contribute to organ dysfunction.
 - Overdistension of the lung through the use of large tidal volumes will cause lung injury, stimulate the release of inflammatory mediators, and effect derangements in organs other than the lung.
 - Small tidal volumes (6 mL/kg) in ALI and ARDS patients will decrease mortality and increase ventilator-free and organ failure-free days.

- Cyclic “opening” and “closing” of collapsed airways during tidal ventilation is also thought to cause lung injury.
- Use of positive end-expiratory pressure above the lower inflection point of the respiratory system compliance curve may reduce mortality and the number of failed organs compared to controls.
- Fluid management is also an important component in the care of the patient with ARDS or ALI.
- Restrictive fluid strategy where cumulative fluid balance is kept close to zero in these patients improves the oxygenation index and increases the number of ventilator-free days without increasing the number of other organ failures.

Acute Renal Failure

- Acute tubular necrosis accounts for more than 75% of the cases of acute renal failure in the ICU.
- Mortality rate ranging from 40% to 80%
- Most common insult that predisposes ICU patients to acute tubular necrosis is persistent prerenal azotemia.
- In the critically ill patient, there is often more than one insult to the kidney: sepsis; exposure to aminoglycosides, amphotericin B, or radiocontrast agents; and the administration of nonsteroidal anti-inflammatory agents.
- Efforts to minimize these insults to the kidneys should be maximized.
 - Timely resuscitation as mentioned previously is very important to prevent renal ischemia.
 - If aminoglycosides must be used to treat infection, once-daily dosing.
 - Liposomal preparations of amphotericin B reduces the risk of renal damage.
 - If patients are to receive contrast agents, hydration with sodium bicarbonate solutions have been shown to reduce the risk of subsequent renal dysfunction.
 - Although N-acetylcysteine has been purported to reduce the risk of contrast-induced acute renal failure, the observed results may be a reflection of the activation of creatinine kinase or an increase in the tubular secretion of creatinine.

Debridement of Necrotic Tissue and Fracture Stabilization

- Presence of dead or devitalized tissue appears to predispose patients to the development of MODS.
- Timely debridement of dead tissue is important in the prevention of the syndrome.
- Early surgical fixation of major lower-extremity fractures results in a lower incidence of ARDS and pneumonia.
- “Damage control” orthopedics has gained popularity and is a concept whereby fractures are initially treated with external fixation. Definitive therapy occurs later when the patient is more stable.
 - Inflammatory response appears to be attenuated in these patients, and the incidence of organ dysfunction is no higher compared to patients undergoing definitive therapy.

Infection

- Sepsis is an important cause (or correlate) of MODS.
- The presence of infection must be excluded in critically ill patients with signs of deteriorating organ function.

- Empiric administration of broad-spectrum antibiotics is often necessary in the patient with suspected infection.
- Failure to administer correct antibiotic(s) in a timely fashion can increase the risk of death.
- Intra-abdominal sepsis: Early and adequate drainage of intra-abdominal sepsis is important to prevent the development of MODS.
 - Without clinical or radiologic evidence of intra-abdominal infection, “blind” laparotomy in the patient with worsening MODS is unlikely to be fruitful.
- Pulmonary sepsis: Ventilator-associated pneumonia can play a role in the development and course of MODS.
 - Preventive measures include noninvasive positive pressure ventilation, elevation of the head of the bed, continuous subglottic suctioning, weaning protocols, optimization of sedation with daily “wake-ups” for the patient, and chlorhexidine oral rinse.
 - Selective digestive decontamination is a technique by which topical nonabsorbable antibacterial and antifungal agents are applied to the oropharynx and proximal bowel in mechanically ventilated patients to reduce the incidence of nosocomial infections, organ dysfunction, and mortality.
 - A meta-analytic review of 57 randomized controlled trials demonstrated a favorable effect on bloodstream infections and mortality.
 - Fears concerning the emergence of resistance organisms do not appear to be well founded.
- Catheter-related sepsis: Catheter-related bloodstream infections may contribute to the development and propagation of MODS. Proven strategies to reduce the risk of catheter-related bloodstream infections include hand washing prior to catheter insertion, use of maximum barrier precautions (cap, mask, sterile gloves and gown, and a large sterile drape that covers the patient), use of an aqueous chlorhexidine skin preparation solution, avoiding the femoral site for catheter insertion, and removing catheters when no longer needed.
 - If these measures are ineffective in reducing the risk of infection, catheters with antiseptic surfaces or impregnated with antibiotics or the use of chlorhexidine dressing sponges can reduce the risk of infection.
- Other sources of sepsis: Many other sources of infection in critically ill patients may contribute to the development of MODS.
 - Purulent sinusitis, suppurative thrombophlebitis, otitis media, perirectal abscess, epididymitis, prostatitis, calculous or acalculous cholecystitis, meningitis or brain abscess (particularly after instrumentation of the central nervous system), prosthetic intravascular graft infection, lower- or upper-urinary tract infection, and endocarditis.
 - Physical examination and appropriate laboratory and radiographic studies should exclude these conditions.

Nutritional Support

- Malnutrition can contribute to the morbidity and mortality of sepsis and MODS.
- Early nutritional support may be beneficial in patients at risk for developing MODS.
 - Consensus is that enteral feeding is preferable to the parenteral route.

- Overfeeding should be avoided.
- Current guidelines for support of hypermetabolic patients with sepsis or MODS include a total caloric intake (exclusive of protein) of 20 to 25 kcal/kg/day—2 to 5 g/kg/day of glucose, plus 0.5 to 1.0 g/kg/day of fat, and 1.2 to 1.5 g/kg/day of protein.
- Specialty formulas: A number of enteral nutritional formulas are available that provide specific nutrients: glutamine, peptides, arginine, omega-3 fatty acids, nucleic acids, and antioxidants (e.g., vitamins E and C, β -carotene). Arginine

is the substrate for NO synthase and is important in lymphocyte proliferation and wound healing.

- The Canadian Critical Care Clinical Practice Guideline Committee recommends that arginine and other “select” nutrients not be used for enteral nutrition.
 - In patients with ARDS, a formula supplemented with fish oil, borage oil, and antioxidants should be used.
 - Although routine use of glutamine is discouraged, in patients with trauma and burns, enteral glutamine should be considered.

SECTION VI ■ SHOCK STATES

CHAPTER 21 ■ SHOCK: GENERAL

- *Shock* is defined as an acute clinical syndrome resulting when cellular dysoxia occurs, ultimately leading to organ dysfunction and failure. Cellular dysoxia or inadequate tissue perfusion is critical in diagnosing shock, as there are many other

causes of organ dysfunction and failure that are not resultant from shock.

- Note the emphasis on shock as a syndrome, as this constellation of signs and symptoms predictably follows a well-described series of pathophysiologic events. Its clinical presentation is complex (Table 21.1) and varies widely based on the underlying etiology, the degree of organ perfusion, and prior organ dysfunction.

TABLE 21.1

CLINICAL RECOGNITION OF SHOCK

Organ system	Symptoms or signs	Causes
CNS	Mental status changes	↓ Cerebral perfusion
Circulatory <i>Cardiac</i>	Tachycardia	Adrenergic stimulation, depressed contractility
	Other dysrhythmias Hypotension	Coronary ischemia Depressed contractility secondary to ischemia or MDFs, right ventricular failure
Systemic	New murmurs	Valvular dysfunction, VSD
	Hypotension	↓ SVR, ↓ venous return
	↓ JVPs	Hypovolemia, ↓ venous return
	↑ JVPs Disparate peripheral pulses	Right heart failure Aortic dissection
Respiratory	Tachypnea	Pulmonary edema, respiratory muscle fatigue, sepsis, acidosis
	Cyanosis	Hypoxemia
Renal	Oliguria	↓ Perfusion, afferent arteriolar vasoconstriction
Skin	Cool, clammy	Vasoconstriction, sympathetic stimulation
Other	Lactic acidosis	Anaerobic metabolism, hepatic dysfunction
	Fever	Infection

CNS, central nervous system; MDFs, myocardial depressant factors; VSD, ventricular septal defect; SVR, systemic vascular resistance; JVPs, jugular venous pulsations.
From Jimenez EJ. Shock. In: Civetta JM, Taylor RW, Kirby RR, eds. *Critical Care*. 3rd ed. Philadelphia: Lippincott-Raven Publishers; 1997:359.

CLASSIFICATION OF SHOCK

- Current classification of shock is based on cardiovascular parameters. The categories include hypovolemic, cardiogenic, extracardiac obstructive, and distributive. Table 21.2 represents an adaptation of this system. It is important to appreciate that most shock states incorporate different components of each of the aforementioned shock categories.

TABLE 21.2

SHOCK CLASSIFICATIONS

Hypovolemic <i>Hemorrhagic</i> –Trauma, gastrointestinal, retroperitoneal <i>Nonhemorrhagic</i> –Dehydration, emesis, diarrhea, fistulae, burns, polyuria, “third spacing,” malnutrition, large open wounds
Cardiogenic <i>Myocardial</i> –Infarction, contusion, myocarditis, cardiomyopathies, pharmacologic <i>Mechanical</i> –Valvular failure, ventricular septal defect, ventricular wall defects <i>Arrhythmias</i>
Obstructive <i>Impairment of diastolic filling</i> –Intrathoracic obstructive tumors, tension pneumothorax, positive-pressure mechanical ventilation, constrictive pericarditis, pericardial tamponade <i>Impairment of systolic contraction</i> –Pulmonary embolism, acute pulmonary hypertension, air embolism, tumors, aortic dissection, aortic coarctation
Distributive –Septic, anaphylactic, neurogenic, pharmacologic, endocrinologic

From Jimenez EJ. Shock. In: Civetta JM, Taylor RW, Kirby RR, eds. *Critical Care*. 3rd ed. Philadelphia: Lippincott-Raven Publishers; 1997:359; and Kumar A, Parrillo JE. Shock: classification, pathophysiology, and approach to management. In: Parrillo JE, Dellinger RP, eds. *Critical Care Medicine*. 2nd ed. St. Louis: Mosby, Inc.; 2002:371.

CHAPTER 22 ■ CARDIOGENIC SHOCK

- Cardiogenic shock is defined as inadequate tissue perfusion due to primary ventricular failure. Its incidence has remained fairly stable, and ranges from 6% to 8%. In the United States, it is the most common cause of mortality from coronary artery disease. Despite medical advances, it remains the number one cause of in-hospital mortality in patients experiencing a transmural myocardial infarction, with rates ranging between 70% and 90%. Other causes include myocarditis, cardiomyopathy, valvular diseases, and arrhythmias (Table 22.1).
- The most common inciting event in cardiogenic shock is an acute myocardial infarction. Historically, once 40% of the myocardium has been irreversibly damaged, cardiogenic shock may result. From a mechanical perspective, decreased cardiac contractility diminishes both stroke volume and cardiac output (Table 22.2). These lead to increased ventricular filling pressures, cardiac chamber dilatation, and ultimately univentricular or biventricular failure with resultant systemic hypotension. This further reduces myocardial perfusion and

TABLE 22.1

SHOCK CLASSIFICATIONS

Hypovolemic

Hemorrhagic

–Trauma, gastrointestinal, retroperitoneal

Nonhemorrhagic

–Dehydration, emesis, diarrhea, fistulae, burns, polyuria, “third spacing,” malnutrition, large open wounds

Cardiogenic

Myocardial

–Infarction, contusion, myocarditis, cardiomyopathies, pharmacologic

Mechanical

–Valvular failure, ventricular septal defect, ventricular wall defects

Arrhythmias

Obstructive

Impairment of diastolic filling

–Intrathoracic obstructive tumors, tension pneumothorax, positive-pressure mechanical ventilation, constrictive pericarditis, pericardial tamponade

Impairment of systolic contraction

–Pulmonary embolism, acute pulmonary hypertension, air embolism, tumors, aortic dissection, aortic coarctation

Distributive

–Septic, anaphylactic, neurogenic, pharmacologic, endocrinologic

From Jimenez EJ. Shock. In: Civetta JM, Taylor RW, Kirby RR, eds. *Critical Care*. 3rd ed. Philadelphia: Lippincott-Raven Publishers; 1997:359; and Kumar A, Parrillo JE. Shock: classification, pathophysiology, and approach to management. In: Parrillo JE, Dellinger RP, eds. *Critical Care Medicine*. 2nd ed. St. Louis: Mosby, Inc.; 2002:371.

exacerbates ongoing ischemia. The end result is a vicious cycle with severe cardiovascular decompensation. Similar to hypovolemic shock, a significant systemic inflammatory response has been implicated in the pathophysiology of cardiogenic shock (Fig. 22.1).

ESSENTIAL DIAGNOSTIC TESTS AND PROCEDURES

- Bedside clinical criteria that provide evidence of reduced organ perfusion include oliguria, confusion, peripheral cyanosis, and evidence of peripheral vasoconstriction.
- An accurate definition of cardiogenic shock also requires persistence of the shock state after correction of extra-cardiac conditions, such as hypovolemia or a variety of metabolic abnormalities including significant disturbances in acid–base metabolism, electrolyte abnormalities, or arrhythmias.
- The pulmonary artery occlusion pressure (PAOP) is frequently in excess of 18 mm Hg, and the cardiac index (CI) is usually less than 2.2 L/minute/m².

LEFT VENTRICULAR ACUTE MYOCARDIAL INFARCTION

- The Killip classification uses pure clinical bedside evaluation of the patient to establish prognostic indicators to predict the mortality associated with an acute myocardial infarction using the physical findings of congestive heart failure.
- *Class I* patients developed no overt signs of congestive heart failure, and these individuals had a low in-hospital mortality rate. This subgroup represented approximately 40% to 50% of all patients who presented with an acute MI. The in-hospital fatality rate was approximately 6%.
- *Class II* patients demonstrated evidence of impaired ventricular function as manifest by persistent bibasilar rales and an audible third heart sound. This subset of patients accounted for approximately 30% to 40% of patients with acute MI. The in-hospital mortality rate of 17% was triple relative to class I patients.
- *Class III* patients were characterized by the development of acute pulmonary edema, which was seen in approximately 10% to 15% of patients admitted to the hospital. A significant mortality rate of 38% was seen in this group treated conservatively before the thrombolytic era.
- *Class IV* patients had established cardiogenic shock with hypotension and signs of organ hypoperfusion. Cardiogenic shock occurred in 5% to 10% of infarct patients in this series but was associated with a high in-hospital mortality rate of 80%, which was a function of both severity of the underlying illness plus the limited availability of definitive treatment at the time this classification was proposed.

RIGHT VENTRICULAR INFARCTION

- Although isolated right ventricular (RV) infarction is rare, evidence of RV infarction and RV dysfunction is found in up to half of all infarcts and is clinically significant in nearly half of all inferior infarcts.
- The clinical diagnosis of RV infarction should be considered when elevated jugular venous pressure is accompanied by hypotension, while the lung fields are clear. But the diagnosis may be difficult to establish clinically unless hemodynamic measurements, special electrocardiographic leads, echocardiography, or nuclear imaging are performed.
- Right-sided precordial leads obtained by electrocardiography that demonstrate at least 1-mm ST elevation is approximately 70% sensitive in the diagnosis of RV infarction and confers a particularly poor prognosis. Echocardiography is an easily obtainable noninvasive study that demonstrates RV dilation and impairment of wall motion of the right ventricle.
- Radionuclide angiography currently is considered to be the most sensitive means to diagnose RV infarction, although more recent data suggest that magnetic resonance imaging is comparable.
- A decrease in RV ejection fraction that is associated with wall motion abnormalities is more than 90% sensitive in the diagnosis of an RV infarction. Hemodynamic studies that are supportive of significant ischemic involvement of the right ventricle are manifest by increases in right atrial pressures plus demonstration of resistance to diastolic filling, as shown by blunting of the y-descent that follows tricuspid valve opening. A “square root” sign or “dip and plateau” pattern in the diastolic pressure curve is commonly demonstrated in RV infarctions but is not specific and may be associated with pericardial tamponade or restrictive cardiomyopathy.
- Cardiogenic shock in patients with RV infarction frequently represents a substantial loss of functioning myocardium and carries a poor prognosis. RV infarction accompanied by cardiogenic shock is frequently associated with a variety of conduction abnormalities, including a high-grade atrioventricular block or significant rhythm disturbances.
- The treatment of RV infarction complicated by cardiogenic shock centers around maintaining RV filling pressures and assurance of adequate volume. Hemodynamic measure-

ments may facilitate the estimate of volume loading required. Nitrates, diuretics, and other predominantly vasodilating compounds should be avoided. Atrial fibrillation is frequently poorly tolerated by these patients and may require immediate electrical cardioversion. The use of digitalis in acute RV infarction, even in the presence of atrial fibrillation, is controversial. Adequate inotropic support with vasodilating inotropic agents such as dobutamine is used if cardiac output fails to optimize after adequate volume loading. Percutaneous revascularization should be considered as it has been shown to improve outcomes.

MECHANICAL DEFECTS

- A variety of mechanical defects that may be associated with cardiogenic shock in the peri-infarction stage are summarized in Table 22.3.

Free Wall Rupture and Tamponade

- Free wall rupture is a major complication of myocardial infarction and is difficult to diagnose premortem. The prevalence of this complication is unknown but may occur in up to 8% of all myocardial infarctions with approximately one-third occurring in the first 24 hours after the onset of the ischemic event and the peak incidence between days 5 and 7.
- Cardiac rupture is a catastrophic event resulting in sudden cardiac death unless a pseudoaneurysm forms. Hemopericardium with cardiac tamponade is difficult to diagnose early enough to institute definitive therapy. Cardiac tamponade after acute myocardial infarction also may be secondary to hemorrhagic pericarditis, but massive hemopericardium is usually due to cardiac rupture with rapid development of electromechanical dissociation and death.
- The diagnosis of free wall rupture is difficult but should be suspected with sudden hypotension, elevated jugular venous pressures, muffled heart sounds, and a pulsus paradoxus. Echocardiography can document the presence of pericardial fluid and occasionally demonstrates the perforated free wall.
- The classic signs of tamponade are present on echocardiography and are caused by the rising intrapericardial pressure compressing the right atrium and right ventricle, resulting

TABLE 22.3

COMPLICATIONS OF MYOCARDIAL INFARCTION

Characteristic	Ventricular septal rupture	Papillary muscle rupture	Papillary muscle dysfunction
Incidence	Unusual	Rare	Common
Murmur			
Type	Pansystolic	Early to pansystolic	Variable
Location	Left sternal border (95%)	Apex → axilla (50%)	Apex
Thrill	>50%	Rare	No
Clinical presentation	Left and right ventricular failure	Profound pulmonary edema	None to moderate left ventricular failure
Catheterization	O ₂ step-up in right ventricle	Large left atrial V wave	Mild to moderate elevation of left atrial pressure

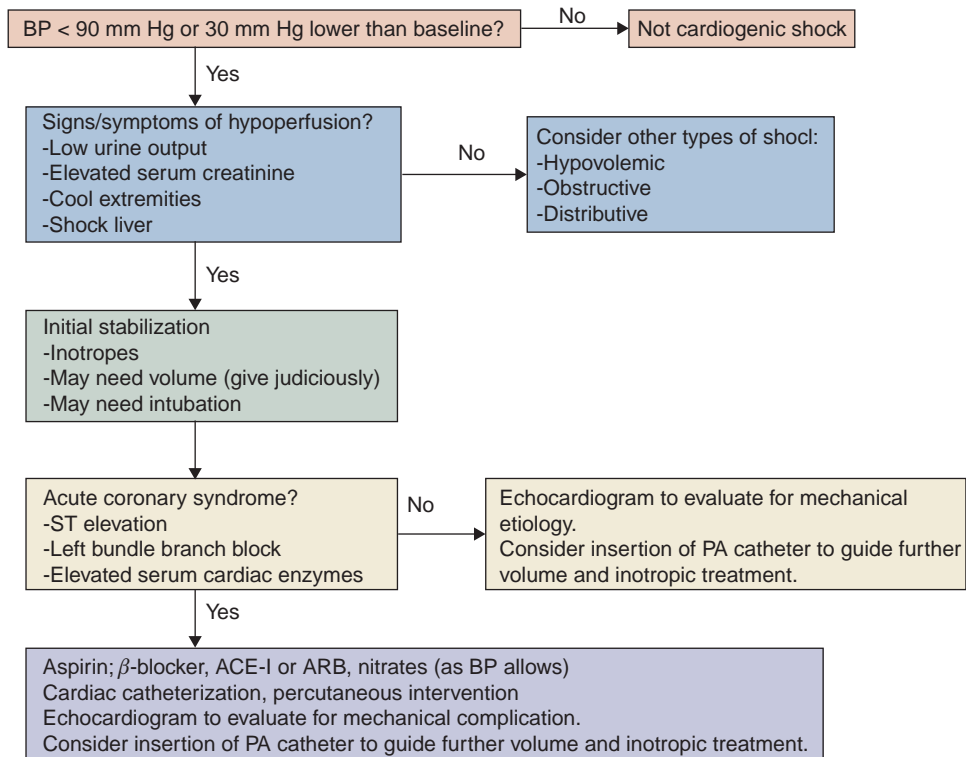

FIGURE 22.2. Management algorithm for cardiogenic shock. ACE-I, angiotensin-converting enzyme inhibitor; ARB, angiotensin II receptor blocker; PA, pulmonary artery.

in equalization of pressures and right ventricular diastolic collapse. Definitive therapy involves pericardiocentesis in addition to volume and pressure support with early surgical intervention being necessary for salvage. Untreated free wall rupture is universally fatal, although isolated instances of successful aggressive intervention with surgical therapy have been reported.

Left Ventricular Aneurysm

- Left ventricular aneurysm is a relatively common complication of MI and may occur in up to 15% of survivors.
- A true aneurysm has a wide base with the ventricular walls composed entirely of myocardium, compared with a pseudoaneurysm, which generally has a narrow base with the walls consisting of pericardium and thrombotic debris. True aneurysms have a relatively low risk of free wall rupture but are associated with increased mortality due to sudden death from ventricular arrhythmias, emboli from mural thrombus, and progressive loss of left ventricular function.
- Aneurysms may develop early in the postinfarction period and can be asymptomatic or present with significant deterioration of left ventricular function. The presence of left ventricular aneurysm may be inferred by persistent ST elevation in the absence of chest pain or enzyme leakage.

THERAPY

- The clinical manifestations of cardiogenic shock are a function of the underlying cause, and mechanical defects must be aggressively sought because of the need for definitive therapy. Clinical recognition of the shock syndrome frequently

requires prompt and aggressive stabilization procedures to be instituted before the definitive diagnosis of the underlying etiology (Fig. 22.2). A history and physical examination should be obtained with special attention to mental status, jugular venous pulsations, quality and intensity of heart sounds, presence and localization of a murmur, and presence of oliguria.

- Diagnostic tests such as electrocardiogram, portable chest radiograph, arterial blood gases, and echocardiography frequently provide adequate clinical information to make a diagnosis and initiate stabilization therapy. A quarter of patients presenting with cardiogenic shock secondary to predominant left ventricular dysfunction do not have evidence of pulmonary congestion.

Surgical Intervention

- Surgical intervention in myocardial infarction has been used to limit infarct size by direct revascularization or to correct the mechanical defects of an acute ischemic event such as ventricular septal defect (VSD), acute mitral insufficiency, free wall rupture, or left ventricular aneurysm. Evidence is accumulating that early revascularization (<6 h) by direct percutaneous transluminal coronary angioplasty (PTCA), intravenous or intracoronary thrombolytic agents, or bypass surgery in selected patients represents the treatment of choice.

OBSTRUCTIVE SHOCK

- In obstructive shock, external forces compress the thin-walled chambers of the heart, the great vessels, or any combination thereof. These forces impair either the diastolic filling or the systolic contraction of the heart. Large obstructive intrathoracic tumors, tension pneumothoraces, pericardial

tamponade, and constrictive pericarditis limit ventricular filling, while pulmonary emboli and aortic dissection impede cardiac contractility.

- The hemodynamic parameters witnessed in obstructive shock include increases in central venous pressure and systemic vascular resistance and decreases in cardiac output and mixed venous oxygen saturation (see Table 22.2). The pulmonary capillary wedge pressure and other hemodynamic indices are dependent on the obstructive cause. In pericardial tamponade, there is equalization of the right and left ventricular diastolic pressures, the central venous pressure, and the pulmonary capillary wedge pressure (increased). However, following a massive pulmonary embolus, right ventricular failure leads to increased right heart pressures and a normal or decreased pulmonary capillary wedge pressure.

DISTRIBUTIVE SHOCK

- Distributive shock is characterized by a decrease in peripheral vascular tone. Septic shock is the most common form. Additionally, distributive shock includes the other oft-quoted classes of shock including anaphylactic, neurogenic, and adrenal shock (see Table 22.1).
- Physiologically, all forms of distributive shock exhibit a decreased systemic vascular resistance (see Table 22.2). Subsequently, these patients experience a relative hypovolemia as evidenced by a decreased (or normal) central venous pressure and pulmonary capillary wedge pressure. The cardiac output is initially diminished; however, following appropriate volume.

CHAPTER 23 ■ SEPSIS AND SEPTIC SHOCK

- Current and previous definitions follow:
 - **Infection:** A microbial phenomenon characterized by an inflammatory response to the presence of microorganisms or the invasion of normally sterile host tissue by these organisms.
 - **Bacteremia:** The presence of viable bacteria in the blood. The presence of other organisms in the blood should be described in like manner—viremia, fungemia, and so on. Bacteremia can either be transient, sustained, or intermittent.
 - **Systemic inflammatory response syndrome (SIRS):** The systemic inflammatory response to various severe clinical insults, including but not limited to infection. Various other clinical insults include pancreatitis, ischemia, multiple trauma and tissue injury, hemorrhagic shock, immune-mediated organ injury, and exogenous administration of inflammatory mediators such as tumor necrosis factor or other cytokines. Previous criteria for SIRS are enumerated in Table 23.1. The more recent revision to sepsis definitions removed these SIRS criteria while retaining the concept. However, some understanding of these criteria remains crucial for the intensivist/clinical researcher, as most trials in the last 15 years have been predicated on patients having three or more of these criteria.
 - **Sepsis:** The systemic response to infection. This response is similar to SIRS, except that it is considered to result from an infection. The previously accepted definition required at least two of the four SIRS criteria in the presence of documented or suspected infection. The recent revision of the criteria enumerates multiple potential diagnostic criteria for sepsis (Table 23.2) and no longer specifically requires the discarded elements of the SIRS criteria.

- **Severe sepsis:** Sepsis associated with organ dysfunction, perfusion abnormalities, or hypotension. Organ system dysfunction can be described by organ failure scoring systems.
- **Septic shock:** Sepsis with hypotension despite adequate fluid resuscitation, in conjunction with perfusion abnormalities. Standard abnormalities in an adult include mean arterial pressure <60 mm Hg, systolic blood pressure <90 mm Hg, or a drop in systolic blood pressure >40 mm Hg from baseline.
- **Multiorgan dysfunction syndrome (MODS):** The presence of altered organ function in an acutely ill patient, such that homeostasis cannot be maintained without intervention. Primary MODS is the direct result of a well-defined

TABLE 23.1

DEFINITION OF SYSTEMIC INFLAMMATORY RESPONSE SYNDROME

Systemic inflammatory response syndrome (SIRS): The systemic inflammatory response to a wide variety of severe clinical insults manifests as two or more of the following conditions:

- Temperature >38°C or <36°C
- Heart rate >90 beats per minute (bpm)
- Respiratory rate >20 breaths per minute or PaCO₂ <32 mm Hg
- White blood cell count >12,000/μL, <4,000/μL, or 10% immature (band) forms

From Bone R. American College of Chest Physicians/Society of Critical Care Medicine Consensus Conference: definitions for sepsis and organ failure and guidelines for the use of innovative therapies in sepsis. *Crit Care Med.* 1992;20:864–874.

TABLE 23.2

REVISED DIAGNOSTIC CRITERIA FOR SEPSIS

Infection,^a documented or suspected, and some of the following:

General variables

- Fever (core temperature $>38.3^{\circ}\text{C}$)
- Hypothermia (core temperature $<36^{\circ}\text{C}$)
- Heart rate >90 min or >2 SD above the normal value for age
- Tachypnea
- Altered mental status
- Significant edema or positive fluid balance (>20 mL/kg over 24 h)
- Hyperglycemia (plasma glucose >120 mg/dL or 7.7 mmol/L) in the absence of diabetes

Inflammatory variables

- Leukocytosis (WBC count $>12,000$ μL)
- Leukopenia (WBC count $<4,000$ μL)
- Normal WBC count with $>10\%$ immature forms
- Plasma C-reactive protein >2 SD above the normal value
- Plasma procalcitonin >2 SD above the normal value

Hemodynamic variables

- Arterial hypotension^b (SBP <90 mm Hg, MAP <70 , or an SBP decrease >40 mm Hg in adults or <2 SD below normal for age)
- $\text{SvO}_2 >70\%$ ^b
- Cardiac index >3.5 L/min/ m^2 ^b

Organ dysfunction variables

- Arterial hypoxemia ($\text{PaO}_2/\text{FiO}_2 <300$)
- Acute oliguria (urine output <0.5 mL/kg/h or 45 mmol/L for ≥ 2 h)
- Creatinine increase >0.5 mg/dL
- Coagulation abnormalities (INR >1.5 or aPTT >60 s)

Ileus (absent bowel sounds)

- Thrombocytopenia (platelet count $<100,000$ μL)
- Hyperbilirubinemia (plasma total bilirubin >4 mg/dL or 70 mmol/L)

Tissue perfusion variables

- Hyperlactatemia (>1 mmol/L)
- Decreased capillary refill or mottling

WBC, white blood cell; SBP, systolic blood pressure; MAP, mean arterial blood pressure; SvO_2 mixed venous oxygen saturation; INR, international normalized ratio; aPTT, activated partial thromboplastin time.

^aInfection defined as a pathologic process induced by a microorganism.

^b SvO_2 sat $>70\%$ is normal in children (normally, 75% – 80%), and CI 3.5 – 5.5 is normal in children; therefore, *neither* should be used as signs of sepsis in newborns or children.

From Levy MM, Fink MP, Marshall JC, et al. 2001 SCCM/ESICM/ACCP/ATS/SIS International Sepsis Definitions Conference. *Crit Care Med.* 2003;31(4):1250–1256.

insult in which organ dysfunction occurs early and can be directly attributable to the insult itself. Secondary MODS develops as a consequence of a host response and is identified within the context of SIRS.

- The relationship of many of these conditions to each other is demonstrated in Figure 23.1. An understanding of sepsis definitions has become increasingly important, as most clinical trials in the last two decades have used the modified version of the 1991 sepsis definitions (usually requiring three

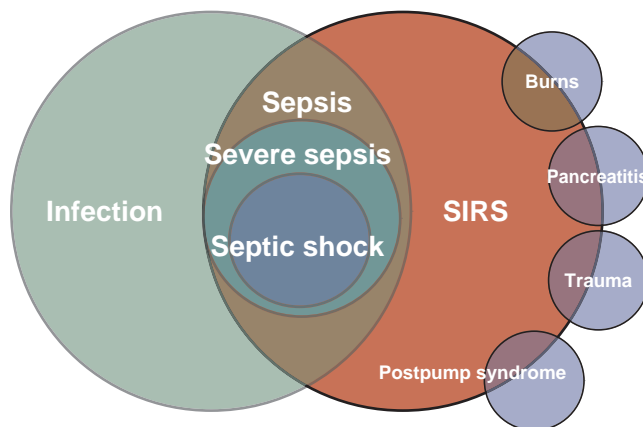

FIGURE 23.1. Venn diagram showing the relationship between infection and other sepsis-associated terms. The intersection of systemic inflammatory response syndrome (SIRS) and infection defines sepsis. Severe sepsis is a subset of sepsis defined by the presence of organ failure. Septic shock is a subset of severe sepsis in which the organ failure is cardiovascular (i.e., shock). Patients with certain inflammatory conditions (e.g., extensive burn injury, pancreatitis, major trauma, postpump syndrome) may demonstrate a “septic” appearance (i.e. SIRS) without the presence of infection required for a diagnosis of sepsis. (Adapted from Bone R. American College of Chest Physicians/Society of Critical Care Medicine Consensus Conference: definitions for sepsis and organ failure and guidelines for the use of innovative therapies in sepsis. *Crit Care Med.* 1992;20:864–874.)

rather than two SIRS criteria) in their entry criteria. The concept of a compensatory anti-inflammatory response has also been introduced after the demonstration that traditional anti-inflammatory mediators were also elevated during sepsis.

- The complex interaction between the infecting organism, host cellular and humoral response, cellular alteration, and clinical manifestation of organ dysfunction are illustrated in Figure 23.2 and Table 23.3.

DIAGNOSIS OF SEPSIS

- To ensure maximally rapid implementation of effective therapy, an initial presumptive diagnosis of severe sepsis and septic shock is mandated. The criteria for this presumptive diagnosis should be highly inclusive and based primarily on clinical criteria.
- The initial presumptive diagnosis of sepsis with organ dysfunction (severe sepsis) may be made in the presence of the following elements:
 - Suspected infection based on a minimal clinical constellation of localizing (e.g., dyspnea, cough, purulent sputum production, dysuria, pyuria, focal pain, local erythema) and systemic signs and/or symptoms of infection and sepsis (Tables 23.4 and 23.5). Supportive/confirmatory findings should follow (Table 23.6).
 - Clinical evidence of organ dysfunction (e.g., hypotension with peripheral hypoperfusion, oliguria, hypoxemia, obtundation)
 - Similarly, an initial diagnosis of septic shock is established in the presence of suspected infection with sustained hypotension without a definitive alternate explanation. Key laboratory values to differentiate infection from septic shock are listed in Table 23.7.

TABLE 23.3**ORGAN SYSTEM DYSFUNCTION IN SEPSIS AND SEPTIC SHOCK**

Central nervous system	Septic encephalopathy Critical illness polyneuropathy/myopathy
Heart	Tachycardia Supraventricular tachycardia Ventricular ectopy Myocardial depression
Pulmonary	Acute respiratory failure Adult respiratory distress syndrome
Kidney	Prerenal failure Acute tubular necrosis
Gastrointestinal	Ileus Erosive gastritis Pancreatitis Acalculous cholecystitis Colonic submucosal hemorrhage Transluminal translocation of bacterial/antigens
Liver	Intrahepatic cholestasis
Hematologic	Disseminated intravascular coagulation Thrombocytopenia
Metabolic	Hyperglycemia Glycogenolysis Gluconeogenesis Hypertriglyceridemia
Immune system	Neutrophil dysfunction Cellular immune (T-cell/macrophage) depression Humoral immune depression

TABLE 23.4**CLINICAL SYMPTOMS AND SIGNS FOR PRESUMPTIVE DIAGNOSIS OF SEVERE SEPSIS AND SEPTIC SHOCK**

Fever or hypothermia
Chills, rigors
Tachycardia
Widened pulse pressure
Tachypnea or hyperpnea
Confusion, decreased level of consciousness or delirium
Decreased urine output
Hypotension

MANAGEMENT OF SEVERE SEPSIS AND SEPTIC SHOCK (THE SEPSIS SIX-PACK)

- Six major areas in the evaluation and treatment of severe sepsis can be identified (Table 23.8). These include the following:
 - Fluid resuscitation
 - Initial resuscitation of septic patients should be aimed at rapid intravascular volume expansion.
 - Initial fluid resuscitation should be titrated to specific clinical end points. Suggested initial targets are heart rate ≤ 100 beats/minute, systolic blood pressure (≥ 90 mm Hg), mean arterial pressure (≥ 60 – 65 mm Hg), urine output (≥ 0.5 mL/kg/hour).
 - Initial fluid resuscitation should be achieved using isotonic crystalloid solutions.
 - Antimicrobial therapy
 - Empiric antibiotic regimens should approach 100% coverage of pathogens for the suspected source of infection (Table 23.9).

TABLE 23.5**LOCALIZING CLINICAL SYMPTOMS AND SIGNS IN SEVERE INFECTIONS**

	History	Physical exam
Central nervous system	Headache, neck stiffness, photophobia	Meningismus (neck stiffness), focal neurologic signs (weakness, paralysis, paresthesia)
Head and neck	Earache, sore throat, sinus pain, or swollen lymph glands	Inflamed or swollen tympanic membranes or ear canal, sinus tenderness, pharyngeal erythema and exudates, inspiratory stridor, and cervical lymphadenopathy
Pulmonary	Cough (especially if productive), pleuritic chest pain, and dyspnea	Dullness on percussion, bronchial breath sounds, and localized crackles
Cardiovascular	Palpitations, syncope	New regurgitant valvular murmur
Intra-abdominal	Abdominal pain, nausea, vomiting, diarrhea, purulent discharge	Abdominal distention, localized tenderness, guarding or rebound tenderness, and rectal tenderness or swelling
Pelvic/genitourinary	Pelvic or flank pain, vaginal or urethral discharge, and urinary frequency and urgency	Costovertebral angle tenderness, pelvic tenderness, pain on cervical motion, and adnexal tenderness
Skin/soft tissue/joint	Localized limb pain or tenderness, focal erythema, edema, and swollen joint	Focal erythema or purple discoloration (subcutaneous necrosis), edema, tenderness, crepitus in necrotizing infections (<i>Clostridia</i> and Gram-negative infections), petechiae, purpura, erythema, ulceration, and bullous formation and joint effusion

TABLE 23.6**SUPPORTIVE/CONFIRMATORY FINDINGS FOR SEVERE SEPSIS AND SEPTIC SHOCK**

Leukocytosis, leukopenia, increased immature white blood cell (WBC) forms, toxic granulation, Dohle bodies
 Thrombocytopenia \pm increased INR or PT
 Increased D-dimer or fibrin split products
 Increased serum bilirubin, AST/ALT, C-reactive protein
 Serum procalcitonin elevation
 Metabolic acidosis with anion gap
 Serum lactate elevation
 Respiratory alkalosis or acidosis
 Mixed venous saturation $>70\%$
 Diagnostic imaging findings
 Positive microbiologic or pathologic samples for abnormal presence of microorganisms, leukocytes, or tissue necrosis

INR, international normalized ratio; PT, prothrombin time; AST/ALT, aspartate aminotransferase/alanine aminotransferase.

Intravenous administration of broad-spectrum antimicrobials should be initiated immediately (preferably <30 minutes) after the clinical diagnosis of septic shock.

Antimicrobial therapy should be initiated with dosing at the high end of the therapeutic range in all patients with life-threatening infection.

Multidrug antimicrobial therapy is preferred for the initial empiric therapy of septic shock.

Empiric antimicrobial therapy should be adjusted to a narrower regimen within 48 to 72 hours if a plausible

pathogen is identified or if the patient stabilizes clinically (i.e., resolution of shock).

Where possible, early source control should be implemented in patients with severe sepsis, septic shock, and other life-threatening infections (Table 23.10).

- Vasopressors and inotropes
 - Rapid volume expansion (500 mL isotonic crystalloid every 10–30 minutes) should be continued until clinical and physiologic treatment targets are met.
 - Vasopressor/inotropic support is required if fluid infusion alone fails to achieve physiologic response targets. Norepinephrine and dopamine are both effective as initial therapy. Dobutamine is indicated for patients with low cardiac index or other evidence of hypoperfusion after achievement of adequate blood pressure. Milrinone can be used as an alternate agent if the response to dobutamine is suboptimal. Continuous infusion of vasopressin (0.01–0.04 U/minute) exerts a strong pressor effect and may be beneficial in catecholamine-resistant septic shock after adequate volume resuscitation. Administration of low- or renal-dose dopamine (1–4 $\mu\text{g/kg/minute}$) to maintain renal or mesenteric blood flow in sepsis and septic shock is not recommended.
- Invasive and noninvasive monitoring
 - Patients with established septic shock should have continuous monitoring of blood pressure, oxygen saturation, electrocardiogram, and urine output in a closed intensive care unit (ICU) staffed with full-time dedicated intensivists and critical care-trained nurses.
 - Patients requiring vasopressor agents for a prolonged period or at high dose should be strongly considered for

insertion of an arterial pressure catheter for continuous blood pressure monitoring and to facilitate frequent measurements of arterial blood gases and chemistry.

- If volume resuscitation requirements exceed 2 L, placement of a central venous catheter for monitoring of central venous pressure (CVP) and for vasopressor/inotrope infusion should be considered. An initial target CVP of ≥ 8 mm Hg is recommended.
- Initiation of invasive cardiac monitoring using a pulmonary artery catheter should be considered if there has been an inadequate response to fluid resuscitation (3–5 L or CVP 8–12 mm Hg), if there is clinical suspicion of intravascular fluid volume overload, or if the patient has impaired cardiac function. An initial target of pulmonary capillary wedge pressure (PWP) of 12 to 15 mm Hg will ensure that hypovolemia is absent in most patients, but higher pressures may be required in certain subgroups.
- In patients with vasopressor-requiring shock who develop progressive organ failure or hypoxemic respiratory failure, pulmonary artery catheterization may be a useful clinical management tool. However, invasive monitoring using a pulmonary artery catheter is not recommended for routine use in all patients with severe sepsis.
- Specific therapy
 - Recombinant human-activated protein C should be administered in patients with suspected sepsis with organ dysfunction. Acceptable criteria include, but are not nec-

TABLE 23.10

COMMON SOURCES OF SEVERE SEPSIS AND SEPTIC SHOCK REQUIRING URGENT SOURCE CONTROL

Toxic megacolon or *C. difficile* colitis with shock

 Necrotizing soft tissue infections (necrotizing fasciitis)
 Clostridial myonecrosis

essarily limited to, a minimum of one organ dysfunction with an acute physiology and chronic health evaluation (APACHE) II score ≥ 25 ; or if an accurate APACHE II score is unavailable, the presence of two or more organ dysfunctions.

- Intravenous immune globulin should be considered for patients suffering from streptococcal toxic shock syndrome.
- Immunosuppressive doses of corticosteroids are contraindicated in the management of sepsis and septic shock.
- Miscellaneous supportive therapy
 - Intensive renal replacement therapy (daily intermittent dialysis or continuous renal replacement therapy) is indicated for severe sepsis or septic shock with renal failure.
 - Intensive insulin therapy maintaining a blood glucose of 4.4 to 6.1 mmol/L (80–110 mg/dL) may be beneficial in critically ill ICU patients with severe sepsis.
 - Stress dose steroids may be administered at presentation to selected patients with septic shock
 - Low-volume (6–8 mL/kg ideal body weight), pressure-limited ventilation is indicated in patients with sepsis-associated acute lung injury or acute respiratory distress syndrome pending the result of an adrenocorticotrophic hormone stimulation test.
 - Endotracheal intubation and mechanical ventilation should be considered early in the management of all patients with sepsis and organ failure.
 - Enteral feeding should be considered within 24 hours of admission to the ICU for most patients with sepsis and septic shock. Parenteral feeding should be used only if enteral feeding is not possible despite best efforts.
 - Intravenous administration of sodium bicarbonate is not indicated for sepsis-associated metabolic acidosis with a pH ≥ 7.15 .

CHAPTER 24 ■ HYPOVOLEMIC AND HEMORRHAGIC SHOCK

- Hypovolemic shock represents a state of decreased intravascular volume. Inciting events include internal or external hemorrhage, significant fluid losses from the gastrointestinal tract (emesis, high-output fistulae, or diarrhea) or urinary tract (hyperosmolar states), and “third spacing” (“capillary leakage” into the interstitial tissues or the corporeal cavities). Additional etiologies include malnutrition and large open wounds (burns and the open abdomen).
- The pathophysiology of shock is dependent upon its classification. Hypovolemic shock is characterized by a decrease in intravascular volume with resultant decreases in pulmonary capillary wedge pressure and cardiac output. There is a subsequent increased sympathetic drive in an attempt to increase peripheral vasculature tone, cardiac contractility, and the heart rate. These initially beneficial measures ultimately turn detrimental, as their resultant hypermetabolic state predisposes tissues to localized hypoxia. Furthermore, the aforementioned increased peripheral vascular tone may result in tissue ischemia through an inconsistent microcirculatory flow. In cases of severe hypovolemic shock, a significant inflammatory component coexists.
- Hypovolemic shock can be due to hemorrhagic and nonhemorrhagic sources. Hemorrhage is the most frequent cause of hypovolemic shock and is most commonly due to blood loss after trauma or major surgery (Table 24.1).
- Nonhemorrhagic sources of hypovolemic shock can also occur. Although not the focus of this chapter, these are due to

external fluid losses such as dehydration, vomiting, diarrhea, polyuria, uncontrolled diabetes mellitus leading to osmotic diuresis, and acute adrenocortical insufficiency. Disorders that lead to interstitial fluid redistribution such as thermal injury, trauma, and anaphylaxis can also lead to hypovolemic shock. Finally, disorders that cause increased vascular capacitance (venodilation) can lead to a relative hypovolemia and include sepsis, anaphylaxis, and the release of toxins/drugs leading to vasodilation.

- There is a progressive hemodynamic deterioration with ongoing blood loss. This classic progression is delineated in Table 24.2. Total blood volume is estimated at approximately 70 mL/kg in the average adult, or nearly 5 L for a person weighing 70 kg.

POTENTIAL PITFALLS

- Despite these guidelines, several potential pitfalls exist that can make the diagnosis more difficult. Concurrent medication, such as β -blockers, may attenuate the physiologic response to hemorrhage. In the presence of β -blockade, tachycardia may be blunted or may not occur at all. Prior hydration status and use of diuretics can also alter the rate at which these signs present. Pregnant patients have a significantly increased total blood volume, and thus can lose up to 1,000 mL of blood before presenting with any clinical signs of hemorrhage. Blood is diverted from the placenta by vasoconstriction; the mother’s total blood circulation is maintained at the expense of the fetus. Elderly patients may have atrial arrhythmias leading to a high ventricular response, making tachycardia less sensitive in this patient population. Concurrent use of antiplatelet or anticoagulant medication can cause relatively small injuries to bleed excessively, and identification and intervention may be delayed. Although unloading of the baroreceptors and activation of the sympathetic nervous system usually lead to tachycardia, some patients may respond to traumatic hemorrhage with bradycardia as a result of a vagal nerve-mediated transient sympathoinhibition due to acute and sudden blood loss. Finally, a significant reduction in skin blood flow (i.e., cool, clammy skin) is an early ominous sign of shock in view of selective cutaneous vasoconstriction. Intervention and resuscitation must be imminent upon presentation of these signs and symptoms.

CIRCULATORY CHANGES

- Hemorrhage results in a predictable pattern of events that begins with acute changes in circulating blood volume and

TABLE 24.1

MAJOR ETIOLOGIES OF HEMORRHAGIC SHOCK

- Trauma (blunt or penetrating)**
 - Intrathoracic
 - Intraperitoneal
 - Retroperitoneal
 - Soft tissue or fractures
- Gastrointestinal**
 - Upper gastrointestinal tract
 - Peptic ulcer disease, reflux esophagitis, variceal bleeding, erosive gastritis, aortoduodenal fistula
 - Lower gastrointestinal tract
 - Hemorrhoids, tumor, arteriovenous malformation, diverticulitis, ulcerative colitis, Crohn’s disease, ischemia
 - Hemobilia
 - Biliary tumor, iatrogenic injury or manipulation, penetrating trauma
 - Pancreatic
 - Pancreatitis, iatrogenic injury, or manipulation
- Retroperitoneal (non-trauma)**
 - Abdominal aortic aneurysm

TABLE 24.2

CLINICAL CLASSES OF HEMORRHAGIC SHOCK

	Class I	Class II	Class III	Class IV
Blood loss (mL)	<750	750–1,500	>1,500–2,000	>2,000
Estimated blood loss	<15%	15%–30%	>30%–40%	>40%
Heart rate (beats per minute)	<100	>100	>120	>140
Systolic blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal	Decreased	Decreased	Decreased
Capillary refill	Delayed	Delayed	Delayed	Delayed
Respiratory rate (breaths per minute)	14–20	20–30	30–40	>35
Urine output (mL/h)	>30	20–30	5–15	Minimal
Mental status	Slightly anxious	Anxious	Confused	Confused and lethargic

culminates in a final common pathway shared by all classifications of shock (Fig. 24.1).

OXYGEN BALANCE

- Critical oxygen delivery is a function of cellular needs for oxygen and the ability of cells to extract oxygen from the

arterial blood. Many factors contribute to this equation. During hemorrhage, tissue oxygen needs may increase due to increased respiratory muscle activity and increased catecholamine circulation. However, some evidence suggests that catecholamines down-regulate the metabolic needs of cells during hypovolemic shock.

- Regional blood flow is modified during hypovolemic shock in an attempt to maintain oxygen delivery to critical tissues. In

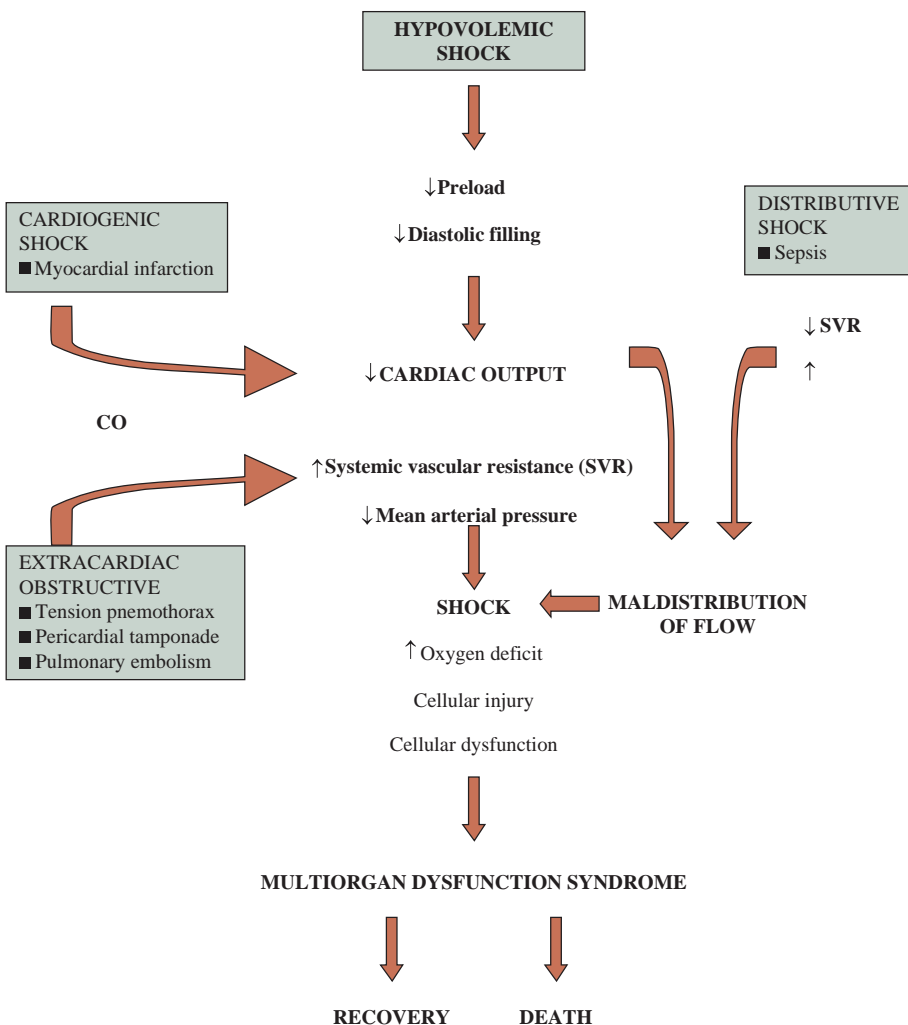

FIGURE 24.1. Final common pathway of shock. Hemorrhagic shock results in acute changes in circulating blood volume that culminates in a final common pathway shared by all classifications of shock.

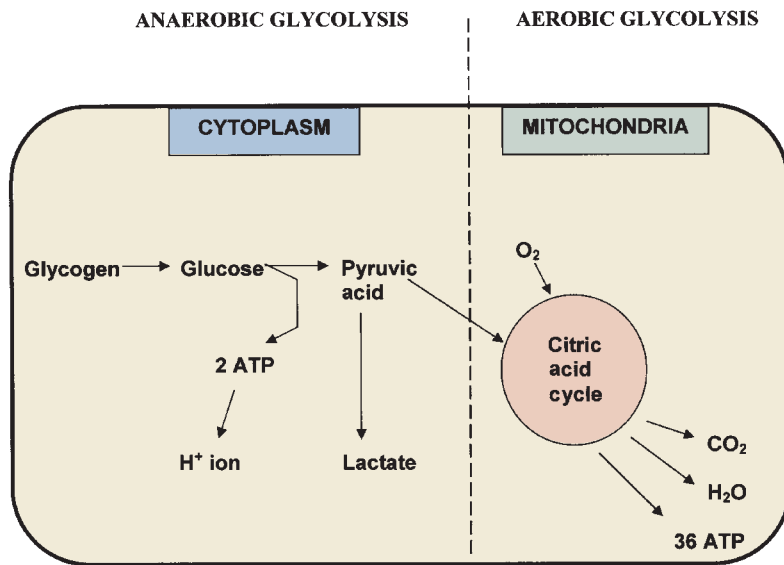

FIGURE 24.2. Cellular mechanisms during anaerobic and aerobic glycolysis. In anaerobic conditions, pyruvic acid cannot enter the citric acid cycle within the mitochondria and is instead shunted to the production of lactate. This process produces only two molecules of adenosine triphosphate (ATP), as opposed to the 36 molecules of ATP produced from glucose in the mitochondria during aerobic glycolysis. Hydrolysis of ATP molecules in anaerobic conditions results in the production of hydrogen ions that cannot be cleared, leading to intracellular acidosis. (Adapted from Mizock BA, Falk JL. Lactic acidosis in critical illness. *Crit Care Med.* 1992; 20[1]:80.)

addition, the individual needs of various tissues may vary during hemorrhagic shock. For instance, the oxygen needs of the kidney may decline during hemorrhage because a fall in renal perfusion leads to a fall in glomerular filtration and a decrease in energy-consuming tubular absorption. In contrast, the gut may experience an increased oxygen debt early due to the high oxygen need of the mucosa, along with redistribution of blood away from the gut to more critical tissues. The severity of oxygen debt during hypovolemic shock has been shown to be a major determinant of survival in animals and in patients following trauma, hemorrhage, and major surgery.

CELLULAR RESPONSE

- During hypovolemic shock, the oxygen deficit in the tissues causes a fall in the mitochondrial production and concentration of high-energy phosphates because of greater breakdown than production, failure of the Na and K pump with rapid decrease of transmembrane potential and heat shock protein production. The process is exacerbated by Ca⁺⁺ influx that further inhibits cellular respiration (Fig. 24.2).

NEUROHUMORAL RESPONSE

- In response to hemorrhage and hypovolemia, a complex neurohumoral response is initiated in an attempt to maintain blood pressure and retain fluid (Fig. 24.3).

MACRO CIRCULATION

- Regional autoregulation takes place by a delicate balance of endogenous vasodilators and vasoconstrictors. Endothelial cells produce potent vasodilators such as endothelium-derived relaxing factor (nitric oxide [NO]), heme oxygenation-derived carbon monoxide (CO), and metabolic byproducts in tissues, including carbon dioxide (CO₂), potassium, and adenosine. The complex interplay of these mechanisms for vasodilation and vasoconstriction ultimately

determines the regional redistribution of blood flow to organs following hemorrhagic shock.

MICROCIRCULATION

- Alterations in microvascular function and flow (vessels < 100–150 μ m) are affected through precapillary and postcapillary sphincters, which are sensitive to both extrinsic and intrinsic control mechanisms.

METABOLIC AND HORMONAL RESPONSE

- The early hyperglycemic response to trauma/hemorrhage is the combined result of enhanced glycogenolysis, caused by the hormonal response to stress including elevated epinephrine, cortisol, and glucagon levels; increased gluconeogenesis in the liver, partly mediated by glucagon; and peripheral resistance to the action of insulin. Without energy for glycolysis, the cell depends on lipolysis and the autodigestion of intracellular protein for energy. Eventually these sources become inefficient, leading to hypertriglyceridemia, increased β -hydroxybutyric acid and acetoacetate levels, and changes in the amino acid concentration pattern.

INFLAMMATORY RESPONSE AND TISSUE INJURY

- Following hemorrhage and resuscitation, macrophages, including lung macrophages and Kupffer cells in the liver, may release proinflammatory cytokines including tumor necrosis factor (TNF)- α and interleukin (IL)-1, -6, and -8. During reperfusion, cytokines may induce and amplify the inflammatory response to ischemia and may further induce local and remote organ damage. Thromboxane, prostaglandins, leukotrienes, platelets activating factor (PAF), complement

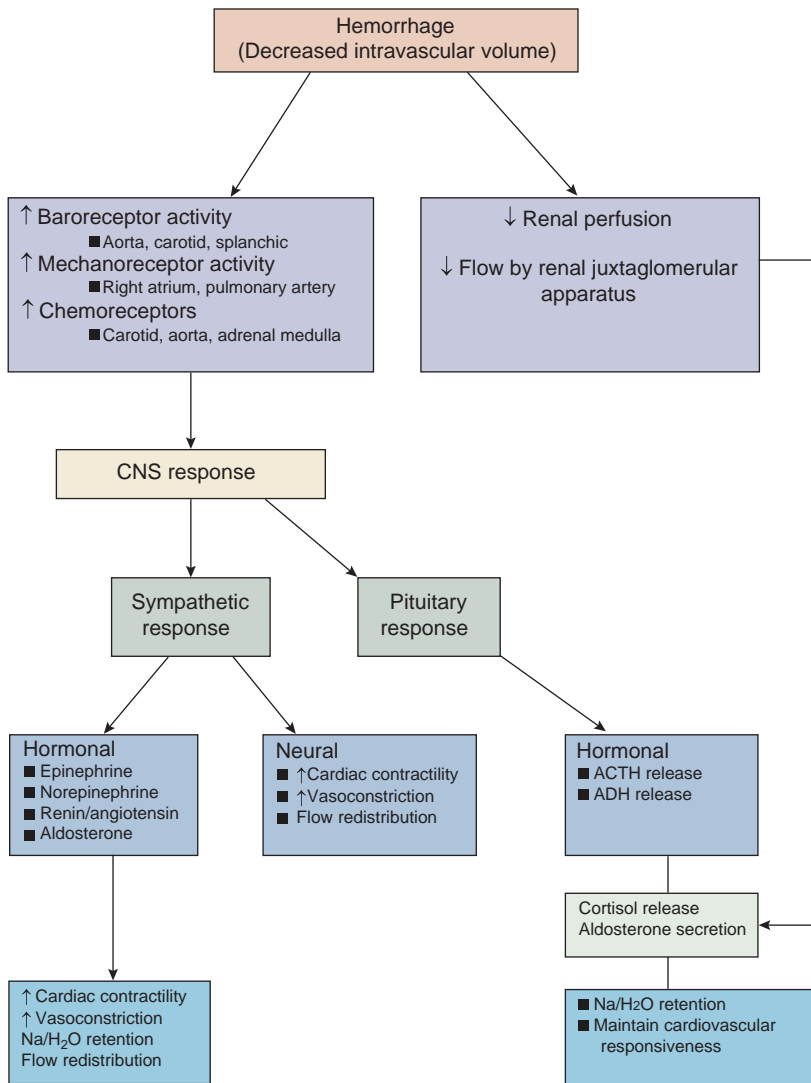

FIGURE 24.3. Neurohormonal response to hemorrhage. Hemorrhage results in a decrease in the circulating intravascular volume, which initiates a complex cascade of compensatory events. CNS, central nervous system; ACTH, adrenocorticotropic hormone; ADH, antidiuretic hormone.

fragments and oxygen radicals contribute to the inflammatory cascade and neutrophil and endothelial cell activation.

IMMUNE FUNCTION

- Despite the initiation of the inflammatory cascade, hypovolemic shock and resuscitation depress the immune system by suppressing the function of lymphocytes, macrophages, and neutrophils, depressing both humoral and cellular immune responses, decreasing antigen presentation and delayed hypersensitivity to skin-test antigens, and increasing susceptibility to sepsis. The immune consequences of hemorrhage and resuscitation differ among cell populations.

Immediate Management

Airway and Breathing

- Most patients with fully developed shock require tracheal intubation and mechanical ventilation, even if acute respiratory failure has not yet developed. If the initial response to

resuscitation is sustained (Table 24.3), then close observation of the airway may be appropriate while additional workup and treatment are pursued. However, in a patient who is not responsive or has a transient response (see below) to fluid resuscitation, control of the airway early is necessary prior to respiratory collapse.

- In addition, if diagnostic and therapeutic interventions, such as angiography and embolization, are required during resuscitation to control hemorrhage, early airway control should be obtained. Once the airway is secured, it is important to closely monitor techniques of ventilation. Studies have shown that there is a tendency of rescue and medical personnel to hyperventilate patients during resuscitation. Hyperventilated patients have been shown to have an increased mortality when compared to non-hyperventilated patients in the setting of severe traumatic brain injury.

Circulation

- The management steps to restore adequate circulation are threefold:
 - Secure access to the bloodstream to initiate infusion of fluids and blood products.

TABLE 24.3**RESPONSE TO INITIAL FLUID RESUSCITATION AND PATIENT MANAGEMENT**

	Rapid response	Transient response	No response
Vital signs	Return to normal	Transient response, recurrent hypotension, and/or tachycardia	Remains abnormal
Estimated blood loss	Minimal (10%–20%)	Moderate (20%–40%)	Severe (>40%)
Additional crystalloid	Unlikely	Yes	Yes
Need for blood transfusion	Unlikely	Moderate to high	Immediate
Blood preparation	Type and cross-match (30–60 min)	Type-specific (10–20 min)	Emergency blood release (immediate type O Rh-negative blood)
Operative intervention	Possible	Likely	Highly likely
Early presence of surgeon	Yes	Yes	Yes

Adapted from American College of Surgeons Committee on Trauma. Shock. In: *Advanced Trauma Life Support*. 7th ed. American College of Surgeons Chicago, IL; 2004:79.

- Control obvious sources of hemorrhage and prevent ongoing hemorrhage.
- Assess extent of shock and hemorrhage.
- Resuscitative thoracotomy is occasionally indicated for exsanguinating hemorrhage (Table 24.4).

LETHAL TRIAD OF RESUSCITATION: HYPOTHERMIA, ACIDOSIS, AND COAGULOPATHY

- Patients with severe hemorrhagic shock requiring massive resuscitation are at risk for exhaustion of their physiologic

reserves, leading to irreversible shock and the inability to recover despite ongoing resuscitation. The common denominator in these patients is the development of the “lethal triad,” “bloody vicious cycle,” or “spiral of death”—terms used to describe the combination of profound acidosis, hypothermia, and coagulopathy (Fig. 24.4). Each of these factors has been independently associated with increased risk of death. There also seems to be a cumulative synergistic effect for each of these risk factors in patients with hemorrhagic shock.

- In particular, *acute traumatic coagulopathy* is present in 25% to 30% of critically injured patients on arrival to the emergency department. The presence of coagulopathy may be even higher in patients with severe closed head injury, with an incidence of 21% to 79% when stratified by injury severity score (ISS). It has also been shown that the presence of early coagulopathy is an independent predictor of mortality following trauma. Early acute traumatic coagulopathy appears to be due to alterations in the thrombomodulin–protein C pathway rather than consumption of coagulation factors; however, additional work needs to be done to clarify these mechanisms.
- *Hemostatic resuscitation* employs blood components *early* in the resuscitation process to restore both perfusion and normal coagulation function while minimizing crystalloid use. Lactated Ringer solution and normal saline resuscitation have been shown to increase reperfusion injury and leukocyte adhesion. As such, standard crystalloid resuscitation

TABLE 24.4**INDICATIONS AND CONTRAINDICATIONS FOR EMERGENCY DEPARTMENT RESUSCITATIVE THORACOTOMY****Indications****Salvageable post-injury cardiac arrest**

- Patients sustaining witnessed penetrating trauma with <15 min of prehospital cardiopulmonary resuscitation (CPR)
- Patients sustaining witnessed blunt trauma with <5 min of prehospital CPR

Persistent severe post-injury hypotension (systolic blood pressure ≤ 60 mm Hg) due to:

- Cardiac tamponade
- Hemorrhage—intrathoracic, intra-abdominal, extremity, cervical
- Air embolism

Contraindications

- Penetrating trauma: CPR >15 min, and no signs of life^a
- Blunt trauma: CPR >5 min, and no signs of life^a or asystole

^aNo signs of life = no pupillary response, respiratory effort, or motor activity.

Adapted from Cothren CC, Moore EE. Emergency department thoracotomy for the critically injured patient: objectives, indications, and outcomes. *World J Emerg Surg*. 2006;1:4.

Metabolic Components of Shock

FIGURE 24.4. Lethal triad of hemorrhagic shock. The development of acidosis, hypothermia, and coagulopathy during resuscitation from hemorrhagic shock is described as the “lethal triad,” “bloody vicious cycle,” or “spiral of death.” Each of these factors has been independently associated with mortality. There is a cumulative synergistic effect for each of these variables, such that irreversible shock may develop if all factors are present.

may worsen, presenting acidosis and coagulopathy in severely injured patients. Several retrospective studies in trauma have shown that survival is associated with an increased use of clotting factors. Many other studies have recommended more aggressive use of clotting factors to treat and correct underlying coagulopathy.

- Although additional prospective studies need to be completed, there seems to be increased literature supporting early aggressive resuscitation with clotting factors while minimiz-

ing crystalloid use during massive resuscitation. Current military experience has moved to using thawed plasma as the primary resuscitation fluid in at least 1:1 or 1:2 ratios with packed red blood cells. Continued resuscitation occurs with a massive transfusion protocol at a ratio of 6 units of plasma, 6 units of packed red blood cells, 6 units of platelets, and 10 units of cryoprecipitate. Recombinant factor VIIa is occasionally used along with early red cell transfusion to promote early hemostasis.

CHAPTER 25 ■ NEUROGENIC SHOCK

- Once other systemic reasons for shock have been ruled out, neurogenic shock should be considered. Three mechanisms can lead to neurogenic shock (Fig. 25.1):
 - *Vasodilatory (distributive) shock* from autonomic disturbance with interruption of sympathetic pathways, with associated parasympathetic excitation, which causes profound vasodilatation and bradycardia, as seen in spinal cord injury or diseases of the peripheral nervous system (Guillain-Barré syndrome).
 - *Cardiogenic shock*, as frequently seen in subarachnoid hemorrhage (SAH) with stunned myocardium after a catecholamine surge or ischemic stroke, especially those involving the right insula. Peripheral and pulmonary vasoconstriction,

platelet aggregation and myocardial dysfunction all participate to the genesis of hemodynamic instability (Fig. 25.2).

- Hypopituitarism/adrenal insufficiency.
- Although some subtypes of neurogenic shock occur more frequently with certain disease entities—for example, cardiogenic neurogenic shock after SAH, vasodilatory neurogenic shock with spinal cord injury—significant overlap exists between different disease entities (intracerebral hemorrhage, SAH, traumatic brain injury, ischemic stroke), and one cannot establish a firm rule by which neurogenic shock occurs. Interestingly, only some patients with neurologic injuries experience true neurogenic shock, and it remains difficult to predict in whom this will be seen.

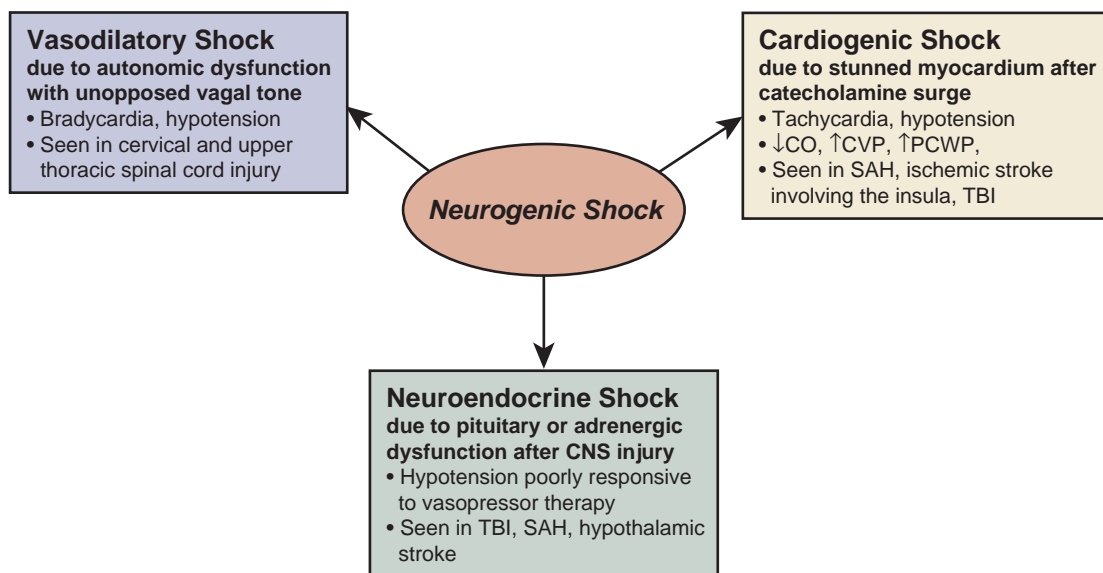

FIGURE 25.1. Neurogenic shock consists of three pathomechanisms. CNS, central nervous system; CO, cardiac output; CVP, central venous pressure; PCWP, pulmonary capillary wedge pressure; SAH, subarachnoid hemorrhage; TBI, traumatic brain injury.

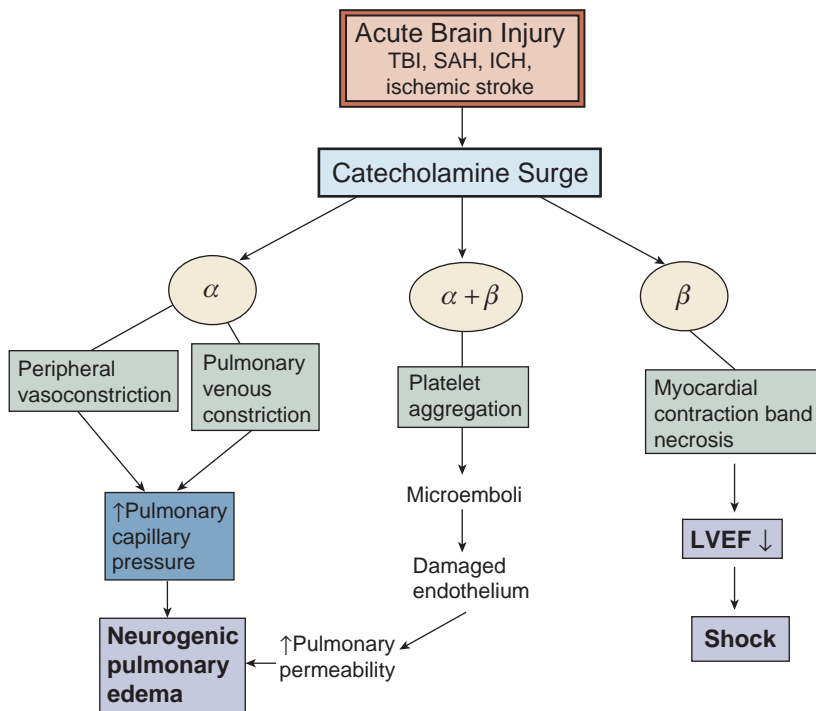

FIGURE 25.2. Summary of the pathophysiology of the cardiogenic type of neurogenic shock. ICH, intracerebral hemorrhage; LVEF, left ventricular ejection fraction; SAH, subarachnoid hemorrhage; TBI, traumatic brain injury.

- Clinical manifestations are illustrated in Figure 25.3 and are based on the relative weight of the three components described previously.

MANAGEMENT

- Two important reasons for early and proactive treatment of patients in neurogenic shock are as follows:

- Prevention of secondary brain injury from hypoxia and hypotension
- The fact that neurogenic shock, especially cardiogenic and neuroendocrine forms, is easily treatable and transient, with potentially good outcomes despite the moribund appearance of the patient in the acute phase.
- Once the diagnosis of neurogenic shock has been established and the pathophysiology (subtype) has been understood, treatment tailored to the specific subtype is initiated.

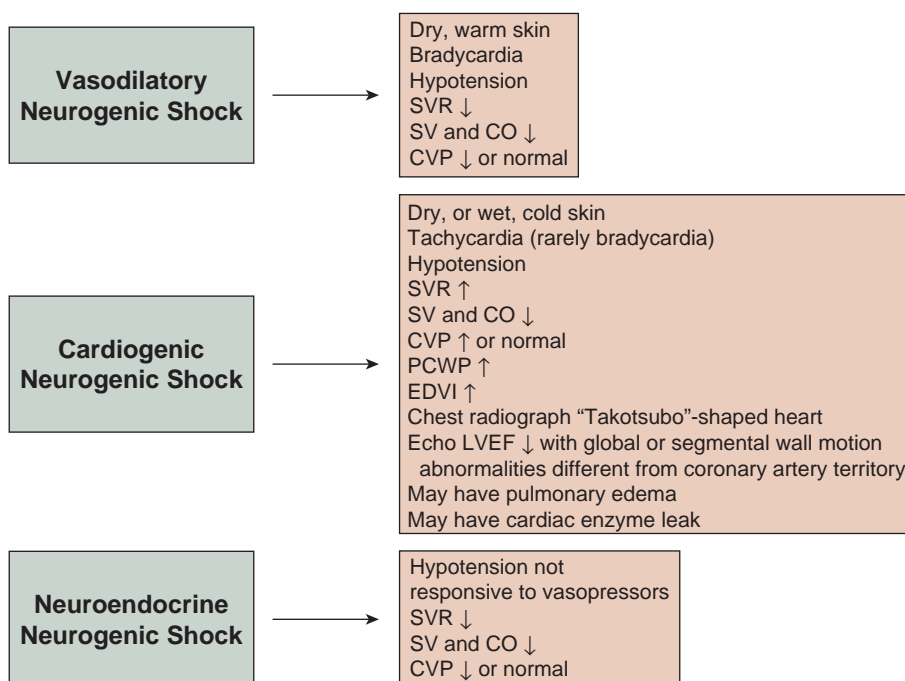

FIGURE 25.3. Clinical manifestations of the different types of neurogenic shock. CO, carbon monoxide; CVP, central venous pressure; EDVI, end-diastolic volume index; PCWP, pulmonary capillary wedge pressure; SV, stroke volume; SVR, systemic vascular resistance.

In all cases, euvolemia is of utmost importance and must be achieved before any other treatment can be successful.

- In general, vasopressor treatment as a continuous infusion is initiated and titrated to a goal mean arterial pressure and cerebral perfusion pressure (CPP). As an important management tool, an intracranial pressure measurement device is very helpful, allowing the indirect measurement of CPP. We recommend a goal CPP of ≥ 65 to 70 mm Hg.
- Vasodilatory neurogenic shock can be difficult to treat. In general, vagal tone predominates; however, in this state, patients frequently have peripheral α -adrenoceptor hypersensitivity, limiting the use of norepinephrine, epinephrine, ephedrine, and phenylephrine. In fact, sympathomimetics should be avoided as they can lead to severe blood pressure fluctuations.
- As arginine vasopressin (AVP) does not affect α - or β -adrenergic receptors, but acts on V_1 receptors, AVP may have an advantage over catecholamines or phenylephrine in this form of neurogenic shock. It has not been studied in neurogenic shock, however, and it remains unclear whether AVP may have adverse effects on neurologically ill patients. This

concern is based on animal studies indicating that vasopressin may promote the development of vasospasm in SAH, and indirect experimental studies showing a reduction in brain edema with vasopressin antagonists. No prospective human study has been undertaken to confirm or dismiss this concern, and the only retrospective study on the use of vasopressin in SAH did not show any of these potentially adverse effects. In addition to vasopressors, a temporary demand pacemaker and/or atropine may be required in cases of refractory bradycardia and hypotension.

- In cardiogenic neurogenic shock, some form of inotropic support may be necessary, either in the form of a dobutamine, milrinone, or norepinephrine infusion. Once diagnosed, neuroendocrine neurogenic shock from primary, or more often secondary, adrenal insufficiency is treated with steroid replacement therapy. We use the same dosing as in adrenal insufficiency in septic shock: hydrocortisone, 50 mg intravenously every 6 hours. As previously discussed, a cortisol stimulation test is usually not helpful, and empiric treatment after a random cortisol level should be initiated.

CHAPTER 26 ■ ANAPHYLACTIC SHOCK

- Anaphylaxis is severe, has a rapid onset, and is potentially fatal—a systemic allergic reaction that occurs after contact with an allergy-causing substance. Activation of mast cell and basophil populations by either IgE-dependent (i.e., anaphylactic reactions) or IgE-independent (i.e., anaphylactoid reactions) mechanisms results in the release of multiple mediators capable of altering vascular permeability and vascular and bronchial smooth-muscle tone and recruiting and activating inflammatory cell cascades.
- Anaphylaxis is a severe, systemic allergic reaction characterized by multisystem involvement, including the skin, airway, vascular system, and gastrointestinal tract. Severe cases may result in complete obstruction of the airway and cardiovascular collapse by vasogenic shock. Anaphylaxis accounts for about 500 to 1,000 deaths per year in the United States. The most common causes of anaphylaxis include insect stings, foods, drugs, and physical factors/exercise. Idiopathic anaphylaxis (where no causative agent is identified) accounts for up to two-thirds of patients referred to allergy/immunology specialty clinics.
- Foods such as shellfish, eggs, nuts, and milk account for one-third of food-induced anaphylactic episodes. Cardiovascular collapse is the most common hemodynamic manifestation. Vasodilation and increased capillary permeability, causing decreased preload and relative hypovolemia up to 37% of circulating blood volume, can rapidly lead to cardiac arrest if not promptly corrected. Hypoxemia from upper-airway obstruction or bronchoconstriction and myocardial ischemia can contribute to the rapid deterioration.

THERAPEUTIC MANAGEMENT

- *Rapidly assess and maintain the airway, breathing, and circulation.* If airway obstruction is imminent, perform endotracheal intubation; if unsuccessful, consider needle-catheter cricothyroid ventilation, cricothyrotomy, or tracheostomy. Patients in anaphylactic shock should be placed in a recumbent position with the lower extremities elevated, unless precluded by shortness of breath or vomiting.
- *Remove the inciting agent* (i.e., remove Hymenoptera stinger). Epinephrine by intramuscular (IM) injection should be administered early to all patients with signs of a systemic reaction, especially hypotension, airway swelling, or definite difficulty breathing at a dose is 0.2 to 0.5 mg (1:1000) IM to be repeated every 5 to 15 minutes in the absence of clinical improvement. Consider gastric lavage and administration of activated charcoal if the inciting agent was ingested.
- For aggressive crystalloid resuscitation, guidelines similar to those for septic shock can be used.
- A continuous use of epinephrine intravenously should be started immediately if hypotension persists despite IV fluids and IM epinephrine.
- There are no prospective randomized clinical studies evaluating the use of other therapeutic agents in anaphylactic shock or cardiac arrest. Adjuvant use of antihistamines (H_1 and H_2 antagonist), inhaled β -adrenergic agents, and intravenous corticosteroids has been successful in the management of a patient with anaphylaxis, and may be considered for the cases refractory to the foregoing measures.

SECTION VII ■ PHARMACOLOGY, NUTRITION, TOXICOLOGY, AND THE ENVIRONMENT

CHAPTER 27 ■ SEDATION AND NEUROMUSCULAR BLOCKADE

PERSPECTIVE

- Anxiety is the human emotion that helps anticipate and prepare for real or perceived threats.
- Results in release of endogenous catecholamines with an accompanying increase in heart rate, blood pressure, tremulousness, and so on
- Can lead to agitation (i.e., anxiety coupled with confusion and movement and, if the confusion is severe enough, delirium).
 - Increasingly, there is recognition that the spectrum of anxiety, agitation, and delirium may be a manifestation of systemic inflammatory response syndrome and multiorgan dysfunction syndrome.
 - Brain is the end organ affected.
- Thus, anxiety warrants increasing attention to monitoring its severity and treatment and to assessing the effects of therapy.

FEATURES

Anxiety

- Often described as heightened sense of awareness, apprehension, dread, or anticipation
- Latter is important characteristic, for anxiety is an emotional state; the individual “anticipates” a threat, and anxiety prepares the individual for “fight or flight”
- Has its anatomic construct in the limbic system
 - Associated with the release of catecholamines
 - Leads to the tremulousness, sweating, tachycardia, and tachypnea—all the hallmarks of anxiety
 - At extreme, an individual may have a “panic attack”
- Anxiety and pain are often a continuum, with the perception of one increasing the perception of the other.
 - Anxiety may lead to insomnia
 - Insomnia (and sleep deprivation) can increase the perception of anxiety
 - Sleep interruption occurs for several reasons
 - Excessive noise levels in many intensive care units (ICUs) at night
 - Patient care activities
 - Measurement of vital signs
 - Laboratory tests, radiographs, and so on
- Intubated/mechanically ventilated patients
 - Even more likely to have interrupted sleep
 - Experience discomfort from the mode of mechanical ventilation and/or tracheal suctioning and hypercarbia and hypoxia

Agitation

- Defined in the 2001 Agitation Consensus Conference
 - “Continual movement characterized by constant fidgeting, moving from side to side, pulling at dressings and bed sheets, and attempting to remove catheters or other tubes”
 - Associated with some degree of cognitive impairment—disorientation, confusion, confabulation, and so on
 - Different from anxiety as agitated patient displays purposeless movement and has some degree of cognitive dysfunction
 - At risk of injuring themselves and, in some circumstances, injuring health care providers
- Factors associated with agitation include:
 - Advanced age
 - Neuropsychiatric comorbidities
 - Seriousness of illness
 - Pain
 - Drugs that have unrecognized interactions/side effects
- Agitation is associated with
 - Increased length of stay
 - Iatrogenic infections
 - Self-extubation
- Prolonged anxiety, depending on the cause, if left untreated may lead to agitation
 - Tools to monitor agitation and the effects of interventions are listed in Table 27.1
 - Some use a variant of the Ramsay Sedation Scale and the Motor Activity Assessment Scale to monitor for agitation (Table 27.2)

Delirium

- Delirium’s hallmark is cognitive dysfunction, commonly manifested as disorientation
 - This used to be termed “ICU syndrome,” a diagnosis of exclusion.
 - Prevalence of delirium
 - Coronary care unit: as low as 7%
 - Medical ICU: as high as 70% to 80%

TABLE 27.2**MOTOR ACTIVITY ASSESSMENT SCALE**

Score	Description	Definition
0	Unresponsive	Does not move with noxious stimulus
1	Responsive only to noxious stimuli	Opens eyes <i>or</i> raises eyebrows <i>or</i> turns head toward stimulus <i>or</i> moves limbs with noxious stimulus
2	Responsive to touch or name	Opens eyes <i>or</i> raises eyebrows <i>or</i> turns head toward stimulus <i>or</i> moves limbs when touched or name is loudly spoken
3	Calm and cooperative	No external stimulus is required to elicit movement, <i>and</i> the patient is adjusting sheets or clothes purposefully and follows commands
4	Restless and cooperative	No external stimulus is required to elicit movement, <i>and</i> patient is picking at sheets or clothes or uncovering self and follows commands
5	Agitated	No external stimulus is required to elicit movement, <i>and</i> patient is attempting to sit up <i>or</i> moves limbs out of bed <i>and</i> does not consistently follow commands
6	Dangerously agitated, uncooperative	No external stimulus is required to elicit movement, <i>and</i> patient is pulling at tubes or catheters <i>or</i> thrashing side to side <i>or</i> striking at staff <i>or</i> trying to climb out of bed <i>and</i> does not calm down when asked

Reprinted from Devlin JW, Boleski G, Mlynarek M, et al. Motor Activity Assessment Scale: a valid and reliable sedation scale for use with mechanically ventilated patients in an adult surgical intensive care unit. *Crit Care Med*. 1999;27:1271–1275, with permission.

- Manifestations include a variety of psychomotor symptoms/signs
 - Hypoactive (listlessness) to hyperactive (combative behavior) is seen
 - A mixed picture may be noted, with patients cycling between overly sedated states to hyperactive, agitated states
 - Delirious patient at risk for developing
 - Long-term cognitive impairment
 - Greater length of ICU and hospital stay
 - Increased mortality

EVALUATION

- Anxiety is a valid emotional response to hospitalization in an ICU.
 - Overexuberant response to the stressors in the ICU environment can be detrimental.
 - Anxious patients have an increase in the incidence of several disease states/processes (Table 27.3).
 - Patients are examined daily to look for signs that increase anxiety likelihood (Table 27.4).
 - Laboratory evaluation (Table 27.5) is helpful in looking for causes.
- When a patient admits to excessive anxiety, first attempt is to decrease the anxiety through nonpharmacologic means (Table 27.6).
 - Recognize that the ICU environment must be calm and nurturing.
 - Attention to such details must be paid
 - Room temperature
 - Noise levels
 - Sleep disturbance—the bane of most modern ICUs
- 60% to 70% of patients in the ICU for longer than 48 hours require pharmacologic therapy (Table 27.7).
 - Opioids, benzodiazepines, haloperidol, propofol, and dexmedetomidine are treatment mainstays.

TREATMENT**Nonsteroidal Anti-inflammatory Drugs**

- Nonsteroidal anti-inflammatory drugs are not sedative but, by decreasing pain, they decrease pain-associated anxiety.
 - When cyclo-oxygenase-2 inhibitors coupled with gabapentin or its precursor, pregabalin, they have analgesic and sedative properties if given preoperatively *per os* to patients who are anticipated to be admitted postoperatively to the ICU.

TABLE 27.5**LABORATORY EVALUATION**

Complete blood count (anemia, leukocytosis/leukopenia)

TABLE 27.6**NONPHARMACOLOGIC THERAPY FOR ANXIETY-PRODUCING EVENTS**

Thorough explanation of situation/findings
 Reassurance
 Increased presence of family members
 Decreased noise
 Decreased nocturnal interruptions
 Assisted ventilation for hypercarbia
 Cardioversion for hemodynamically significant tachyarrhythmias
 Decrease/stop tube feedings if (partial) ileus
 Foley catheter for bladder distention
 Re-establishment of sleep cycle

- A combination of 400 mg of celecoxib and 150 mg of pregabalin improved patients' sedation levels by approximately 33% for up to 24 hours postoperatively.

Opioids

- Opioids have not only analgesic but also anxiolytic properties.
 - Morphine is anxiolytic.
 - Not nearly as effective as newer opioids
 - Because of the buildup of active metabolites in patients with renal insufficiency, it is not recommended for patients in the ICU.
 - Fentanyl and remifentanyl are more than 90% effective in providing adequate sedation for intubated and mechanically ventilated patients in the ICU.
 - With equal efficacy and differences in cost, fentanyl is recommended in most patients, except those with significant renal/hepatic impairment (Table 27.8).

Benzodiazepines

- Benzodiazepines potentiate gamma-amino butyric acid (GABA) effects via the benzodiazepine receptor and suppress central nervous system (CNS) activity.
 - They have hypnotic, muscle-relaxant, anticonvulsive, and antegrade and variable retrograde amnesic properties.
 - No analgesic properties

TABLE 27.7**THERAPY FOR ANXIETY-PRODUCING EVENTS**

 Opioids
 Benzodiazepines
 Haloperidol
 Propofol
 Dexmedetomidine
 Ketamine

TABLE 27.8**OPIOIDS AS SEDATIVE DRUGS IN THE INTENSIVE CARE UNIT**

Drug ^a	Bolus dose	Infusion
Fentanyl	1 $\mu\text{g/kg}$	1–2 $\mu\text{g/kg/h}$
Remifentanyl	—	9 $\mu\text{g/kg/h}$

^aSide effects: Hypotension, nausea and vomiting, respiratory depression.

- Similar to the opioids, they produce respiratory depression in a dose-dependent fashion.
- Benzodiazepines are metabolized in the liver with the metabolites excreted by the kidneys.
 - Half-lives ($t_{1/2}$) are prolonged, and active metabolites may accumulate.
 - Commonly, benzodiazepines are administered by continuous infusion.
 - Context-sensitive $t_{1/2}$ is more germane but independent of the method of administration because of the potential prolonged effect.
 - Daily “off” period should be established to avoid over-dosage.
 - Commonly used ICU benzodiazepines are diazepam, midazolam, and lorazepam (Table 27.9).

Additional Cautions and Recommendations Regarding Benzodiazepine Use

- The US Food and Drug Administration has administered black box warnings for benzodiazepines.
- Anyone administering these respiratory depressants must be skilled in airway management and resuscitation.
- Must have the benzodiazepine antagonist flumazenil available in the ICU
 - Flumazenil has maximum effect within 5 to 10 minutes after IV administration and has a mean $t_{1/2}$ of approximately 1 hour.
 - Usually given in 0.1 to 0.2 mg increments, repeated every 5 to 10 minutes, to a total dose of 1 mg
 - Recommended that infusions of benzodiazepines be stopped for a daily drug “holiday”
 - Infusion stopped typically every morning around 7:00 or 8:00 AM.
 - Infusion remains off until the patient exhibits symptoms or signs that warrant restarting the infusion.
- Ramsey Sedation Scale can be used to monitor sedation (Table 27.10).
- Several others exist that may be used are more comprehensive (see Table 27.1).
- Once these medications are completely discontinued, up to one-third of the patients will exhibit signs of withdrawal.
 - Thus, discontinue the benzodiazepines slowly over several days.
 - Treat side effects of withdrawal—tachycardia and hypertension—with a beta-blocker or an alternative drug, including chronic low doses of benzodiazepines if beta-blockers are contraindicated.

TABLE 27.9

BENZODIAZEPINES USED FOR ANXIOLYSIS IN THE ICU

Drug (classification)	$t_{1/2}$ (h)	Active metabolite(s) ($t_{1/2}$)	Intermittent IV bolus	Continuous IV infusion
Diazepam (long-acting)	20–50	Desmethyldiazepam (30–200)	1–2 mg (max 0.1–0.2 mg/kg)	—
Lorazepam (intermittent-acting)	10–20	None ^a	0.5–2 mg (max 4 mg)	Up to 0.025 mg/kg/h
Midazolam (short-acting)	1–2.5	1-hydroxy midazolam	0.5–2 mg (max 0.1 mg/kg)	Up to 0.05 mg/kg/h

^a3–O-phenolic glucuronide is the inactive metabolite.

Propofol

- Propofol (di-isopropylphenol)
 - Highly lipophilic compound formulated in an isotonic oil in water emulsion (Intralipid) unrelated to other sedative/anesthetic agents.
 - Side effects include hypertriglyceridemia and bacterial contamination of infusions.
 - Addition of ethylenediaminetetraacetic acid or bisulfite as preservatives decreases the incidence of bacterial overgrowth.
 - Rare side effect is propofol infusion syndrome
 - Metabolic acidosis and ventricular fibrillation in children and in young adults with neurologic injury receiving >100 $\mu\text{g/kg/minute}$ for more than 12 to 24 hours.
 - Propofol probably most commonly used IV anesthesia induction agent.
 - Advocated for use in moderate sedation (endoscopy suite) protocols
 - Rapid onset and offset, few residual aftereffects, and low side-effect profile makes it often used for short-term sedation in the ICU.
 - Propofol has no analgesic properties.
 - For patients with pain, an analgesic drug should be co-administered.
- Propofol has also been used to treat status epilepticus and to induce sleep in the ICU.

Dexmedetomidine

- Alpha-2 (α_2) agonists, such as methyl dopa and clonidine, long known to have sedative properties.

- Clonidine is administered epidurally for its antinociceptive effects in the spinal cord.
- Dexmedetomidine is an α_2 agonist that binds to α_2 receptors in the locus ceruleus.
 - α_2/α_1 ratio of approximately 1,620:1
 - Approximately seven times more avidly than clonidine
 - Binding to the α_2 receptor releases norepinephrine and decreases sympathetic activity
 - Net effect is sedation, analgesia, and amnesia
 - Dexmedetomidine is unique compared to the other anxiolytic drugs because patients are not only calm but appear to be sleeping.
 - Commonly used to sedate patients after cardiac surgery and after neurosurgical procedures
 - Patients who abuse alcohol, cocaine, and marijuana may benefit the most because dexmedetomidine treats many of the symptoms and signs of withdrawal.
 - Dexmedetomidine not associated with respiratory depression, unlike opioids or benzodiazepines.
 - Because of its central alpha agonist, hypotension can and does occur.
 - Low-dose dexmedetomidine (6 $\mu\text{g/kg/hour}$ for 10 minutes followed by an infusion of 0.2 $\mu\text{g/kg/hour}$) is as effective as higher doses (0.6 $\mu\text{g/kg/hour}$), with fewer side effects.
 - Concern of a hyperdynamic state if dexmedetomidine used for more than 24 hours and discontinued abruptly
 - Similar to the one that develops when clonidine is stopped abruptly after long-term use
 - Dexmedetomidine is FDA approved for 24-hour use.
 - Many clinicians are using it for longer than 24 hours.
 - Dexmedetomidine the most expensive of common sedatives.

TABLE 27.10

RAMSEY SEDATION SCALE

Patient:	
} Awake	1. Anxious or agitated
	2. Cooperative/tranquil
	3. Responds to commands only, response to glabellar tap
} Asleep	4. Brisk
	5. Sluggish
	6. None

Butyrophenones

- Neuroleptic drugs also known as antipsychotic drugs or major tranquilizers
- Induce apathy, a state of mental detachment in patients with psychoses or delirium
- Inhibit dopamine-mediated neurotransmissions in CNS and decrease the frequency of hallucinations, delusions, and other abnormal thoughts
- Patients may develop a characteristic flat affect.
- Active in the chemoreceptor trigger zone in the brainstem and thus are effective antiemetics
- Also used to treat hiccups

- A synergistic anxiolytic drugs when used with benzodiazepines
- Haloperidol used most often to treat delirium in the ICU
 - Has a wide therapeutic margin
 - Rare but important side effects including hypotension, extrapyramidal symptoms, anticholinergic effects (tachycardia, urinary retention, ileus), neuroleptic malignant syndrome, and seizures
 - Hypotension after a dose of haloperidol almost always seen in patients who are hypovolemic
 - Extrapyramidal symptoms are more often seen in younger patients and in patients with depleted dopamine stores (e.g., patients with Parkinson disease).
- Initial dose of haloperidol
 - Usually 0.5 to 2 mg administered parenterally
 - Depending on the patient's size, age, and degree of agitation/delirium, 5 mg can be given.
 - Has a slow onset, so peak effects may not be seen for 15 to 30 minutes
 - Repeat doses then administered at 30- to 60-minute intervals
 - Recurrence of agitation or an increase in delirium is an indication for repeat doses, which may be increased if the initial dose was inadequate
 - Tardive dyskinesia or neuroleptic malignant syndrome can occur even during the short duration of therapy used in the ICU.
 - Because of its anticholinergic effects, may prolong the QT in a dose-dependent fashion
 - Resulting in arrhythmias and torsades de pointes
 - Those receiving haloperidol should have electrocardiogram monitored
- Retrospectively in mechanically ventilated ICU patients, those receiving haloperidol had significantly lower mortality than those who did not

Other Agents

- **Barbiturates:** Have pronounced effects on the CNS, lowering intracranial pressure and raising the seizure threshold
 - Used to induce a “barbiturate coma” in patients with increased intracranial pressure and terminate seizures
 - Administered by IV bolus to produce hypotension
 - Because of lipid solubility, if given by continuous infusion, accumulate in fat stores
 - Thus have a duration of action that can be significantly long (i.e., days to weeks)
 - Infrequently administered by continuous infusion for long-term use except as salvage for elevated
- **Ketamine:** A phencyclidine derivative nonbarbiturate, rapid-acting, general anesthetic
 - Administered parenterally
 - Induces “dissociative anesthesia” because it interrupts association pathways of the brain before blocking sensory pathways
 - Patients may perceive pain, but it does not bother them.
 - Because it is a phencyclidine derivative, 10% to 20% of adult patients may have psychological sequelae including hallucinations.
 - Used as a general anesthetic because it raises cardiac output, pulse rate, and arterial and venous pressures

- Maintains pharyngeal and laryngeal reflexes without suppressing respiration
- A bronchodilator and advocated as the anesthetic agent of choice in patients with reactive airways disease
- Dose
 - 1-mg/kg bolus of ketamine can be administered, followed by an infusion of 1.0 mg/kg/hour, titrated up to 4.5 mg/kg/hour
 - Administer a benzodiazepine to reduce the frequency of psychologic sequelae
 - Ketamine is contraindicated in patients with cardiac ischemia or raised intracranial pressure.

Neuromuscular Blockade

- Even with effective doses of anxiolytic drugs, some patients remain delirious and agitated, and a further increase in the dose of anxiolytic drugs is proscribed because of side effects.
- Such patients, along with those with closed-head injuries, tetanus, and ALL, may require other therapeutic modalities.
- If patient is tracheally intubated, mechanically ventilated, and receiving adequate sedation, chemical paralysis with a neuromuscular blocking agent (NMBA) is an option (Table 27.11).

Monitoring

- Before administering NMBAs, patients must be mechanically ventilated, sedated, and monitored.
- Most practitioners will first implement sedation therapy to the point that the patient is unconscious before initiating NMBA therapy.
- Monitoring the depth of blockade and the necessity of blockade is essential in minimizing these side effects.
 - Assessing the degree of blockade by measuring the amount of block of the neuromuscular receptor with a twitch monitor is the preferred technique.
 - An electrical stimulus is applied to a peripheral motor nerve, and the effects of the stimulus on the motor group supplied by that nerve are observed (Figs. 27.1 and 27.2).
 - Most often performed using a twitch stimulator that generates a stimulus of up to 160 mA intensity that lasts 10 ms and is repeated every 500 ms so that four stimuli (train-of-four [TOF]) are delivered
 - Effects can be visualized, but the preferred technique is for the observer to palpate the response.

TABLE 27.11

INDICATIONS FOR THE MANAGEMENT OF PATIENTS WITH NEUROMUSCULAR BLOCKING AGENTS

Closed-head injury with raised intracranial pressure
Tetanus
Decreased SvO_2 in hypermetabolic, agitated states

Purpose:

To describe the process of utilizing a nerve stimulator to stimulate the ulnar nerve, usually with tactile assessment of a neuromuscular twitch, usually tactile assessment of an abducted thumb, to assess the degree of neuromuscular block.

Definitions:

Neuromuscular block: the process by which the postsynaptic acetylcholine receptor is depressed and variably response to release of acetylcholine in the neuromuscular junction cleft

Peripheral nerve stimulation: electrical stimulation, usually from 40 to 120 mA at a peripheral nerve, usually the ulnar, either at the elbow or at the wrist

Train-of-four: a specific type of nerve stimulation in which the nerve stimulator delivers an electrical stimulus to the nerve lasting 10 ms and repeated every 500 ms for a total of 4 stimuli

Equipment:

1. Peripheral nerve stimulator
2. Two electrode pads (electrocardiogram pads may be used)

Procedure:

1. Clean the area where the electrode pads will be placed with alcohol to remove any skin oils. This will reduce the resistance at the skin and decrease the amount of current needed to stimulate the nerve. If the resistance of the skin is still high, then an abrasive compound can be used to remove dead skin.
2. Place two electrodes over the ulnar nerve, usually 3 to 5 cm apart.
3. Attach electrodes to the leads, usually the positive electrode proximally.
4. Cover the fingers and abduct the thumb. Increase the amperage of the stimulator until 4 twitches of the thumb are palpated by tactile assessment. Stimuli should not be delivered more frequently than every 20 seconds. Once 4 twitches are palpated, a supramaximal stimulus can be delivered by increasing the amperage 10% to 30% over the amperage required to palpate 4 twitches.

Goals:

1. To achieve a level of train-of-four of 2 to 4. If with 3 or 4 twitches the patient either spontaneously triggers the ventilator or exhibits muscular activity that adversely affects oxygenation or airway or intracranial pressure, then increased neuromuscular block is required.
2. A train-of-four of 1 to 0 indicates that the degree of neuromuscular block is too great, and the dosage of neuromuscular blocking agent should be decreased.

FIGURE 27.1. Protocol for monitoring degree of neuromuscular block using a nerve stimulator and assessment of the train-of-four twitch. (Reproduced from Murray MJ, Oyen L, Bazzell CM. Use of sedatives, analgesics, and neuromuscular blockers. In: Parillo JE, Dellinger RP, eds. *Critical Care Medicine: Principles of Diagnosis and Management*. 2nd ed. St. Louis, MO: Mosby; 2001:296–311, with permission.)

- Probably easiest to measure the TOF response by stimulating the ulnar nerve at the wrist
- Goal of therapy is to provide a sufficient amount of drug so that the patient has only one to two twitches,

as opposed to none (overblocked) or three to four (possibly underblocked) twitches.

FIGURE 27.2. Train-of-four monitoring. A: With the twitch stimulator at 40 to 10 mA, four twitches are measured. B: As the neuromuscular blocking agent (NMBA) takes effect, the second, third, and fourth twitches are weaker/fade. C: The goal with additional time or drug is to have one to two twitches.

Complications of Neuromuscular Blocking Agents

- One of the most feared complications of neuromuscular block is accidental extubation.
 - Should a paralyzed patient become accidentally extubated, time is of the essence, especially in patients with adult respiratory distress syndrome
 - Ventilation must begin immediately with a mask and anesthesia bag using 100% oxygen while steps are taken to reintubate the patient.
- Another complication is profound weakness once the drug is discontinued.
 - Approximately 10% of patients who receive NMBAs will develop a myopathy from which it takes days or weeks to recover.
 - Known as critical illness myopathy (CIM)
 - Cause of CIM in ICU multifactorial
 - Prolonged use of NMBAs in the ICU is one of the causative factors
 - Corticosteroids are also known to produce myopathy
 - Daily assessments must be made to determine whether NMBA use is justified, and the TOF should be maintained at one to two twitches

Agents: Aminosteroids

- **Pancuronium:** A long-acting, nondepolarizing, aminosteroidal compound
 - Produces effective block for up to 90 minutes after a bolus dose of 0.06 to 0.08 mg/kg
 - Intermittent boluses often administered but can be used as a continuous infusion, titrating the dose to one or two twitches by TOF monitor
 - Induces vagolysis, limiting its use in patients who cannot tolerate an increase in heart rate
 - With renal or liver failure, pancuronium's effects are prolonged because of the increased elimination $t_{1/2}$ of pancuronium and its 3-hydroxypancuronium metabolite, which has one-third to one-half the activity of pancuronium.
- **Vecuronium:** Related to pancuronium, but an intermediate-acting NMBA without the vagolytic properties of pancuronium
 - IV bolus dose of 0.08 to 0.10 mg/kg produces block within 2½ to 3 minutes that typically lasts 35 to 45 minutes.
 - After a bolus, may be administered as a continuous infusion of 0.8 to 1.4 µg/kg/minute, titrating the rate to the degree of block desired
 - The 3-desacetylvecuronium metabolite has 50% of the pharmacologic activity of the parent compound
 - Patients with hepatic dysfunction may have increased plasma concentrations of both the parent compound and the active metabolite, causing prolonged block.
 - Renal dysfunction also prolongs the duration of block.
 - Associated with CIM, especially in patients receiving corticosteroids
- **Rocuronium:** A newer aminosteroidal NMBA, with an intermediate duration of action and a rapid onset
 - A bolus of 0.6 to 0.1 mg/kg results in a block almost always achieved within 2 minutes, with maximum block occurring within 3 minutes.
- Continuous infusions are administered at 8 to 10 µg/kg/minute.
 - Rocuronium's metabolite, 17-desacetylrocuronium, has approximately only 5% to 10% activity compared to the parent compound.
 - Renal failure should not have an effect on duration of action, but hepatic failure may prolong rocuronium's duration of action.

Agents: Benzylisoquinolinium Compounds

- **Atracurium:** An intermediate-acting NMBA with minimal cardiovascular side effects
 - Associated with histamine release at higher doses
 - Unique metabolism (ester hydrolysis and Hofmann elimination) so that renal or hepatic dysfunction does not affect its duration of block

- Has been associated with persistent neuromuscular weakness as has been reported with other NMBAs
- **Cisatracurium:** One of atracurium's 16 isomers
 - An intermediate-acting benzylisoquinolinium NMBA
 - Produces few cardiovascular effects
 - Has fewer tendencies to produce mast cell degranulation than does atracurium
 - Bolus doses with a 0.10 to 0.2 mg/kg result in paralysis in an average of 2.5 minutes, and recovery begins at approximately 25 minutes.
 - Maintenance infusion rates should be started at 2.5 to 3.0 µg/kg/minute.
 - Metabolized by ester hydrolysis and Hofmann elimination, so duration of block should not be affected by multiorgan dysfunction syndrome.
 - Not yet been reports of significantly prolonged recovery associated with cisatracurium
 - Mean peak plasma laudanosine concentrations are lower in patients receiving cisatracurium as compared to patients receiving clinically equivalent doses of atracurium.
 - Laudanosine at high doses produces seizures in animals.
 - A case of seizures in a human receiving atracurium or cisatracurium has not been reported.

Recovery

- Patients receiving an NMBA should have daily drug holidays.
 - When NMBA is no longer required, it is discontinued.
 - With all the NMBAs, the TOF should normalize (four twitches) within 3 to 4 hours
 - If not, the patient may have a CIM associated with the NMBA (with an increased incidence in patients receiving corticosteroids and patients with sepsis, etc.).
 - If, after 24 hours, the patient has inadequate strength, additional studies should be done to include an assessment of the antibiotics the patient is receiving, electrolytes (calcium, magnesium, phosphorus), and temperature (hypothermia prolongs neuromuscular block).
 - If no comorbid condition accounts for the degree of neuromuscular block, a neurology consult should be considered.
 - Electromyography is typically performed (to rule out critical illness polyneuropathy).
 - In some circumstances, a muscle biopsy is obtained.
 - Patients with CIM secondary to the neuromuscular blockade will have loss of myosin.
 - Treatment is supportive with maintenance of sedation, mechanical ventilation, physical therapy, skin care, eye care, and so on.

CHAPTER 28 ■ NUTRITIONAL ISSUES

IMMEDIATE CONCERNS

- There is no medical evidence that starvation is therapeutic.
 - More than 25 years ago, it was noted that the catabolic response to multiple injuries resulted in loss of up to 20% of normal body weight within 3 weeks despite some oral intake started during the first week.
 - Catabolic rapid wasting of large weight-bearing muscle groups of critically injured patients in a hospital setting has been noted (Table 28.1).
 - Critical illness most frequently compromises a patient's ability to normally take in adequate nutrition; critical care technology offers several alternative routes of providing nutritional support (Table 28.2).
 - Intravenous routes—total parenteral nutrition (TPN) and peripheral parenteral nutrition
 - Enteral routes with various formulae tailored to the patient's unique requirements

NUTRITIONAL ASSESSMENT

- Critically ill patients are at risk for nutritional deficiencies.
 - Diagnostic criteria for various protein and calorie-deficient states are noted in Table 28.3.
 - Because of the risk that a critically ill patient with underlying nutritional deficiency will develop marasmic kwashiorkor, they are screened for chronic undernutrition on admission to the hospital/intensive care unit.
 - One such screening tool, the Malnutrition Universal Screening Tool (MUST), provides a numerical index.
 - 0: minimal risk
 - 1: medium risk
 - 2: high risk of malnutrition
 - Urgency of instituting nutritional support increases for patients with a score of 1 and especially 2.
 - MUST evaluates

TABLE 28.1

EBB—FLOW PHASE OF RESPONSE TO INJURY

	Ebb	Catabolic flow	Anabolic flow
O ₂ consumption	↓	↑↑	↑
Nitrogen balance	↓	↓↓	↑
Cortisol	↑	↑	
Epinephrine	↑↑↑		
Insulin	↑	↑	↑↑
Glucagon	↑↑	↑↑	↑
Glucose	↑	↑	

- Patients' body mass index (weight in kilograms [kg] divided by height in meters squared [m²])
- Prehospital involuntary weight loss as a percent of body weight
- Potential for critical illness-induced starvation for the next 5 days.
- Many biochemical markers are available to track a patient's nutritional state.
 - Albumin concentration—a good prognostic marker of a patient's *chronic* nutritional state
 - Perioperative mortality has been shown to increase when albumin concentration is <30 g/L.
 - Serum albumin has a long serum half-life and, hence, does not reflect acute responses to nutritional therapy.
 - Estimates of whole-body potassium
 - Total body potassium represents lean cellular mass and can be a useful measurement of changes in lean tissue mass that occur rather slowly.

TABLE 28.2

COMMONLY USED ROUTES OF NUTRITION

Enteral	Parenteral	
	Central	Peripheral
Advantages Uses gut barrier to control water and electrolyte absorption; natural relationship for hepatic “first pass” metabolism; cost-effective	Uninterrupted nutrient administration; can be continued in operating room; rapid change in formula possible; does not interfere with oral drug administration; does not depend on gut motility	Avoids central venous catheter
Disadvantages Frequent interruptions for NPO status; interference with drug absorption (e.g., phenytoin); frequent feeding tube complications	Hyperosmolar, hyperglycemic coma; expensive; central venous line complications/infections	Partial nutritional support to supplement low levels of enteral intake
NPO, nothing by mouth.		

TABLE 28.3**INDICES OF MALNUTRITION: PROTEIN-ENERGY MALNUTRITION**

% IBW	Undernutrition 80%	Marasmus less than 60%	Kwashiorkor 60%–80% with edema	Obesity
BMI	18.5–20	<18.5	<18.5	30
Unplanned weight loss past 3–6 mo	5%–10%			<5%
Acute disease effect	Iatrogenic starvation	Prolonged underfeeding with catabolic illness	Severe protein-energy deprivation, usually prolonged fasting with catabolic diseases	Eating
Arm circ. (cm)	23.5	<23.5	<23.5	32.0
MUST score	1	2	2	0
Edema	–	–	+	–
Cause	Low nutrition intake, chronic illness	Low protein calorie intake	Low protein intake	Excess energy intake
T-lymphocyte count (cells/ μ L)	<1,800	<800	<800	2,000

IBW, ideal body weight; BMI, body mass index; circ., circumference; MUST, Malnutrition Universal Screening Tool.

- Similarly, 24-hour creatinine production is a marker of total skeletal muscle mass.
- Both of these markers change relatively slowly and may not be useful to monitor the patient's response to nutritional therapy for critical illness.

- Water balance
- Visceral proteins such as prealbumin, transferrin, and retinol-binding protein
 - Short half-lives make these useful to monitor protein synthetic response to nutritional support therapy.
- Nitrogen (N) balance via a 24-hour urine urea nitrogen excretion is a useful technique to monitor response to nutritional support (Table 28.4).
- If the patient's blood urea nitrogen is not stable, corrections for retained N must be performed.

- Energy expenditure may be calculated by the Harris-Benedict equation or measured directly with an indirect calorimeter (Table 28.5).
- Overall monitoring of a patient's response to nutrition support performed by a battery of the tests described earlier
 - Daily weights are tracked to monitor a patient's response to nutritional support.
 - Initially, weight gain will represent an increase in total body water, which will start decreasing (diuresing) as the patient becomes anabolic.
 - During the anabolic phase, the patient will initially lose weight via diuresis of water, then gain weight as lean body mass.
 - Obese patients may continue to lose weight from fat stores if they are fed a high-protein, restricted calorie diet.

TABLE 28.4**ASSESSMENT OF DAILY NITROGEN BALANCE**

Nitrogen intake = protein administered in g/day divided by 6.25 = g N/day
 [0.1 g protein = 0.16 g N (6.25 g protein contains 1 g N)]
 Urine urea nitrogen = 80% of total urine nitrogen
 1 g (16.6 mMol) urea = 28/60 g nitrogen^a
 1) 24-h urine urea N in g/day = (A) in g
 2) Measure of proteinuria, if any = Y

$$Y \times 0.16 = (B) \text{ in g}$$

3) Correction for any rise of BUN assuming no change in body weight in kg
 Rise in blood urea (in 24 h) = Z in g · L⁻¹
 Z in g × 60% body weight × 28/60 = Z × body weight × 0.28 = (C) in g
 (A) + (B) + (C) = nitrogen loss
 N balance = (nitrogen intake – nitrogen loss)

BUN, blood urea nitrogen.

^a28 is molecular weight of N in urea and 60 is total molecular weight of urea (i.e., 1 g urea = 0.47 g N).

TABLE 28.5**INDIRECT CALORIMETRY—DAILY ENERGY EXPENDITURE**

$$\text{Kcal/day} = 3.94 \times \text{VO}_2 \text{ (L/24 h)} + 1.11 \times \text{VCO}_2 \text{ (L/24 h)} \times 2.17 \text{ UN (g/24 h)}$$

$$\text{VO}_2 = [(\text{FiO}_2 \times \text{V}_1) - (\text{FE}_2 \times \text{V}_E)] \times 1,440 \text{ min/24 h}$$

$$\text{VCO}_2 = (\text{FE}_2 \times \text{V}_E - \text{FiCO}_2 \times \text{V}_1) \times 1,440 \text{ min/24 h}$$

$$\text{V}_1 = \frac{\text{VE}[(1 - \text{FE}_2) - \text{FE}_2 \text{CO}_2]}{(1 - \text{FiO}_2)} \text{ Haldane correction}$$

VO₂ = oxygen consumption (L/24 h)
 VCO₂ = carbon dioxide production (L/24 h)
 V₁ = inspired ventilation (L/min)
 V_E = expired ventilation (L/min)
 FiO₂ = mole fraction inspired oxygen
 FE₂ = mole fraction expired oxygen
 FiCO₂ = mole fraction inspired carbon dioxide (assumed to be 0)
 FE₂CO₂ = mole fraction expired carbon dioxide
 UN = 24-hour urinary nitrogen loss (g/24 h)

- Functional measurements that indirectly depend on the nutrition response, such as immunologic function, can be followed.
 - Severely malnourished patient exhibits immunocompromise by skin test anergy, low absolute lymphocyte count, low T-cell lymphocyte count, difficulty mounting a fever, and increased susceptibility to infections.
 - These functions should improve with aggressive nutritional support.

Timing of Nutritional Support

- Once the decision is made to provide nutritional support for the critically ill, one has to decide on the best route of administration—parenteral or enteral.
- One to two decades ago, parenteral nutrition (TPN) was thought to be associated with a higher mortality rate than enteral nutrition in patients who had abdominal trauma.
 - More recently, the major difference between total enteral nutrition (TEN) and TPN was the fact that enteral-fed patients had more frequent interruptions of nutrition).
- There has been grave concern that TPN puts a patient at risk for serious infection complications.
 - Bloodstream infections are relatively rare during TPN.
 - TEN patients have a significantly higher incidence of feeding tube complications than TPN patients have from central venous catheter complications.
- Inadequate nutritional intake (<7 kcal/kg/day) was associated with sepsis.
- Those who received TEN were equally likely to have infectious complications as those who received TPN.
 - Starting early and adequate nutrition support to prevent infectious morbidity is important.
- An alleged benefit of early enteral feeding is to maintain the integrity of the gut mucosal lining and thus limit translocation of microorganisms from intestinal lumen to bloodstream.
 - This may not be correct, as bacterial translocation from the gut to the bloodstream is not the source of bloodstream infections in patients who are fed parenterally.
- TEN does have some demonstrated advantages over TPN.
 - Lower cost
 - Using gut absorption to regulate total body water balance
 - Ability to utilize larger molecules as a food source
- TPN has advantages over TEN that include fewer interruptions for NPO status prior to procedures and no interference with drug absorption.

Nutritional Support for Specific Organ Dysfunction

Hepatic Failure

- One of the most vexing morbidities requiring prescriptions for nutritional support
- Nitrogen from amino acid metabolism remains as ammonia because it is not metabolized to urea in severe disease.
- Hyperammonemia leads to secondary neurologic dysfunction including hepatic coma.
- Protein needs to be administered in amounts to replace catabolic losses but not high enough to lead to high levels of ammonia.
- Sorbitol may be administered enterally to try to lower ammonia by increasing gut motility and decreasing intestinal transit time to decrease the absorption of proteins and ammonia from bacterial metabolism of intraluminal amino acids.
- Hepatic glycogen stores are also depleted in end-stage hepatic failure.
 - Maintenance of normoglycemia is extremely difficult.
 - High glucose feedings may be required to compensate for lack of hepatic glucose production.

Renal Failure

- Rising blood levels of the nitrogenous waste product urea and creatinine are the hallmarks
- Acute renal failure is rather common in critically ill patients in response to intrarenal insults from circulating inflammatory mediators and changes in renal perfusion.
- Modern critical care uses renal replacement therapy.
 - Either hemodialysis or continuous venovenous hemofiltration to maintain acceptable levels of urea, creatinine, and electrolytes until the kidney regains its function.
 - One of the few evidence-based therapies that enhances the repair of acute renal failure is nutritional support with adequate protein for renal healing.

Glycemic Control

- Hyperglycemia is a common occurrence in critically ill patients.
- Not all hyperglycemic critically ill patients have diabetes.
- The hormonal milieu of the stress response tends to cause hyperglycemia.
 - Among the hormones that increase plasma glucose are growth hormone, cortisol, glucagon, and epinephrine.
 - A diagnostic hallmark of sepsis is glucose intolerance/insulin resistance.
 - Normoglycemia has a significant improvement in outcome effects that persists for several months after recovery.
 - These effects included decreased intensive care unit length of stay, reduced infectious complications, and survival.
 - It is recommended that critically ill patients be managed with normal glucose levels.
 - Insulin infusion is the best method to manage glucose concentrations.

Brain Injury

- The injured brain is characterized by an impairment of the blood–brain barrier.
- Causes increased susceptibility to changes in plasma concentrations of glucose and electrolytes.
- Important goal is the prevention of edema in the injured brain.
- Nutritional goals for the head-injured patient include avoidance of hyperglycemia, hyperosmolar state, and maintenance of normal sodium and potassium.
 - Hyperglycemia, even with normal osmolality, is detrimental to the injured brain by causing cerebral edema in ischemic areas of the brain.

- Occurs when one glucose molecule diffuses into the brain and is anaerobically metabolized to two lactic acid molecules that are highly polar and do not diffuse out into the bloodstream.
- The interior of the cell increases in osmolality (more nondiffusible particles) relative to plasma and attracts increased cell water.
- Sodium replacement is important in brain-injured patients.
- Many patients with brain injuries develop hyponatremia.
 - Tends to increase the risk of cerebral edema from excess plasma water and decreased serum osmolality
 - Cerebral salt-wasting syndrome or inability to conserve sodium in the kidney needs to be differentiated from syndrome of inappropriate antidiuretic hormone secretion.
- Cerebral salt-wasting patients tend to be hypovolemic and need extra sodium replacement in their nutrition support.
- Syndrome of inappropriate antidiuretic hormone patients tend to be hypervolemic and generally need fluid restriction to correct their serum sodium levels.
- Brain-injured patients require adequate protein to compensate for their increased demands to provide brain healing.
- Metabolic rate should be measured directly
- Caloric needs met by appropriate amounts of nutritional support
- Some concern about excitatory amino acids having deleterious effects on the injured brain but unclear that nutritional support affects the central nervous system concentration of these amino acids.

CHAPTER 29 ■ PRACTICAL ASPECTS OF NUTRITIONAL SUPPORT

WRITING A TOTAL PARENTERAL NUTRITION ORDER

- Life-threatening errors continue to occur in the preparation and delivery of total parenteral nutrition (TPN).
- Many errors are related to the ordering process.
- One solution—albeit imperfect—is to use an institution-specific standardized TPN form.
- The ultimate goal of nutritional support is to minimize loss of lean body mass, especially in patients with burns, sepsis, acute respiratory distress syndrome, and trauma.
- Energy expenditure of the critically ill patient depends on the underlying disease state and on the nutritional status of the patient before the injury or illness.
- The Harris–Benedict equation, widely used to estimate the basal energy expenditure, may be excessive and can lead to overfeeding.
 - The American Society of Parenteral and Enteral Nutrition (ASPEN) guidelines and American College of Chest Physicians (ACCP) suggest using a total energy requirement of 25 kcal/kg/day.
 - An adjusted body weight should be used in the calculation for the obese.
- Protein requirements for critically ill patients with normal renal function range from 1.3 to 2 g/kg/day (moderate to severe stress), using the premorbid body weight or the adjusted body weight if obese.
 - In acute renal failure patients, ASPEN recommended protein amounts are as follows:
 - 0.8 to 1.2 g/kg/day if patients are not dialyzed
 - 1 to 1.4 g/kg/day in patients receiving dialysis
 - 1.5 to 2.5 g/kg/day in patients undergoing continuous renal replacement therapy (CRRT)
 - For chronic kidney disease, the ASPEN recommends 0.5 to 0.6 g of protein per kilogram per day.
 - ACCP recommends no change in the amount of protein given to patients with acute renal failure versus patients with normal kidney function (i.e., 1.2 to 2 g/kg/day).
 - In chronic renal failure, the ACCP recommends 0.5 to 0.8 g of protein per kilogram per day.
- There are three different ways parenteral nutrition (PN) can be ordered.
 - If the patient has only peripheral venous access, peripheral parenteral nutrition (PPN) is used.
 - Compared to TPN, PPN is lower in osmolality (<900 mOsm/L) to minimize thrombophlebitis.
 - For formulas to be given via central line, TPN can be administered in two ways.
 - A two-in-one TPN formula, which is protein and dextrose in one bag, with the intravenous fat emulsions hung separately.
 - A three-in-one TPN formula, in which all three fuel substrates (amino acids [AAs], dextrose, and fats) are mixed in one bag.
 - Each has advantages and disadvantages. ASPEN guidelines do not favor one formulation over another.
 - For two-in-one formulas, fat is administered separately, usually three times a week.
 - To calculate the total caloric contributions, the amount of calories per week from fat is totaled and then divided

TABLE 29.1**RESPIRATORY QUOTIENT AND CALORIES PER GRAM OF DIFFERENT FUEL SUBSTRATES**

Fuel substrates	RQ	Kilocalories per gram
Fats	0.7	9 kcal/g; Intralipid 10% contains 1.1 kcal/mL and 20% contains 2 kcal/mL due to the presence of phospholipids
Proteins	0.8	4 kcal/g (these are not factored into the total calories administered per day)
Carbohydrates	1	3.4 kcal/g

by 7 days per week to obtain the calories per day. For example, Intralipid 20% 500 mL containing 1,000 kcal is given three times a week. The caloric contribution per day would be 3,000 kcal/week ÷ 7 days/week, which equals 429 kcal/day from fat.

- This amount is then added to the known calories provided by the dextrose and AAs in the two-in-one formula (Table 29.1).
- Most institutions have default amounts of additives (electrolytes) to facilitate the ordering process.
- Ordering electrolytes and other additives is as much an art as it is a science.

- With practice, one can develop a “feel” for how patients will respond to the additives depending on their condition.
- The most difficult part of the ordering process is how much electrolyte to add initially; subsequent adjustments are easier with adjustments to increase, decrease, or keep the additives the same, depending on the laboratory values (Table 29.2).

Initiating Parenteral Nutrition

- ASPEN guidelines suggest ≤ 150 to 200 g/day of glucose initially to ensure tolerance.
- Prudent to infuse only 1 L of the TPN on the first day at 42 mL/hour.
- Achieve goal rate on day 2 or 3, depending on the patient's tolerance.
- Central line placement must be verified by radiography before initiating TPN.
- TPN should be administered through a dedicated infusion port via an infusion pump that is equipped with protection from “free flow” and has reliable alarms.
- To reduce the chance for infusing particulates, microorganisms, and pyrogens, a 1.2- μ filter may be used in a three-in-one formula.
- A 0.22- μ filter may be used for a two-in-one formula.
- PPN formula is not as calorie dense and contains less protein; therefore, it may be initiated at goal rate.

TABLE 29.2**PARENTERAL NUTRITION (PN) ADDITIVES AND SUGGESTED AMOUNTS**

Electrolytes/additives	Suggested amounts	Comments
Sodium	1–2 mEq/kg/d	Assess the current IV fluid the patient is receiving and how the sodium level is responding (i.e., if the patient is receiving lactated Ringer solution [130 mEq/L], and Na^+ is within desired range, then add 130 mEq/L in the PN). Patients no longer requiring fluid resuscitation will need 1/2 normal saline or 80 mEq/L of Na^+ in PN.
Potassium	1–2 mEq/kg/d	Major intracellular cation. There is obligatory daily loss. Assess current repletion and patient's response as this will guide the clinician on how much to add to the PN.
Chloride	Default salt	This is the “acidifying” salt; acidemia is preferable in most situations to alkalemia (improved unloading of O_2 to the tissues). It can be given as either NaCl or KCl.
Acetate (Ac)	Add if patient has metabolic acidosis	May be useful in patients with metabolic acidosis secondary to renal failure; acetate is metabolized into bicarbonate in the body. Bicarbonate is not compatible in the PN solution. It can be given as NaAc or KAc.
Calcium gluconate	10–15 mEq/d	Use ionized calcium as a guide rather than total calcium.
Magnesium sulfate	8–20 mEq/d	Intracellular cation. It can accumulate in renal failure; 1 g = 8 mEq.
Phosphorus	20–40 mEq/d	Major intracellular anion. May be given as KPO_4 (4.4 mEq K^+ /3 mEq PO_4^-) or NaPO_4 (4 mEq Na^+ /3 mEq PO_4^-) depending on cation deficiency. Amount of calcium or phosphorus in total PN is limited by the calcium-phosphate solubility curve.
Trace elements	Standard amount daily	Adjust to twice a week in patients with severe renal failure and severe hepatic failure.
Insulin	Add 50%–70% of insulin sliding scale needs	Use amounts of insulin used by the sliding scale used in the last 24 h to guide how much to add to the PN bag. Start conservatively with 50%–70% of total insulin used during last 24 h.
H_2 blocker	Add total daily dose	Continuous infusion of H_2 blocker is superior in keeping pH elevated compared to intermittent dosing. ^a Protein pump inhibitors are not compatible in total PN.

^aBallesteros MA, Hogan DL, Koss MA, et al. Bolus or IV infusion of ranitidine: effects on gastric pH and acid secretions. A comparison of efficacy and cost. *Ann Intern Med.* 1990;112:334–339.
From Merritt R, ed. The ASPEN Nutrition Support Practice Manual. 2nd ed. Silver Spring, MD: ASPEN; 2005.

- PN administration set must be changed every 24 hours using aseptic techniques and universal precautions.
- If the PN does not contain fat emulsions, the administration set may be changed every 72 hours.
 - The administration set used in infusing the IV fat separately must be discarded after use or at least every 12 hours.

Transitional Feeding and Weaning Parenteral Nutrition

- The transitional period is when enteral feeding is started and PN is discontinued.
- Young patients with no history of malignancy, and were well nourished before PN was started can have it discontinued as soon as they are able to tolerate solid food.
 - Generally, PN can be discontinued once 60% of energy needs is met enterally.
 - In older debilitated patients who have a history of malnutrition and malignancy, transitioning to enteral feeds may be more challenging.
 - Calorie counts help to guide the reduction or discontinuation of PN.
 - Factors such as aspiration risk, appetite, strength, and ileus play a role in whether patients successfully transition to enteral feeds.
- Terminating TPN is just the opposite of initiating.
 - Major concern is rebound hypoglycemia from rapid cessation of PN.
 - Recommended that the TPN be decreased by half for 1 to 2 hours before discontinuation if the current infusion rate is >42 mL/hour.
 - This allows body to adjust its insulin secretion to decreasing amounts of circulating dextrose and avoid hypoglycemia.
 - Weaning of PN is not necessary in patients receiving oral nutrition.
- If problems occur with the TPN bag that render it not usable (e.g., a leak in the bag) and the patient is on a rate >42 mL/hour, dextrose 10% or dextrose 10% with 0.9% sodium chloride should be infused at the same rate as the TPN to avoid rebound hypoglycemia.
 - In the same scenario, dextrose 5% may be substituted in place of PPN, not because of rebound hypoglycemia but more for maintaining caloric intake.

Cyclic Parenteral Nutrition

- PN that is infusing 24 hours a day means.
 - Patient is tethered to the IV pole, limiting mobility.
 - Getting the patient to eat more may be problematic because the satiety center is constantly being stimulated.
 - Reduced oral intake can be expected if more than 25% of caloric needs is provided by PN.
- Cyclic PN may be a good option.
 - Cyclic or nocturnal PN has the same volume infused over a shorter period (12 or 14 hours) starting in the evening and finishing in the morning.

- Allows patients to be more mobile during the day and have more of an appetite.
- May see less deterioration of liver function.
- Nutritional goal needs to be defined.
 - Full support means that the total amount of protein and calories will be provided. In this case, it is important to make sure that the TPN is already concentrated, as the patient will be receiving the same volume that was previously given over 24 hours over a shorter period of time.
 - If the goal is to have the patient eat more but not get behind in nutrition, one can provide 50% of assessed needs as cyclic PN while the patient is fed orally or enterally.
 - An important aspect of cyclic TPN is calculating the tapered flow rate to minimize harmful fluctuations of blood sugar.
 - One simplified method of calculating the tedious cyclic PN rate comes from Stanford University:
 - $v = r + 2r + 4r(t - 4) + 2r + r$, where t = cyclic PN time, v = volume infused, and r = rate of PN
 - $v = 6r + 4rt = 16r$
 - $v = 4rt - 10r$
 - $v = r(4t - 10)$
 - $r = v/(4t - 10)$
 - $r = 1,500 \text{ mL}/[4(12 \text{ hours}) - 10]$
 - $r = 39.47$ or ~ 40 mL/hour
 - For example, the patient will be receiving a total of 1,500 mL (“v”) of PN formula X over 12 hours (“t”). To calculate the cyclic TPN rate (“r”), the formula uses the model $(r \text{ mL/hour} \times 1 \text{ hour}) + (2r \text{ mL/hour} \times 1 \text{ hour}) + [4r \text{ mL/hour} \times (\text{cyclic PN time} - 4)] + (2r \text{ mL/hour} \times 1 \text{ hour}) + (r \text{ mL/hour} \times 1 \text{ hour})$. Therefore, the cyclic TPN will be ordered as follows: 40 mL/hour \times 1 hour, then 80 mL/hour \times 1 hour, then 160 mL/hour \times 8 hour, then 80 mL/hour \times 1 hour, then 40 mL/hour \times 1 hour, then stop.
 - It is important that there be a “ramp up” and “ramp down” during cyclic TPN infusion to avoid significant glucose fluctuations. Glucose may be drawn 60 minutes after the maximal infusion rate or 60 minutes after discontinuation of cyclic PN to make sure the patient is tolerating.

Hidden Sources of Kilocalories

- Inadvertent hypercaloric feeding can result in increased carbon dioxide production, hyperglycemia, and hepatomegaly.
- Propofol, which is suspended in 10% Intralipid, contributes 1.1 kcal/mL.
 - Patient receiving 50 $\mu\text{g/kg/minute}$ (assuming a 70-kg patient) can easily receive an extra 554 kcal/day.
- Dextrose concentration in the dialysate fluid of patients receiving CRRT.
 - Diffusion greatly influences dextrose absorption across the hemofilter.
 - Daily caloric contribution ranges from 123 to 2,388 kcal depending on the dextrose concentration of 0.5% to 4.25% in the dialysate solution.

- Approximately 43% to 45% of dextrose can be absorbed by the body across the hemofilter.

Electrolyte Abnormalities

- Refeeding syndrome is an imbalance of electrolytes and vitamins, micronutrients, and fluids that occurs within the first few days of refeeding malnourished patients as nutrients replete the intracellular space.
- The hallmark biochemical findings include the following:
 - Hypophosphatemia (intracellular shift plus depletion of phosphorus substrate to synthesize adenosine triphosphate)
 - Hypomagnesemia (intracellular shift plus magnesium is a cofactor in many enzymatic functions)
 - Hypokalemia (intracellular shift of potassium with insulin secretion as a response to dextrose infusion)
- Patients may exhibit respiratory distress, cardiac arrhythmias, congestive heart failure, hemolytic anemia, or paresthesias, or they may die.
- The three most important steps in preventing refeeding are as follows:
 - Identify high-risk patients (chronic alcoholism, kwashiorkor, marasmus, rapid refeeding) and those receiving high TPN rates.
 - Baseline electrolytes must be checked before the initiation of PN and low magnesium, phosphorus, or potassium levels must be corrected immediately.
 - The TPN rate should be advanced slowly (<150 g/day of carbohydrates) as tolerated over several days before going to the goal rate.
- Patients receiving enteral nutrition could be advanced more aggressively if needed, provided that electrolytes are monitored closely and repleted in a timely manner.
- Replacing electrolytes is both a science and an art, because patients respond differently.
- Table 29.3 will help guide the clinician in managing electrolyte imbalances that occur. There are two things to remember when adjusting the electrolytes in PN: First, the degree of metabolic derangements must be determined before any adjustments are made. Second, PN should not be used to replace electrolytes rapidly, but should be used for maintenance.

Monitoring

- Potential for serious complications is high in patients receiving PN unless careful monitoring is conducted.
- Appropriate monitoring can be cost-effective by avoiding complications.
- Suggested protocols for monitoring PN in adults are shown in Table 29.4.

WRITING ENTERAL ORDERS

- Enteral feeding should be started as early as possible, as it is a “pharmacotherapy” for the gut (improves mesenteric blood flow and maintains gut integrity).
- Feeding early, defined as 48 hours within mechanical ventilation onset, is associated with a 20% decrease in intensive care unit (ICU) mortality and a 25% decrease in hospital mortality.
- When choosing enteral formulas, consideration depends on the patient’s digestive capability, fluid restriction status, electrolyte balance, nutrient requirements, disease state, and possible routes available for administration.
- Enteral formulas may be categorized.
 - The monomeric (which contain free amino acids with or without peptides, with modified fat)
 - The polymeric
 - Most enteral formulas fall in the semisynthetic polymeric formulas, which are more cost-effective but require patients to have digestive capability.
 - Monomeric formulas are for patients with malabsorption, such as short-gut syndrome.
 - Because of the cost, polymeric formulas should be tried first.
 - For instance, in patients with pancreatitis, instead of using monomeric formulas, adding pancreatic enzyme tablets may help with polymeric tube feed tolerance. If the patient continues to have absorption issues, monomeric formulas could be substituted.
- Enteral formulas also vary by caloric density.
 - In patients with chronic renal failure with fluid restriction, a high caloric-density polymeric (high caloric-to-fluid ratio) may be helpful.
- Enteral formulas also differ in the amount of protein, the carbohydrate-to-fat ratio, and the fiber content.
- Each enteral feed formula has known amounts of kilocalories per milliliter and grams per liter of protein.
 - Once caloric and protein needs are assessed, the volume needed can be calculated.
 - Enteral feeding formulas are fixed, but there are protein powders available if supplemental protein is necessary.
- Before starting any enteral feeds, feeding tube placement must be confirmed by abdominal radiography and documented in the orders.
- Once the enteral feeding formula has been selected, indicate initial strength (e.g., full or half-strength), initial rate in milliliters per hour, and desired progression regimen, followed by the goal rate.
 - Rate can be started at 10 to 20 mL/hour and be advanced by 10 to 20 mL/hour every 8 hours as tolerated until goal reached
 - As long as residual is <200 mL via nasogastric tube, or <100 mL via gastrostomy tube, in 4 hours.
 - Many institutions have converted to a “closed system” to reduce the risk of microbial contaminations by minimizing the number of times the formula is manipulated
 - These enteral feedings thus start at full strength as a “closed system” will make it difficult to order partial-strength formulas.
- When the patient is ready to transition over to a regular diet, similar strategies employed with the cyclic PN can be used.

- Ordering enteral feedings is less complex than ordering PN but just as confusing with many different formulas.

TABLE 29.3

AN EXAMPLE OF MANAGEMENT GUIDELINES FOR METABOLIC COMPLICATIONS IN ADULTS INDUCED BY PARENTERAL NUTRITION

Hyperglycemia	>200 mg/dL	Once daily requirements of insulin are known from the insulin sliding scale, add 50%–75% into TPN. Consider insulin drip if blood sugar is uncontrolled, or if patient is edematous with unreliable absorption of subcutaneous insulin. Goal blood sugar is 80–140 mg/dL in critically ill surgical patients
Hypoglycemia	<80 mg/dL	If related to sudden discontinuance of TPN, administer D10W or D10NS at the same rate as the TPN. If related to insulin in TPN, initiate continuous glucose supplement (e.g., D10W). If glucose is still below desirable level, discontinue TPN and hang D10W or D10NS at the same rate as the TPN
Hypernatremia	>150 mEq/L	If hypovolemic, give isotonic or hypotonic fluid depending on degree of hypovolemia. If euvoletic or hypervolemic, reduce sodium from TPN and/or other source. If patient is symptomatic, consider discontinuing TPN and starting D10W at the same rate as the TPN
Hyponatremia	<130 mEq/L	If hypervolemic, restrict fluid intake \pm diuretics; if euvoletic/hypovolemic, increase sodium content in TPN; if hypovolemic, give additional isotonic fluid
Hyperkalemia	>5 mEq/L	If TPN related and patient symptomatic, discontinue TPN and initiate D10W or D10NS at the same rate as the TPN. If patient is asymptomatic, decrease K ⁺ in TPN and other sources.
Hypokalemia	<3.5 mEq/L	Give KCl bolus either IV or enterally (4 mEq for each 0.1 <4.5 of K ⁺ ; maximum IV KCl concentration is 20 mEq/50 mL via central venous access and 10 mEq/50 mL via peripheral vein). Add K ⁺ in TPN
Hypermagnesemia	>2.6 mEq/L	If TPN related and patient is symptomatic, discontinue TPN and start D10W or D10NS at the same rate as the TPN. If patient is asymptomatic, decrease Mg ²⁺ in TPN
Hypomagnesemia	<1.8 mEq/L	Give magnesium bolus either IV or enterally (1 g MgSO ₄ = 8 mEq; 1 tablet magnesium oxide = 6 mEq). Maximum rate of IV infusion is 1 g in 7 min. (If level is <1, give 4–6 g IV or enteral equivalent; if level is >1 but <1.8, give 2–4 g IV or enteral equivalent). Increase Mg ²⁺ in TPN
Hypercalcemia	>10.2 mg/dL	If TPN related and patient is symptomatic, discontinue TPN and initiate D10W or D10NS at the same rate as the TPN. If patient is asymptomatic, decrease Ca ²⁺ in TPN. Check ionized calcium in critically ill patients
Hypocalcemia	<8.5 mg/dL	Correct for hypoalbuminemia [True Ca ²⁺ = Ca ²⁺ observed + 0.8 (4 – albumin observed)]. Increase Ca ²⁺ in TPN if corrected Ca ²⁺ is trending low. If hemodynamically unstable and/or critically ill, obtain an ionized calcium level (normal range 1.05–1.35 mg/dL). Give calcium chloride bolus via slow IV push if ionized calcium is low (<1.05) and patient is symptomatic (e.g., hypotensive). 1 g CaCl ₂ = 13.6 mEq; 1 g calcium gluconate = 4.7 mEq
Hyperphosphatemia	>4.8 mg/dL	If TPN related and patient is symptomatic, discontinue TPN and run D10W or D10NS at the same rate as the TPN. If patient is asymptomatic, decrease phosphate (PO ₄ ⁻) in TPN
Hypophosphatemia	<2.4 mg/dL	Phosphorus replacement should be given over 6 h to avoid hypotension. If level is <1, give 30 mMol PO ₄ ⁻ \times 2 doses IV plus check phosphorus level 1 h after end of infusion; if level is \geq 1 but <1.8, give 30 mMol PO ₄ ⁻ \times 1 dose or enteral equivalent and check phosphorus level 1 h after end of infusion; if level is \geq 1.8 but <2.4, give 15 mMol PO ₄ ⁻ or enteral equivalent. One packet of Neutra-Phos enterally = 8 mMol of PO ₄ ⁻ . Increase phosphorus in TPN
Metabolic acidosis	pH <7.4 HCO ₃ ⁻ <23	Consider increasing acetate-to-chloride ratio
Metabolic alkalosis	pH >7.4 HCO ₃ ⁻ >29	Consider increasing chloride-to-acetate ratio

TPN, total parenteral nutrition; D10W, dextrose 10%; D10NS, dextrose 10% with 0.9% sodium chloride.

- Patient may be converted to bolus feeding of full-strength enteral formula with increases of 60 to 120 mL every 8 to 12 hours as tolerated up to goal volume.
 - Bolus feedings are more physiologic, allowing the brain to stimulate sensations of hunger and satiety.
 - When patient is able to consume 60% of nutritional needs by mouth discontinue the tube feeds.

"Designer" Enteral Feedings: Facts and Myths

- Specialized formulas contain modified protein and other ingredients to assist patients in stressed states.
 - Sometimes the ratio of carbohydrate to fat, and the sources of fat, may also be altered to achieve desired effects.

TABLE 29.4**MONITORING PARAMETERS FOR CRITICALLY ILL ADULT PATIENTS ON PARENTERAL NUTRITION**

Parameter	Frequency
Na ⁺ , K ⁺ , Cl ⁻ , HCO ₃ ⁻ , BUN, serum creatinine	Daily
Ca ²⁺ , Mg ²⁺ , phosphorus, liver function tests	Two to three times per week
Serum triglycerides	Weekly
CBC with differential	Weekly
Input/output	Daily
Prealbumin	Weekly
Indirect calorimetry	As needed. Highly recommended in the following patients: Difficult to estimate accurately caloric requirements, inadequate response to nutrition support, and clinical signs of over- or underfeeding
24-h urine urea nitrogen	As needed. Highly recommended in the following patients: Difficult to estimate accurately protein requirements, inadequate response to nutrition support, and clinical signs of over- or underfeeding
Weight	Daily
Serum glucose	As needed to keep blood sugar control of 80–140 mg/dL

BUN, blood urea nitrogen; CBC, complete blood count.
From Merritt R, ed. *The ASPEN Nutrition Support Practice Manual*. 2nd ed. Silver Spring, MD: ASPEN; 2005.

Hepatic Formula

- Specialized hepatic formulas (e.g., NutriHep) differ from the standard formulas in two ways
 - Actual protein content is usually lower (around 40–46 g/L).
 - Ratio of branched-chain amino acids (BCAAs) to aromatic and ammonia-forming amino acids is higher in the hepatic formula.
 - Theory is that in liver dysfunction, depletion of BCAAs might enhance passage of ammonia-forming amino acids across the blood–brain barrier, resulting in the synthesis of false neurotransmitters.
 - By giving a higher BCAA formula, the altered ratio is returned to a more normal state.
- Although there are conflicting data, there is evidence of the beneficial effects of “special hepatic formulas” to support their use in the treatment of malnourished patients with advanced cirrhosis.
 - Based on the available studies and cost consideration of up to 20 times more, the “hepatic formula” should be restricted to patients who present with grade II or higher encephalopathy or whose grade of encephalopathy worsens with the advancement standard enteral formulation.

Renal Formula

- Formulas in this class (e.g., Nepro) are more calorie-dense and low in electrolytes and mineral contents (especially potassium and phosphorus)
 - These modifications are to provide adequate nutrients but minimize complications such as uremia, fluid overload, and electrolyte accumulation.
 - Older renal formulas differ from standard amino acids in that they were designed for patients who could not tolerate dialysis or for whom dialysis was being avoided.

- Thus, the formulas tend to be enriched with essential amino acids. The rationale with this admixture is that the urea from essential amino acids would be recycled to produce nonessential amino acids.
- Evidence supporting the use of the older renal formulas is scant and of poor quality.
 - Cost of the older renal formulas is 10 to 15 times that of standard polymeric formulas.
- These formulas have now been replaced with standard polymeric proteins, as most patients with acute renal failure are now being dialyzed or are receiving CRRT.
 - The new renal formulas are more calorie dense (usually 2 kcal/mL) with minimal electrolytes or additives (K⁺, Mg²⁺, PO₄⁻) that could accumulate in renal failure.
 - They are appropriate for patients whose serum electrolyte and mineral levels are difficult to control.

Pulmonary Formula

- Respiratory quotient (RQ) is defined as the molecules of carbon dioxide produced per molecule of oxygen consumed (VCO₂/VO₂).
- Pulmonary formulas (e.g., PulmoCare) are designed to decrease CO₂ by providing the fuel substrate with the lower respiratory quotient (see Table 29.1).
 - To achieve this, the manufacturer decreases the carbohydrate-to-fat ratio to achieve fat calories of about 38% to 55%.
 - By decreasing the carbohydrates (RQ = 1)–to–fat (RQ = 0.7) ratio, the assumption is that CO₂ production is reduced.
 - Studies looking at the benefit of high-fat enteral feeds are poor.
 - More recent evidence suggests that reducing total calories is more important than the source of calories, in terms of reducing CO₂ production (as the RQ of lipogenesis or overfeeding is 1–1.2).

- The source of fat has also changed over the years. Whether the data from the earlier studies can be extrapolated to reflect the effect of the modern formulas on CO₂ remains to be answered.

Metabolic Stress (Critical Care) Formula

- The critical care formulas (e.g., Perative) are somewhat similar to the hepatic formulas in that both have a high percentage of BCAAs, which are the preferred substrate of muscles during critical illness.
- Differences include higher protein content and fewer aromatic amino acids in the critical care formulas compared to the hepatic formulas.
- The data on use are equivocal from the standpoint of nutritional markers.
 - Overall, BCAA-enriched enteral formulas are not the current standard of practice.
 - This class of enteral formula, like the immunomodulating formulas, may contain immune-enhancing agents (i.e., arginine) and must be used cautiously in critically ill septic patients.

Immunomodulating Formula

- A subset of the metabolic stress formulas
- Designed to reduce inflammatory response (e.g., acute respiratory distress syndrome [ARDS])
- These so-called immunomodulating formulas are standard enteral formulas fortified with omega-3 fatty acids, nucleotides, arginine, and/or glutamine.
- Oxepa contains no glutamine and arginine but does contain 55% of calories as fat, of which the omega-6-to-omega-3 ratio is optimized to 2:1.
- Impact has 25% of calories as fat, has arginine and glutamine, and contains 17.1% BCAAs in protein, and the omega-3-to-omega-6 ratio is 1.4:1.
- Immun-Aid has 36% protein as BCAAs, contains arginine and glutamine, has 20% fat calories, and has an omega-6-to-omega-3 ratio of 2.1:1 (ratio similar to Oxepa).
- Theory behind this class of enteral feeds is that by minimizing omega-6 fatty acids and optimizing the ratio of omega-6 to omega-3 fatty acids, the inflammatory response is reduced, resulting in less lung injury.
- Based on the early clinical trials and meta-analyses, which have mainly looked at Immun-Aid and Impact, it appears that surgical patients benefited most from this class of enteral formula.
 - One prospective, double-blind, placebo-controlled, randomized trial in 165 critically ill patients with severe sepsis found that this formula decreased mortality (19.4% absolute risk reduction) and ventilator days.
 - Another prospective, randomized, controlled trial looking at enteral diet enriched with EPA + GLA in 100 patients with acute lung injury concluded that the formula reduced ventilator days.
 - Despite the many pieces of evidence pointing toward the benefit of immunomodulating formulas, it does have to be used with caution and at the right time.

Glycemic Control Formula

- Glycemic control enteral formulas are similar to the pulmonary formulas in design.

- Carbohydrate (35%–40%)-to-fat (40%–50%) ratio is reduced compared to standard formulas.
- With varying ratios of omega-6 to omega-3 fatty acids (e.g., Glucerna)
- Results in a greater proportion of fat calories than recommended (American Heart Association recommends $\leq 30\%$ of calories from fat)
- Various soluble fibers and/or soy polysaccharides are also added to the glycemic enteral formulas
- Clinical trials limited
 - High fat content in the glycemic formulas can decrease stomach emptying.
 - Tolerance to these formulas may be decreased even more in patients with diabetic gastroparesis.
 - If glycemic control is needed, consider insulin infusion.

Timing of Specialized Enteral Feeding (Immunonutrition) and Manipulation of Immune and Inflammatory System

- Immunonutrition enteral feedings (e.g., Impact and Immun-Aid) are formulas containing nutrients that have been shown to influence immunologic and inflammatory responses in humans.
- Immune-enhancing agents usually include the following:
 - Glutamine
 - Arginine
 - Omega-3 fatty acids
 - Nucleotides
 - Antioxidants
- An extensive meta-analysis to determine whether immunonutrition is safe and effective in critically ill patients found a trend toward higher mortality in the critically ill patients.
 - Recommendation that immunonutrition not be used in critically ill patients until more clinical trials are conducted.
- A randomized multicenter trial comparing parenteral and early enteral nutrition containing immune-enhancing formula (Perative) in patients with and without severe sepsis noted in an interim analysis that mortality in severely septic patients receiving immune-enhancing enteral formulas was significantly higher than in those receiving parenteral nutrition (44.4% vs. 14.3%), and the study was aborted.
 - In patients without sepsis, there was no 28-day mortality difference between the patients receiving parenteral nutrition versus immune-enhancing enteral formulas.
 - However, those receiving immunonutrition had fewer episodes of septic shock, and the ICU length of stay was 4 days shorter.
- Thus, immunonutrition formulas should be used with caution in critically ill septic patients.
 - Based on expert opinions, the immune-modulating nutrient likely to be responsible for the excess harm is arginine (see later), which has not been well studied in a randomized, clinical fashion in critically ill patients.
 - In the critically ill nonseptic patients, immune-enhancing formulas appear to be beneficial if started within 48 hours.

Immunomodulators

- *Glutamine*: Normally nonessential, glutamine becomes conditionally essential during times of high stress as evidenced

by a decrease in glutamine concentration in the body during this period.

- Comes in the free form (unstable in solution, so only found in dried form) and protein-bound form as seen in all protein sources used in enteral formulas.
- Important amino acid because of its involvement in many vital functions, such as the following:
 - Gluconeogenesis
 - Synthesis of glycogen, nucleotides, nucleic acid, and urea
 - Ammoniogenesis
 - Ammonia reduction
 - Also the preferred fuel substrate for rapidly dividing cells in both the small intestine mucosa and the immune system
 - Plays a big part in the antioxidation process, as it is the precursor of glutathione, a strong antioxidant
- Critically ill patients need about 30 g/day (0.5 g/kg/day) of glutamine to meet both basal and increased enterocyte requirements.
- Meta-analysis of 14 randomized trials concluded that glutamine supplementation in critically ill patients may be associated with a reduction in complication and mortality rates.
 - Supplementation in surgical patients may be associated with a reduction in infectious complication rates and shorter hospital stay without any adverse effect on mortality.
 - Parenteral glutamine is more effective than enteral glutamine.
- The effectiveness and benefits of glutamine supplementation are still not conclusive.
- **Arginine:** Like glutamine, considered to be a conditionally essential amino acid
 - About 5% to 6% comes from intake of proteins, and the rest is synthesized by the body via the urea cycle.
 - Arginine is important in the following:
 - Ammonia detoxification
 - Production of nitric oxide
 - Purported to enhance wound healing in humans, mainly via improvements in *in vitro* markers of immune function (e.g., CD4 count), rather than outcome measures like infection rates.
 - Optimal dose of arginine in the critically ill patient is unknown.
 - However, up to 30 g/day is generally well tolerated by relatively healthy people.
 - Arginine supplementation may increase nitric oxide production, which can lead to vascular smooth-muscle dilation.
 - Should use arginine-containing formulas with caution in critically ill septic patients
- **Nucleotides:** The structural units for nucleic acids and various enzymes involved in energy transfer and essential for the

formation of new cells (e.g., intestinal epithelium) and in the synthesis of protein, lipids, and carbohydrates.

- Of interest because supplementation of infant formulas with nucleotides was noted to enhance bifidobacteria growth in the gastrointestinal tract, which decreases the colonic lumen pH and inhibit growth of enteric bacteria.
- Studies involving nucleotide use in humans are limited.
 - Studies available often involve immune-enhancing diets fortified with nucleotides, making it difficult to determine the effects of the nucleotides *per se*.
- A prospective, controlled trial studied the effects of nucleotide-supplemented formula in 26 severely malnourished children (younger than 4 years old) found that insulin-like growth factor, growth factor-binding protein-3 were notably affected, which could stimulate the catch-up growth of severely malnourished infants and toddlers.
- **Structured lipids:** Triglycerides are three fatty acid chains attached to a glycerol backbone. Structured lipids are triglycerides with combinations of long-, medium-, and short-chain fatty acids on a single glycerol backbone not found in nature.
 - Intent is to make a product that has improved absorption (compared to long-chain triglycerides), minimizes immune dysfunction, and provides essential fatty acids.
 - Not yet commercially available in IV forms, although it has been a component of immunomodulating enteral formulas.
- **Antioxidant therapy:** Antioxidants such as vitamin C, vitamin E, selenium, and β -carotene are often found in immunomodulating formulas.
 - Role of antioxidant supplementation during critical illness is unclear.
 - Critically ill patients often have low serum concentrations of some antioxidants, the significance of which is unclear.
 - Good evidence now to suggest that reactive oxygen species induce direct oxidative tissue injury by means of peroxidation of cellular membranes, oxidation of critical enzymatic and structural proteins, and induction of apoptosis.
 - Thus, importance of antioxidants seems obvious.
 - A prospective, observational clinical trial looking at 595 critically ill surgical patients (91% trauma patients) were administered vitamin E 1,000 international units every 8 hours via nasogastric tube and vitamin C 1 g IV every 8 hours.
 - Found that early administration of vitamin E and vitamin C reduced the incidence of organ failure by 57% and shortened the ICU stay by 1 day
 - Another randomized study looking at 37 burned patients (>30% of body surface area) concluded that high-dose vitamin C (66 mg/kg/hour) for 24 hours reduced resuscitation fluid volume requirements, body weight gain, wound edema, and the severity of respiratory dysfunction.

CHAPTER 30 ■ TOXICOLOGY

HISTORY

- The American Association of Poison Control Centers (AAPCC) maintains the National Poisoning and Exposure Database (NPED).
 - Database suffers from many obvious limitations.
 - Many exposures go unreported.
 - In one study, only 12% of poisoning deaths identified by the medical examiner were reported to poison centers.
 - Those reported are usually unconfirmed.
 - The NPED categorizes exposures based on outcome, designating effects as minor, moderate, or major.
 - *Major effects* are those where the patient exhibits signs or symptoms as a result of exposure that is life-threatening or results in significant disability or disfigurement; this category constitutes a large portion of ICU toxicology cases.
 - In 2005, the AAPCC received nearly 2.5 million reports of exposures.
 - 16,545 major effects
 - 1,261 deaths (0.005% of total exposures)
 - Herein, any substance introduced to the body will be referred to as a *xenobiotic*.
 - Terms *drug* and *pharmaceutical* identify the subgroup of xenobiotics that are commercially produced.
 - A *toxin* is a xenobiotic produced by a biologic system, such as plant, animal, or fungi.
 - An *exposure* occurs whenever a human comes into contact with a xenobiotic.
 - Exposures may be dermal, oral, ophthalmic, or inhalational.
 - *Poisoning*, *intoxication*, and *toxicity* characterize the harmful consequences of a xenobiotic exposure.
 - Vital signs should be obtained, and cardiac and respiratory monitoring should be applied and supplemental oxygen used as needed.
 - Significant abnormalities or oxygen desaturation should be addressed immediately.
 - Bedside serum glucose concentration should be rapidly obtained in any patient with altered sensorium or an abnormal neurologic examination.
 - Hypoglycemia may present with almost any altered mental status, including agitation, delirium, coma, seizure, or focal neurologic deficit.
 - Though common and easy to correct, this may be life threatening.
 - A thorough physical examination will identify the presence of a toxic syndrome, or “toxidrome” (Table 30.1).
 - Electrocardiogram (ECG) should be obtained.
 - Several well-defined exposures (such as tricyclic antidepressants) will be identified based on a characteristic ECG
 - Xenobiotics such as cocaine or lidocaine can produce life-threatening dysrhythmias via direct myocardial effect.
 - Xenobiotics can also produce dysrhythmias by causing an electrolyte abnormality.
 - Exposure to hydrofluoric acid, even dermally, can result in hypocalcemia, resulting in QTc prolongation and torsades de pointes
 - History should attempt to identify the specific xenobiotic exposure, the amount, the time and reason for exposure, and general medical history.
 - A specific antidote may be warranted based on the history (Table 30.2).
 - Thoughtful use of laboratory studies is important.
 - Electrolyte abnormalities complicate many severe poisonings.
 - Serum chemistries are warranted for all critically ill patients.
 - Blood gas analysis and aminotransferases are judiciously used.
 - Routine urine toxicologic screen rarely aids in management and is not recommended.
 - Urine toxicologic screen generally focuses on select drugs of abuse and omits the vast majority of potential toxins.
 - Assays included in the commonly used qualitative urine screen have either too many false-positive or false-negative results.
 - Fentanyl, a synthetic opioid, will not produce a positive result on an opiate screen.
 - Dextromethorphan may yield a positive result for phencyclidine.

DIAGNOSIS AND GENERAL APPROACH TO THE POISONED PATIENT

- By the time the patient reaches the ICU, initial stabilization will have already occurred.
- Nevertheless, the initial approach to the poisoned patient deserves mention.
- “Treat the patient, not the poison.”
- The management of the poisoned patients begins with the following:
 - Addressing airway compromise, breathing difficulty, and circulatory problems

TABLE 30.1**TOXIDROMES**

Group	BP	P	R	T	Mental status	Pupil size	Peristalsis	Diaphoresis	Primary treatment
Anticholinergic	-/↑	↑	+/-	↑	Delirium	↑	↓	↓	Benzodiazepines
Cholinergic	+/-	+/-	-/↑	-	Normal/depressed	+/-	↑	↑	Atropine, oximes
Ethanol, sedative-hypnotic	↓	↓	↓	-/↓	Depressed	+/-	↓	-	Airway support
Opioid	↓	↓	↓	↓	Depressed	↓	↓	-	Naloxone
Sympathomimetic	↑	↑	↑	↑	Agitated	↑	-/↑	↑	Benzodiazepines
Withdrawal from ethanol or sedative-hypnotic	↑	↑	↑	↑	Agitated, disoriented	↑	↑	↑	Benzodiazepines
Withdrawal from opioids	↑	↑	-	-	Normal, anxious	↑	↑	↑	Opioids

BP, blood pressure; P, pulse; R, respirations; T, temperature.

Adapted with permission from Flomenbaum NE, Goldfrank LR, Hoffman RS, et al. Initial evaluations of the patient: vital signs and toxic syndromes. In: Flomenbaum NE, Goldfrank LR, Hoffman RS, et al., eds. *Goldfrank's Toxicologic Emergencies*. 8th ed. New York: McGraw-Hill; 2006:37–41.

- Acetaminophen concentration should be obtained after all overdoses where self-harm was intended, even if the history is negative for acetaminophen ingestion.

Determining the Need for Intensive Care Unit Admission

- Criteria that are traditionally used to determine whether patients need critical care may not apply to poisoned patients.
- Dangerous xenobiotic poisonings may appear well but require precautionary ICU admission and monitoring.
- Factors that influence the need for critical care can be divided into three general categories:
 - Patient characteristics
 - Xenobiotic characteristics
 - Hospital unit capabilities
- Unstable poisoned patients require ICU care.
- Patients with significant laboratory abnormalities, unresponsiveness, inability to protect the airway, hypotension, dysrhythmias, or conduction abnormalities are admitted to the ICU.
 - Pre-existing medical conditions—severe liver or renal insufficiency, congestive heart failure, or pregnancy—may also influence disposition.
- Disposition for minimally symptomatic patients is determined by the xenobiotic involved.
 - Most important considerations are the potential for deterioration or the requirement for a therapeutic agent with potentially adverse effects.
 - Sustained-release products, potentially lethal doses, or xenobiotics that may cause dysrhythmias have the potential to cause rapid clinical deterioration.
 - Thus, asymptomatic patients with exposure to calcium channel blockers or sulfonyleureas often are admitted to the ICU for observation.
 - When xenobiotics require therapy with potentially adverse effects—such as high-dose atropine for organic phosphorus insecticides—ICU admission is appropriate.

- Hospital capabilities influence patient disposition.
 - Time-consuming nursing activities—hourly bedside glucose checks or the administration of drug infusions—may not be possible on general inpatient units and are indications for ICU admission.
 - If admitting team or nursing staff is not familiar with the complications associated with a particular xenobiotic exposure, ICU admission may also be indicated.

NONOPIOID ANALGESICS: ACETAMINOPHEN, NONSTEROIDAL ANTI-INFLAMMATORY DRUGS, AND SALICYLATES

Acetaminophen

- More than 100,000 reports of acetaminophen exposure were received by the NPED in 2005.
 - Vast majority of exposures do not result in significant morbidity.
 - Only 333 were fatal and another 3,310 considered major.
 - Although the data set is controversial, acetaminophen is estimated to be responsible for 51% of all cases of acute liver failure in the United States.
 - Acetaminophen ingestions require ICU admission when hepatotoxicity is established.
- **Mechanism of action and metabolism:** Acetaminophen is an analgesic and antipyretic with less anti-inflammatory activity than the nonsteroidal anti-inflammatory drugs (NSAIDs).
 - Analgesic effects are mediated by central cyclo-oxygenase-2 and prostaglandin synthase inhibition.
 - Less than 5% is eliminated unchanged in urine.
 - Metabolism of acetaminophen occurs principally in the liver.
 - Ninety percent of absorbed acetaminophen undergoes hepatic conjugation with either glucuronide or sulfate to produce inactive metabolites.

TABLE 30.2

SELECTED ANTIDOTES WITH COMMON DOSES

Xenobiotic	Antidote and dose
Acetaminophen	N-acetylcysteine- IV: 150 mg/kg infused over 60 min, followed by 50 mg/kg over 4 h, then 100 mg/kg over 16 h Oral: 140 mg/kg, followed by 70 mg/kg every 4 h for 17 doses
β -Adrenergic antagonists	Atropine (for bradycardia): 0.5–1 mg IV Glucagon: 3–5 mg IV (50 μ g/kg in children) up to 10 mg/h Calcium: 13–25 mEq of Ca^{2+} IV bolus (10–20 mL of 10% calcium chloride or 30–60 mL of 10% calcium gluconate) Hyperinsulinemia/euglycemia: Insulin 0.5–1 U/kg/h accompanied by 0.5 g/kg/h dextrose, titrated to maintain euglycemia
Calcium channel blockers	Atropine (for bradycardia): 0.5–1 mg IV Calcium: 13–25 mEq of Ca^{2+} IV bolus (10–20 mL of 10% calcium chloride or 30–60 mL of 10% calcium gluconate) Glucagon: 3–5 mg IV (50 μ g/kg in children) up to 10 mg/h Hyperinsulinemia/euglycemia: Insulin 0.5–1 U/kg/h accompanied by 0.5 g/kg/h dextrose, titrated to maintain euglycemia
Cholinergic compounds	Atropine: 1 mg IV (0.05 mg/kg in children) doubled every 2 min until muscarinic symptoms are controlled Pralidoxime: Adults: 1–2 g IV over 30 min followed by 500 mg/g infusion for sickest patients. Children: 20–50 mg/kg (max 1–2 g) infused IV over 30–60 min and then 10–20 mg/kg/h (max 500 mg/h)
Cyanide	Adults: 1. Sodium nitrite: 300 mg (10 mL of a 3% conc.) infused IV over 2–5 min 2. Sodium thiosulfate: 12.5 g (50 mL of a 25% conc.) infused IV over 10–20 min or as a bolus 3. Hydroxocobalamin IV 70 mg/kg (up to 5 g) Children: 1. Sodium nitrite: 6–8 mL/m ² (0.2 mL/kg of a 3% conc., up to adult dose) infused IV over 2–5 min 2. Sodium thiosulfate: 7 g/m ² (0.5 g/kg, up to adult dose) infused over 10–30 min or as a bolus
Cyclic antidepressants	Sodium bicarbonate: 1 mEq/kg IV bolus, followed by infusion of 150 mEq in 1 L of D5W, infused at twice maintenance rate
Digoxin	Digoxin-specific Fab: Known level: # of vials = [wt (kg) \times level (ng/mL)/100] rounded up to nearest vial. Empiric dosing: Acute: 10–20 vials. Chronic: Adults, 3–6 vials; children, 1–2 vials. Usually given as IV infusion over 30 min (administer as IV bolus for asystole)
Ethylene glycol, methanol	Fomepizole: 15 mg/kg infused IV over 30 min; next 4 doses at 10 mg/kg every 12 h; additional doses at 15 mg/kg every 12 h if needed Ethanol (when fomepizole not available): 0.8 g/kg infused IV over 20–60 min, followed by initial infusion of 100 mg/kg/h
Methemoglobin	Methylene blue: 1–2 mg/kg IV over 5 min followed by a 30 mL fluid flush
Salicylates	Sodium bicarbonate: 150 mEq in 1 L of D5W, infused at twice maintenance rate. Activated charcoal, 1g/kg every 4 h
Sulfonylurea-related hypoglycemia	Octreotide: 50 μ g SQ every 6 h. Children: 1.25 μ g/kg (up to adult dose) SQ every 6 h

Adapted with permission from Flomenbaum NE, Goldfrank LR, Hoffman RS, et al., eds. *Goldfrank's Toxicologic Emergencies*. 8th ed. New York: McGraw-Hill; 2006.

- Remainder (5%–15%) is oxidized by the cytochrome P450, forming *N*-acetyl-*p*-benzoquinoneimine (NAPQI), a toxic oxidant.
 - Thiol-containing compounds, such as reduced glutathione, are used as electron donors to detoxify NAPQI.
- **Toxicity:** Single dose generally thought to be required to produce toxicity is ≥ 150 mg/kg.
 - In overdose, absorption may be delayed.
 - Peak absorption generally occurs at 2 hours and rarely after 4 hours.

- Absorption is further delayed in the presence of peristalsis-decreasing opioid or anticholinergic coingestants or if the acetaminophen is formulated for extended release.
- In overdose, metabolism by sulfation becomes saturated, and the formation of NAPQI exceeds that which can be detoxified by available glutathione.
 - As toxic metabolite is formed in the liver, hepatic toxicity is the key clinical feature.
 - *N*-acetylcysteine (NAC), the key to management of acetaminophen poisoning, acts as a precursor to glutathione synthesis, a substrate for sulfation; it directly

binds to NAPQI itself; and enhances the reduction of NAPQI to acetaminophen.

- **Clinical manifestations:** Acute acetaminophen toxicity has been divided into four clinical stages. Not every untreated patient will advance through each, and spontaneous improvement is possible at any point.
 - **Stage I:** Patient is either asymptomatic or has nonspecific clinical findings (nausea, vomiting, malaise), and no laboratory abnormalities are recognized.
 - **Stage II:** This begins with onset of liver injury, 24 to 36 hours after ingestion.
 - Symptoms are similar to other causes of hepatitis.
 - Initial laboratory findings include elevated aminotransferases (aspartate aminotransferase [AST]/alanine aminotransferase [ALT]), but progress to signs of hepatic dysfunction, including prolonged prothrombin time (PT), metabolic acidosis, and hypoglycemia.
 - **Stage III:** Time of peak hepatotoxicity is usually 72 to 96 hours from ingestion. AST and ALT may ultimately exceed 10,000 IU/L, but creatinine, lactate, phosphate, and PT are better prognostic indicators.
 - Fatalities usually occur within 3 to 5 days of ingestion.
 - **Stage IV:** Hepatic regeneration will be histologically and functionally complete in survivors
- **Management:** NAC is the key to managing acetaminophen poisoning. Decontamination with activated charcoal should be considered only if significant coingestants are expected.
 - Oral protocol for acute ingestions is a 140 mg/kg loading dose, followed by 17 doses of 70 mg/kg every 4 hours for a total of 72 hours.
 - IV regimen is 150 mg/kg over 45 minutes, followed by 50 mg/kg over 4 hours, and then 100 mg/kg over 16 hours.
 - Both regimens have equal efficacy for simple acute ingestion.
 - IV regimen has shorter course and is the only route that has been studied adequately in patients with hepatic failure.
 - Parenteral NAC carries the risk of anaphylactoid reactions.
 - Simple, acute ingestion occurs when a single dose of acetaminophen is ingested over a short period of time, within 24 hours of presentation.
 - Little controversy in managing this type of ingestion
 - Serum acetaminophen concentration should be plotted against the number of hours after ingestion on the Rumack–Matthew nomogram to determine whether treatment with NAC is necessary.
 - Currently recommended line intersects 150 $\mu\text{g/mL}$ at 4 hours, incorporating a 25% safety margin over the original nomogram line, which was itself nearly 100% sensitive for predicting hepatotoxicity.
 - Treatment initiated within 8 hours of ingestion has complete efficacy in preventing hepatotoxicity.
 - NAC should be started immediately in any patient with suspected acetaminophen poisoning when the laboratory result for the acetaminophen concentration is not expected to be available within 8 hours of the initial ingestion.
 - Once the serum acetaminophen concentration is available, the decision whether to continue the NAC can be made based on the nomogram (Fig. 30.1).
 - If any uncertainty with regard to the exact time of ingestion, the physician should use the most conser-

FIGURE 30.1. Acetaminophen nomogram. (Adapted with permission from Hendrickson RG, Bizovi KE. Acetaminophen. In: Flomenbaum NE, Goldfrank LR, Hoffman RS, et al., eds. *Goldfrank's Toxicologic Emergencies*. 8th ed. New York: McGraw-Hill; 2006: 523–543.)

vative estimate (i.e., the earliest possible time) when using the nomogram.

- Indications less clear for the use of NAC for hepatotoxicity after suspected chronic acetaminophen use
- The vast majority of people who take acetaminophen have no adverse clinical manifestations. Clinical trials involving daily dosing of 4 g of acetaminophen in both alcoholics and nonalcoholics showed that patients have either normal aminotransferase concentrations or very minor increases.
 - Nonetheless, NAC should be administered to all patients with suspected acetaminophen hepatotoxicity until the diagnosis has been excluded.
- Nomogram cannot be used for patients who present more than 24 hours after ingestion.
 - In such cases, NAC should be started immediately upon presentation.
 - If the patient has both undetectable acetaminophen concentration and normal aminotransferases, acetaminophen overdose is highly unlikely, and NAC need not be continued
 - If either acetaminophen or aminotransferase concentrations are elevated (even minimally so), the patient should be administered 20 hours of IV NAC.
- When acetaminophen-induced hepatotoxicity is encountered, IV NAC should be administered as described previously.
 - Maintenance dose should be continued until clinical improvement, liver transplantation, or death.
 - Even in the presence of fulminant hepatic failure, IV NAC has been shown to decrease mortality, cerebral edema, and the need for vasopressors.
- **Hepatic transplantation:** Generally, patients with significant acetaminophen poisoning will have AST and ALT concentrations >1,000 IU/L by 24 to 48 hours after ingestion.
- Several prognostic criteria are available.

- The King's College Hospital Criteria suggest that pH <7.3 after resuscitation or the combination of PT >100, creatinine >3.3 mg/dL, and grade III or IV encephalopathy are predictive of death in the absence of a transplantation.
- Serum phosphate is a good predictor.
 - A 48-hour serum phosphate concentration >1.2 mMol/L has been shown to be sensitive and specific for predicting the need for transplant and the probability of death from acetaminophen hepatotoxicity.
 - Presumably, a low or normal phosphate concentration is evidence that the phosphate is being utilized by hepatocytes for adenosine triphosphate (ATP) generation.

Salicylates and Other Nonsteroidal Anti-inflammatory Drugs

- ICU admission is required when patients present with metabolic acidosis and hemodynamic instability or if they require bicarbonate infusion or frequent measurements of salicylate concentration.
- **Mechanism:** Therapeutic effects result from the inhibition of cyclo-oxygenase, a mediator of prostaglandin synthesis.
 - Salicylates uncouple oxidative phosphorylation, meaning that some of the proton gradient across the mitochondrial matrix is dissipated in the formation of heat, rather than ATP, forcing the production of lactate.
- **Clinical manifestations of salicylate poisoning:** Acute salicylate poisoning may cause epigastric pain, nausea, and vomiting. Salicylates induce hyperventilation (both tachypnea and hyperpnea) by direct stimulation of the brainstem respiratory center.
 - Neurologic signs and symptoms of salicylate poisoning range from mild to severe and include tinnitus, delirium, coma, and seizure.
 - Initial feature of toxicity is primary respiratory alkalosis.
 - A primary metabolic acidosis is characterized by the presence of lactic acid, ketoacids, and salicylic acids.
 - Net result is an increased anion gap metabolic acidosis.
 - In adults, the presence of an acidemia or even normal pH indicates advanced poisoning.
 - Chronic salicylate poisoning presents with the same signs and symptoms as acute poisoning but typically occurs in elderly patients taking supratherapeutic amounts of salicylate to treat a chronic condition.
 - It often is not suspected.
 - Elderly salicylate-poisoned patients presenting with metabolic acidosis and an altered sensorium may initially be misdiagnosed with sepsis, dehydration, or cerebrovascular accident if a salicylate concentration is not obtained.
 - Serum salicylate concentrations correlate loosely with toxicity because the principal site of poisoning is the central nervous system (CNS).
 - Threshold for toxicity is usually considered to be 30 mg/dL when tinnitus develops.
 - Chronically poisoned patients have a lower salicylate concentration for the same degree of illness because much of their total body burden has redistributed into the CNS.
 - Degree of poisoning is determined by evaluating the serum concentration in context of the patient's clinical appearance, laboratory results, and acuity of ingestion.
- **Management of salicylate poisoning:** The key principles for management of salicylate poisoning are to minimize absorption, speed elimination, and minimize redistribution to tissues.
 - Gastric emptying is attempted if a significant amount of drug is expected to be in stomach.
 - Activated charcoal, 1 g/kg, should be administered every 4 hours if it can be given safely.
 - Salicylates cause pylorospasm and may form concretions in overdose, leading to delayed absorption.
 - Multiple-dose activated charcoal prevents delayed absorption and may speed elimination of salicylates by disrupting the drug's enteroenteric circulation.
 - Serum chemistry, venous or arterial blood gas, and salicylate concentration should be obtained every 2 hours until the salicylate concentration demonstrates an interval decrease.
 - Moderately poisoned patients (increased anion gap or a salicylate concentration greater than 40 mg/dL) should also have blood and urine alkalinized with sodium bicarbonate.
 - As a weak acid (pKa 3.5), salicylates will be ionized in an alkaline environment and "trapped" (i.e., unable to passively move through lipid membranes).
 - Alkalinization is achieved with infusion of sodium bicarbonate of 150 mEq in 1 L of D5W at twice the maintenance rate (ideal body weight in kg + 40 = maintenance rate in milliliters per hour).
 - Urine pH should be maintained from 7.5 to 8.0 and systemic arterial pH between 7.45 and 7.55.
 - Replete potassium, as low serum potassium will cause preferential reabsorption of potassium over hydrogen ions in the proximal tubule and compromise attempts to alkalinize the urine.
 - Endotracheal intubation and sedation should be avoided whenever possible.
 - Tachypnea and hyperpnea of salicylate poisoning does not necessarily represent "tiring" and produces a helpful alkalosis.
 - If intubation is unavoidable, patients should be administered 1 to 2 mEq/kg of bicarbonate prior to the procedure, intubated quickly and hyperventilated afterward.
 - Early consultation with a nephrologist is recommended for seriously ill patients.
 - Extracorporeal elimination is reserved for patients who are very ill, those who cannot tolerate alkalinization, or those with serum concentrations so elevated that their clinical status is expected to deteriorate.
 - Hemodialysis is used for severe acid-base disturbances, mental status changes, inability to tolerate alkalinization (renal failure or congestive heart failure), and serum concentrations of 100 mg/dL after acute poisoning and 60 mg/dL in chronic poisoning (Table 30.3).
 - **Clinical manifestations of NSAID poisoning:** NSAIDs are considered safer than salicylates in therapeutic dosing.
 - Acute overdose of NSAIDs can cause gastric injury.
 - Chronic NSAID use is associated with interstitial nephritis, nephritic syndrome, or analgesic nephropathy; acute overdose sometimes accompanied by a reversible azotemia caused by vasoconstriction from decreased prostaglandin production.

TABLE 30.3**INDICATIONS FOR HEMODIALYSIS IN SALICYLATE POISONING**

Renal failure
 Congestive heart failure (relative)
 Acute lung injury
 Persistent CNS disturbances
 Progressive deterioration in vital signs
 Severe acid-base or electrolyte imbalance, despite appropriate treatment
 Hepatic compromise with coagulopathy
 Salicylate concentration (acute) >100 mg/dL or (chronic) >60 mg/dL

CNS, central nervous system.

Adapted with permission from Flomenbaum NE. Salicylates. In: Flomenbaum NE, Goldfrank LR, Hoffman RS, et al., eds. *Goldfrank's Toxicologic Emergencies*. 8th ed. New York: McGraw-Hill; 2006:550–564.

- In severe overdose, the most consequential effects are elevated anion gap metabolic acidosis, coma, and hypotension.
- **Management of NSAID poisoning:** Activated charcoal should be administered if the patient presents within several hours of overdose.
- Good supportive care is the mainstay of therapy after overdose.
- Elimination is not increased with alkalinization.
- High degree of protein binding precludes removal with hemodialysis.
 - Hemodialysis has been used to correct acidemia and electrolyte abnormalities in patients with multiorgan system failure.

Psychiatric Medications

- Represent a disproportionate number of poisonings in the United States
- Antidepressants, antipsychotics, and sedative-hypnotics accounted for more than half of all deaths reported to poison control centers in 2005.
 - High mortality figure is a function of the prevalence of these ingestions, as these drugs do not have a high case-fatality rate.
 - With sound supportive care, most patients can be managed successfully.

Antipsychotic Medications

- Antipsychotics are categorized as either typical or atypical.
 - Typical antipsychotics, which include haloperidol, chlorpromazine, and thioridazine, antagonize dopamine primarily at the D₂ receptor.
 - Newer medications, atypical drugs, are exemplified by clozapine, olanzapine, quetiapine, risperidone, and ziprasidone.
 - Have less dopaminergic antagonism
 - More serotonergic effects than the typicals

- When antipsychotic medications produce coma, conduction abnormalities, or hyperthermia, patients require ICU admission.
- **Clinical manifestations of overdose:** All antipsychotics produce sedation in overdose, though respiratory depression is usually not consequential.
- Varying degrees of muscarinic and α -adrenergic antagonism occur, often resulting in tachycardia and moderate hypotension.
 - Many of the typical antipsychotics have type IA antidysrhythmic properties.
 - Most typicals and a few of the atypical drugs (notably ziprasidone) can cause QTc prolongation and torsades de pointes.
- Management of overdose generally requires only supportive care.
- **Clinical manifestations of the neuroleptic malignant syndrome:** The dopamine antagonism required for control of psychosis can cause a group of distinct movement disorders that range in severity from mild to life threatening.
 - Conditions—dystonia, akathisia, parkinsonism, tardive dyskinesia, and neuroleptic malignant syndrome (NMS)—are more likely to occur in the presence of the typicals, although the atypicals can cause them as well.
 - NMS is the most consequential of the movement disorders associated with the antipsychotics.
 - Characterized by altered mental status, muscular rigidity, hyperthermia, and autonomic dysfunction
 - Symptoms usually begin within weeks of starting treatment but occur in individuals taking the drug chronically.
 - Risk factors include the following:
 - Young age
 - Male gender
 - Extracellular fluid volume contraction
 - Use of high-potency antipsychotics
 - Depot drug preparations
 - Concomitant lithium use
 - Rapid increase in dose, or simultaneous use of multiple drugs
 - Diagnosis is not always clear because there is no reference standard.
 - Differential diagnosis of hyperthermia and altered mental status is very broad, including:
 - Infection
 - Environmental hyperthermia
 - Hyperthyroidism
 - Serotonin syndrome
 - Ethanol and sedative-hypnotic withdrawal
 - Sympathomimetic intoxication
 - Anticholinergic intoxication
 - Management of NMS
 - Immediate treatment of life-threatening hyperthermia: Ice-water immersion and paralysis by neuromuscular blockade should not be delayed if temperature is >106°F (41.1°C).
 - In instances of environmental hyperthermia, a delay of cooling longer than 30 minutes has been associated with significant morbidity and mortality.
 - Benzodiazepines should be titrated to sedation and muscle relaxation.

- Rhabdomyolysis, electrolyte disorders, and hypotension should be aggressively treated.
- Bromocriptine, a centrally acting dopamine agonist given at 2.5 to 10 mg three to four times a day is of theoretical benefit but has not been well studied.
 - NMS may not be controlled for days after the introduction of bromocriptine.
 - After signs and symptoms begin to improve, bromocriptine should be decreased by no more than 10% a day as decreasing the dose too rapidly may precipitate a relapse of NMS.
- No evidence for the antidotal use of dantrolene in the management of NMS
 - Dantrolene drug of choice in malignant hyperthermia, a disorder affecting the sarcoplasmic reticulum seen in susceptible individuals receiving inhalational anesthetics or succinylcholine
 - May be confused with neuroleptic malignant syndrome because of their similar names and clinical manifestations

Benzodiazepines

- In 2005, the AAPCC received reports of 3,018 major effects and 243 fatalities from benzodiazepines.
 - These are widely used for their sedative, anxiolytic, and anti-convulsant properties.
 - All effects result from increasing the frequency of opening of γ -aminobutyric acid (GABA)-mediated chloride channels in the CNS.
 - In overdose, these drugs produce somnolence, coma, and minimal decreases in blood pressure, heart rate, and respiratory rate.
- **Management of benzodiazepine overdose:** Supportive
 - Care focuses on supporting airway and blood pressure while waiting for the drug elimination.
 - Flumazenil, a competitive benzodiazepine antagonist, plays a limited role.
 - It can precipitate withdrawal in individuals who are tolerant to benzodiazepines and induce seizures in those with seizure disorders.
 - Flumazenil may be indicated in patients without tolerance to benzodiazepines who suffer from a pure benzodiazepine overdose; overdoses in children may meet these criteria.
 - When indicated, flumazenil should be given IV, 0.1 mg/min, up to 1 mg.
 - Dosing may be repeated if the clinical response is inadequate.
 - Duration of the effect of flumazenil is shorter than the effect of the benzodiazepine, so recurrence of symptoms should be expected.
 - Alternatively, redosing or a continuous IV infusion at 0.1 to 1.0 mg/hour may be administered.
 - If any doubt as to whether the patient has tolerance to benzodiazepines, flumazenil should not be administered

Cyclic Antidepressants

- Until introduction of the selective serotonin reuptake inhibitors, the cyclic antidepressants were the principal pharmacologic treatment available for depression.

FIGURE 30.2. Terminal elevation of aVR and QRS prolongation. (Adapted with permission from Clancy C. Electrocardiographic principles. In: Flomenbaum NE, Goldfrank LR, Hoffman RS, et al., eds. *Goldfrank's Toxicologic Emergencies*. 8th ed. New York: McGraw-Hill; 2006:51–62.)

- Roughly 12% of the 11,198 reported cyclic antidepressant exposures in 2005 had either a major outcome or fatality.
- The cyclic antidepressants (CAs) differ slightly from one another in their receptor affinities but can be treated as a group.
 - CAs are usually absorbed within hours of ingestion.
 - Antimuscarinic effects may delay absorption in overdose.
 - Drugs also exhibit α -adrenergic antagonism, inhibition of reuptake of norepinephrine, and anticholinergic properties.
 - CAs act as type IA antidysrhythmics, blocking sodium entry into myocytes during phase 0 of depolarization.
- **Clinical manifestations:** Important CNS effects include lethargy, delirium, coma, and seizures. Tachycardia and hypotension develop early in toxicity.
 - IA antidysrhythmic properties cause prolongation of the QRS interval.
 - CAs also produce a characteristic rightward shift of the axis in the terminal portion of the QRS, best seen as an R wave in the terminal 40 msec of lead aVR (Fig. 30.2).
- **Management:** Gastrointestinal decontamination should be considered in every patient. If the history suggests a recent large ingestion, gastric lavage may be attempted.
 - Acute ingestions of 10 to 20 mg/kg of most CAs can cause significant poisoning.
 - Activated charcoal should be administered.
 - Serum drug concentrations do not correlate well with toxicity.
 - The ECG is the most important diagnostic test when managing CA overdose.
 - QRS duration is an indicator of severity of poisoning.
 - No patients with QRS <160 msec had ventricular dysrhythmias, and no patients with a QRS duration <100 msec had seizures.
 - Sodium bicarbonate should be administered if the QRS duration is ≥ 100 msec.
 - High sodium concentration and alkaline pH of sodium bicarbonate solution are responsible for salutary effects.
 - Sodium load increases the sodium gradient across the poisoned myocardial sodium channel, resulting in a narrowing of the QRS complex.
 - Bicarbonate raises the pH, reducing CA binding to the sodium channel.

- Sodium bicarbonate should be administered as a 1 to 2 mEq/kg bolus during continuous ECG monitoring.
- If the complex narrows, sodium bicarbonate can be administered as an infusion.
- If the complex remains unchanged, the diagnosis of CA poisoning should be reconsidered.
- Sodium bicarbonate infusion may be performed by adding 150 mEq of bicarbonate to 1 L of D5W and infusing at twice the maintenance rate.
- Arterial pH should be targeted to 7.50 to 7.55.
- Occasional repeat boluses of 1 to 2 mEq/kg may be necessary.
- Hypertonic sodium chloride (3% NaCl) may be indicated when the QRS complex widens and the serum pH precludes further alkalinization.
- Hyperventilation may be used to induce alkalemia in intubated CA-poisoned patients.
- If hypotension persists despite fluid resuscitation and vasopressors become necessary, norepinephrine may be superior to dopamine.
- Seizures should be rapidly controlled.
 - Convulsions result in a metabolic acidosis, causing even more avid binding of the CA to the cardiac sodium channels, potentially resulting in more cardiotoxicity.
 - Benzodiazepines, propofol, or barbiturates are appropriate.
 - Phenytoin, a type IA antidysrhythmic, may worsen cardiac toxicity and is not indicated.
- Therapy should continue until vital signs and ECG improve.
- Unless there is significant secondary injury (such as from shock), those who survive to 24 hours are expected to make a complete recovery.
- Because of protein binding, hemodialysis is ineffective.

Lithium

- Used in the treatment of bipolar affective disorders
 - Patients will require ICU admission when they have signs of CNS toxicity, do not tolerate fluid therapy, or have serum concentrations >2 mEq/L.
 - Of 5,559 exposures reported to the AAPCC, 5.7% were classified as major or fatal.
- **Pharmacology:** Thought to increase serotonin release and increase receptor sensitivity to serotonin and modulate the effects of norepinephrine on its second-messenger system
- Kidney handles lithium (Li) and sodium similarly.
 - Li is freely filtered by the glomerulus, and 80% is reabsorbed, with 60% occurring in the proximal tubule.
 - Immediate-release Li preparations produce peak serum concentrations within hours; sustained-release Li may not peak for 6 to 12 hours.
 - Li generally accepted therapeutic range is 0.6 to 1.2 mEq/L.
 - In overdose and therapeutic dosing, clinical signs and symptoms are a better guide than the serum concentration.
- **Clinical manifestations of overdose:** Acute and chronic Li toxicity have similar neurologic features; acute toxicity usually associated with significant gastrointestinal (GI) manifestations
 - Acute toxicity occurs when an individual without a body burden of Li takes a supratherapeutic dose of drug.
 - Chronic toxicity is usually the result of decreased elimination of drug in a patient who is receiving a fixed dose (e.g., after developing renal insufficiency).
 - Acute-on-chronic toxicity occurs when a patient with a pre-existent total body drug takes a supratherapeutic dose.
 - In acute toxicity, a large ingestion of Li—a GI irritant—will initially cause GI symptoms, such as vomiting and diarrhea.
 - Neurotoxicity (which is clinically more significant) will be delayed until the drug has been absorbed and is redistributed into the CNS.
 - In chronic toxicity, GI symptoms may be absent.
 - Neurotoxicity manifests as movement disorders and alterations in mental status.
 - Mild toxicity: Only a fine tremor is present.
 - More advanced poisoning: Fasciculations, hyperreflexia, dysarthria, and nystagmus may be seen.
 - Mental status changes range from confusion to coma and seizures.
 - Nephrogenic diabetes insipidus and hypothyroidism occur after chronic therapeutic Li use but are not features of overdose.
 - The syndrome of irreversible Li-effectuated neurotoxicity (SILENT) is a chronic neurologic disorder with many of the same features of Li neurotoxicity.
 - SILENT persists even when body burden of Li eliminated.
 - Mechanism is not completely elucidated but may involve demyelination.
 - SILENT has been reported both as a result of chronic therapeutic use and as a sequela of Li intoxication.
- **Management:** GI decontamination should be considered after acute Li toxicity.
 - Li does not bind to activated charcoal, so its use is only considered when a mixed overdose is suspected.
 - For sustained-release preparation ingestion, whole-bowel irrigation has been shown to decrease serum Li concentration.
 - Whole-bowel irrigation is performed by administering 2 L of polyethylene glycol orally every hour (25 mL/kg/hr in children) until rectal effluent clear.
 - In both acute and chronic toxicity, IV fluids are given to optimize volume.
 - Volume-depleted patient will have decreased GFR and increased Li reabsorption.
 - When fluid deficits are restored, 0.9% saline can be administered at twice the maintenance rate or approximately 200 mL/hour in adults to aid in Li elimination.
- Extracorporeal elimination may be necessary to treat Li toxicity.
 - Li can be removed by hemodialysis due to its low volume of distribution and limited protein binding.
 - Li concentrations may rebound after dialysis—movement from intracellular to extracellular compartments—but tissue burden has actually decreased.
 - Hemodialysis is performed when signs of significant end-organ damage, when lithium cannot be eliminated without dialysis, or when the serum concentration is elevated such that severe toxicity is highly likely.
 - Recommend dialysis in the following:
 - Significant CNS toxicity such as clonus, obtundation, coma, or seizures

- Patient with milder toxicity cannot eliminate lithium efficiently (renal insufficiency) or tolerate saline resuscitation (congestive heart failure)
- Serum Li concentration >4.0 mMol/L after acute poisoning or >2.5 mMol/L after chronic poisoning
- Repeat dialysis may be necessary, so reapply the preceding criteria 4 hours after dialysis is completed to determine whether dialysis should be repeated.
- Common clinical pitfall is to deny dialysis to patients with an elevated Li concentration and signs of toxicity because consecutive concentrations have shown small decrease.
- Unfortunately, duration of exposure to the toxic Li levels may predispose the patient to SILENT.
- Though not adequately studied, it seems prudent to hemodialyze.

TOXICOLOGIC BRADYCARDIA: DIGOXIN, β -ADRENERGIC ANTAGONISTS, AND CALCIUM CHANNEL BLOCKERS

- In 2005, the AAPCC NPED reported more than 30,000 exposures to cardioactive steroids (including digoxin), β -adrenergic antagonists, and calcium channel blockers.
- Among these were 1,085 major outcomes and 167 fatalities.
- These xenobiotics have narrow therapeutic index, drawing a fine line between therapeutic dosing and poisoning.

Digoxin

- Digoxin is a cardioactive steroid derived from the foxglove plant.
- Digoxin and digitoxin are the only pharmaceuticals in the class.
- Plants such as oleander, yellow oleander, dogbane, and red squill contain cardioactive steroids with similar toxicity.
 - Some of these plants cause a great deal of morbidity worldwide.
- Of 2,828 reported exposures to cardiac steroid medications in 2005, 7.4% classified as major or fatal.
- **Mechanism:** Multiple therapeutic and toxic cardiovascular effects, all of which result from inhibition of the $\text{Na}^+\text{-K}^+\text{-ATPase}$
 - $\text{Na}^+\text{-K}^+\text{-ATPase}$ extrudes sodium from the myocardial cell, creating a sodium gradient that drives an $\text{Na}^+\text{-Ca}^{2+}$ -antiporter moving calcium extracellularly.
 - Inhibition of $\text{Na}^+\text{-K}^+\text{-ATPase}$ by digoxin increases intracellular Ca^{2+} , which therapeutically triggers Ca^{2+} -mediated Ca^{2+} release from the sarcoplasmic reticulum; commonly called Ca-mediated Ca release.
- Slows conduction through the sinoatrial (SA) and atrioventricular (AV) nodes
 - Probably through direct and vagally mediated mechanisms
 - In therapeutic use, decreases heart rate and increases inotropy
 - In overdose, the increased intracellular Ca^{2+} brings the cell closer to threshold, resulting in increased automaticity.
- Does not exert its therapeutic and toxic effects until it redistributes from the serum into the myocardium
- Has large volume of distribution, precluding elimination by hemodialysis
- Mostly eliminated renally, although some hepatic metabolism
- Maximal effect from therapeutic dose:
 - Seen at 4 to 6 hours when administered orally
 - Seen at 1.5 to 3 hours when given IV
- **Clinical manifestations:** Poisoning can be either acute or chronic.
 - Acute toxicity occurs when an individual without a tissue burden of digoxin ingests a supratherapeutic dosage of the drug.
 - Chronic toxicity usually occurs when an individual on a fixed dose of the drug loses the ability to excrete it effectively.
 - Both syndromes have similar cardiovascular manifestations.
 - Acute toxicity may feature more prominent GI symptoms.
 - Acute poisoning may result in nausea, vomiting, and abdominal pain, whereas chronic poisoning develops more insidiously.
 - In addition to GI symptoms, chronic poisoning may present with weakness, confusion, or delirium.
 - Bradycardia with a preserved blood pressure typically occurs in digoxin toxicity.
 - ECG is the most important test in establishing the diagnosis.
 - No single ECG manifestation is consistently seen in patients with digoxin toxicity.
 - Almost any rhythm is possible, with the exception of a rapidly conducted supraventricular rhythm.
 - Most common rhythm disturbance on initial ECG is the presence of ventricular ectopy.
 - ECG could potentially exhibit increased automaticity from elevated resting potential, conduction disturbance from AV and SA nodal block, both, or neither.
 - Ectopy may degrade into ventricular tachycardia or ventricular fibrillation.
 - If conduction disturbance predominates, the ECG may demonstrate sinus bradycardia or varying degrees of AV block.
 - Therapeutic range for digoxin is usually reported as 0.5 to 2.0 ng/mL.
 - Serum digoxin concentration is interpreted in the context of the history and ECG.
 - Digoxin cardiotoxin and serum concentrations do not necessarily reflect the degree of poisoning.
 - Digoxin requires several hours to redistribute from the serum to the tissues.
 - Shortly after an acute ingestion, the serum concentration may overestimate toxicity.
 - A mild increase in serum concentration in a patient chronically on digoxin may underestimate the high extent of the increased tissue burden.
 - Serum potassium concentration a better predictor of illness after acute ingestions.
 - In the pre-digoxin-specific antibody fragment era, no mortality when the potassium concentration was less than 5.0 mEq/L
 - 50% mortality when the potassium concentration was 5.0 to 5.5 mEq/L

- **Management of toxicity:** Acute toxicity can cause vomiting, so activated charcoal and gastric lavage may be of limited value.
- Atropine can be given IV in 0.5-mg doses for bradycardia.
 - Probably not important to “correct” the heart rate if the blood pressure is preserved
- If necessary, potassium should be supplemented.
 - Hypokalemia inhibits the function of the Na^+/K^+ -ATPase, and thereby exacerbates digoxin poisoning.
 - A pitfall in managing digoxin-poisoned patients is the administration of calcium in response to the recognition of hyperkalemia.
 - When hyperkalemia is the result of an increase in total body burden of potassium, such as in renal failure, calcium is the treatment of choice.
 - However, calcium administration is not recommended in the setting of digoxin poisoning where extracellular distribution of potassium is the result of a poisoned Na^+/K^+ -ATPase, not an increase in total body potassium.
 - Here, increasing extracellular calcium may accentuate toxicity.
- Digoxin-specific immune fragments
 - Digoxin-specific antibody fragments (Fab) is the most important intervention in digoxin-poisoned patients.
 - Prepared by cleaving the Fc fragment from IgG
 - Resulting Fab fragments less immunoreactive than the whole IgG antibodies
 - Causes allergic reaction in 0.8% of patients
 - Should be administered to anyone with the following:
 - Digoxin-induced cardiotoxicity
 - Serum potassium concentration ≥ 5.0 mEq/L after an acute overdose
 - Serum digoxin concentration ≥ 1.5 ng/mL at any time or ≥ 10 ng/mL at 6 hours after ingestion
 - Given by IV infusion and dosed according to serum concentration (Table 30.4)
 - In presence of suspected severe toxicity, treatment should not be dependent on nor await serum digoxin concentration results.
 - First clinical effect of Fab should be seen within 20 minutes and a maximal response within several hours.
 - After immune-specific antibody fragment administration, the serum digoxin concentration determined by most laboratories will be a total digoxin concentration.

TABLE 30.4**DIGOXIN-SPECIFIC FAB DOSE CALCULATION**

When serum digoxin concentration (SDC) known:
 No. of vials = $[\text{SDC (ng/mL)} \times \text{patient weight (kg)}]/100$

When SDC unknown, dose known:
 No. of vials = $\text{Amount ingested (mg)}/0.5 \text{ mg/vial}$

When both SDC and dose unknown (acute poisoning):
 Empiric therapy
 10–20 vials (adult or pediatric)

When both SDC and dose unknown (chronic poisoning):
 Empiric therapy
 Adult: 3–6 vials
 Pediatric: 1–2 vials

- This will include the antibody-bound digoxin, a result without clinical utility.
- Free digoxin concentration would be useful.

β -Adrenergic Antagonists and Calcium Channel Blockers

- In 2005, 18,207 reports to NPED of exposures to β -adrenergic antagonists
 - Including 60 fatalities and 525 major outcomes
- 10,500 reports of exposures to calcium channel blockers
 - Including 75 fatalities and 384 major outcomes

β -Adrenergic Antagonists

- Receptors are coupled to G proteins, which activate adenylyl cyclase, resulting in increased production of ATP from cyclic adenosine monophosphate.
 - Cyclic adenosine monophosphate activates protein kinase A, which initiates a series of phosphorylations.
 - Phosphorylation of L-type calcium channels on cell membranes increases intracellular calcium, which allows more activation of the SR and further calcium release from the SR, causing muscle contraction.
 - Calcium influx brings pacemaker cells closer to threshold.
 - Net result is increased inotropy and chronotropy.
- Most β -adrenergic antagonists are exclusively metabolized or biotransformed in the liver and then renally eliminated.
 - Exception to the rule is atenolol, which is exclusively renally eliminated.
- **Clinical manifestations of overdose:** All β -adrenergic antagonists have the potential to produce dose-dependent bradycardia and hypotension.
 - β -Adrenergic antagonists differ from one another in their selectivity for α -, β_1 -, and β_2 -adrenergic receptors.
 - Drugs with α - and β -adrenergic antagonist effects, such as labetalol and carvedilol, produce more hypotension and afterload reduction.
 - The more β_1 -selective drugs, including metoprolol and atenolol, have less potential for β_2 -related adverse effects such as bronchospasm.
 - The more lipid-soluble β -adrenergic antagonists, such as propranolol, penetrate the CNS more readily, causing obtundation or seizures prior to hemodynamic collapse.
 - Membrane-stabilizing activity, similar to type I antidysrhythmic activity, produces lengthening of the QRS interval, tachydysrhythmias, and hypotension.
 - Membrane-stabilizing effect usually is associated with propranolol and other lipid-soluble drugs but is observed after overdose with others.
 - Sotalol and acebutolol can produce QTc prolongation due to potassium channel blockade, which may result in torsades de pointes.

Calcium Channel Blockers

- The calcium channel blockers (CCBs) are formulated as both immediate and sustained release, but in overdose, the effects of either type may be prolonged.
 - CCBs undergo hepatic metabolism.
- Three major classes of CCBs
 - Dihydropyridines (including amlodipine, nifedipine, and others ending with the suffix “-pine”)

- Phenylalkylamines (verapamil)
- Benzothiazepine (diltiazem)
- More clinically useful to divide them into two classes: the dihydropyridines and the nondihydropyridines
 - All the drugs inhibit function of L-type calcium channels.
 - Dihydropyridines have greater affinity for calcium channels in vascular smooth muscle than the myocardium.
- **Clinical manifestations of overdose:** The most consequential clinical features of CCB overdose are cardiovascular. All of the CCBs produce hypotension with reflex tachycardia.
- Effects on heart rate and contractility vary based on the class of the particular drug.
 - Diltiazem produces little peripheral blockade but suppresses contractility and conduction through the SA and AV nodes, resulting in bradycardia and decreased inotropy.
 - These effects can be much more difficult to treat than the peripheral vasodilation of the dihydropyridines.
 - In severe poisoning, heart block or complete cardiovascular collapse results.
 - Verapamil, active in the peripheral vasculature and in the myocardium, produces a combination of the effects of the dihydropyridines and diltiazem.
 - This is considered to be the most dangerous of the CCBs, although any of them can cause death in overdose.
- CCBs have effects outside the cardiovascular system.
 - Blockade of L-type calcium channels in pancreatic β -islet cells trigger blockade of insulin release and may result in hyperglycemia.
- **Management of overdose of β -adrenergic antagonists and CCBs:** Patients who initially present without symptoms may rapidly become very ill.
- These overdoses should be taken very seriously and treated aggressively.
- Many antidotes have been investigated, with varying degrees of clinical success.
 - Patients with β -adrenergic antagonist and CCB overdose do not benefit from hemodialysis.
 - No single antidote exists for either β -adrenergic antagonists or CCBs.
- Optimal treatment
 - GI decontamination should be considered in all patients.
 - Gastric lavage may be indicated if there are pills still expected to be in the stomach (usually in the first hour or two after ingestion).
 - Activated charcoal should be administered.
 - Whole-bowel irrigation with polyethylene glycol is indicated for patients with a history of ingesting sustained-release drugs.
 - Initial management for hypotension
 - IV crystalloid fluid
 - IV atropine, 0.5 mg to 1 mg, may be given for bradycardia, though studies of atropine efficacy in CCB toxicity not definitive.
 - Calcium has a role in calcium channel blocker toxicity and β -adrenergic antagonist poisoning.
 - Increasing extracellular calcium helps to overcome calcium channel blockade and increase intracellular calcium, typically with greater improvement in blood pressure than heart rate.
 - The ideal dosing of calcium is not yet established.
 - IV bolus of 13 to 25 mEq of Ca^{2+} (10–20 mL of 10% calcium chloride or 30–60 mL of 10% calcium glu-

conate) can be followed by repeat boluses or an infusion of 0.5 mEq/kg/hour of Ca^{2+} .

- Calcium concentration should be closely monitored.
- Glucagon, an endogenous polypeptide hormone released by pancreatic α cells
 - Glucagon has significant inotropic effects mediated by its ability to activate myocyte adenylate cyclase without the β -adrenergic receptor.
 - Calcium channel opening occurs “downstream” from adenylate cyclase; glucagon may not be as effective for overcoming calcium channel blockade.
 - Glucagon should be given IV, at an initial dose of 3 to 5 mg (50 $\mu\text{g/kg}$ in children), up to 10 mg.
 - The total initial dose that produces a response should be given hourly as an infusion.
 - Glucagon may cause hyperglycemia or vomiting, but neither complication should limit the therapy if effective.
- Hyperinsulinemia/euglycemia therapy should be instituted early in patients with moderate to severe poisoning.
 - Insulin is a positive inotrope and may independently increase Ca^{2+} entry into cells.
 - Insulin may allow the myocardium, which usually relies on fatty acids, to use more carbohydrate for metabolism.
 - Ideal dose is not known.
 - Recommend IV bolus of 1 unit/kg, followed by an infusion of 0.5 to 1 unit/kg/hour.
 - Initial bolus should be preceded by a 1 g/kg bolus of dextrose, followed by an infusion to maintain euglycemia.
 - Initial infusion of 0.5 g/kg/hour of dextrose can be instituted and adjusted based on the subsequent glucose concentration.
- In severe poisoning, all of the preceding measures should be performed.
 - In addition, institute inotropes and vasoactive drugs.
 - Intra-aortic balloon counterpulsation should also be considered if cardiac output is severely compromised.
 - Technique may be ideal for these patients because cardiac output can recover in a relatively short period of time.

TOXIC ALCOHOLS

Mechanism of Toxicity

- *Toxic alcohols* refers to particular to methanol and ethylene glycol, which are the most important chemicals in the class because they are both of high potential toxicity and wide availability.
- In 2005, NPED received the following:
 - 6,220 reports of exposure to ethylene glycol, including 5.4% classified as major or fatal
 - 2,276 exposures to methanol, with 3.2% major or fatal
- Toxic alcohols have numerous industrial and consumer uses.
 - Methanol is commonly found in windshield wiper fluid.
 - Ethylene glycol is in automobile antifreeze.
 - Isopropanol is a ubiquitous topical disinfectant.
 - Specific laboratory testing is usually not available for these chemicals; establishment of the diagnosis of toxic alcohol

poisoning will necessitate skilled use of the serum osmolality and anion gap.

- Toxic alcohols are readily absorbed and have a volume of distribution similar to total body water.
- Parent compounds and the toxic metabolites are dialyzable.
- It is the metabolites that produce significant toxicity.
 - Methanol and ethylene glycol are metabolized in a stepwise fashion by alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH) to the clinically important metabolites formic acid (methanol) and glycolic, glyoxylic, and oxalic acid (ethylene glycol).
 - Isopropanol is less clinically consequential, as it is converted by ADH to acetone, which is an end product rather than a substrate of ALDH.
- ADH preferentially metabolizes ethanol over all other alcohols.
 - No significant metabolism of toxic alcohols will occur while high concentrations of ethanol are present.
 - When ADH is inhibited, the parent compounds are eliminated very slowly without metabolism.
 - Absent ADH, ethylene glycol is renally eliminated with a half-life of 8.5 hours, whereas methanol, which is eliminated as a vapor, has a half-life of 30 to 54 hours.
- When suspected, toxic alcohol poisoning requires ICU admission.
 - Patients may be obtunded and require therapeutic medication infusions and hemodialysis.

Clinical Manifestations

- The physical examination may be unremarkable.
- All toxic alcohols can produce significant CNS depression.
 - Compensatory tachypnea may be present if there is a metabolic acidosis.
- Acetone, generated from ADH metabolism of isopropanol, produces nausea, hypotension, hemorrhagic gastritis, and tachycardia, but these are not usually life threatening.
- Formate, a methanol metabolite, can produce blindness from toxicity to the retina and optic nerve.
- Laboratory studies can suggest—not establish or exclude—the diagnosis of toxic alcohol poisoning.
 - Metabolites of methanol or ethylene glycol may cause an elevated anion gap metabolic acidosis.
 - The hallmark laboratory finding of isopropanol poisoning is ketonemia without acidosis.
 - Ethylene glycol may cause nephrotoxicity when the primary metabolite oxalic acid precipitates as calcium oxalate crystals in the renal tubules.
 - Osmolar gap, the difference between the measured and unmeasured osmoles, may be increased when the serum contains toxic alcohol osmoles.
 - Very high osmolar gap does suggest the presence of toxic alcohol.
 - Low or normal gap does not exclude the presence of ethylene glycol or methanol.
 - The “normal” osmolar gap varies widely in population, from—0 to 10, such that very high concentrations of toxic alcohols might not be apparent when the gap is calculated.
- Fluorescence of the urine or presence of calcium oxalate crystals in the presence of ethylene glycol poisoning is neither sensitive nor specific.
- Fluorescein is added to some brands of ethylene glycol-based antifreeze to facilitate detection of radiator leaks.
 - Woods lamp may be used to detect urine for fluorescence as a screen for ethylene glycol.
 - However, a large group of children not exposed to ethylene glycol had urinary fluorescence.
 - Because of limitations of laboratory studies, treatment should be started empirically as soon as the diagnosis is considered.

Management

- Several clinical presentations suggest poisoning with a toxic alcohol, and each requires different management considerations.
- First type presents without acidosis and either a history of ingesting ethylene glycol or methanol or a very elevated osmolar gap.
 - Immediately begin an ADH inhibitor.
 - Obtain toxic alcohol concentrations (when available).
 - Decision to continue treatment or begin hemodialysis can be made based on the presence of a toxic alcohol in a high concentration.
 - If result is not expected in a timely manner, dialysis should be presumptively performed.
- Second scenario presents with an unexplained elevated anion gap metabolic acidosis that is not explained by the presence of lactate, ketoacids, or uremia.
 - Diagnosis should be considered.
 - ADH inhibition and hemodialysis should be instituted.
 - A helpful test in this scenario is a serum ethanol concentration.
 - As long as there is elevated ethanol concentration present in the serum, toxic alcohols cannot be converted into their metabolites.
 - Thus, if a patient has a very elevated ethanol concentration, the elevated anion gap metabolic acidosis cannot be explained by toxic alcohol poisoning, unless the ethanol was consumed only hours after the ingestion of the toxic alcohol.
- In the third scenario, if a serum toxic alcohol concentration is available, the diagnosis can be established rapidly, and management is straightforward.
 - If the serum concentration of methanol is <25 mg/dL—or ethylene glycol <50 mg/dL—and there is no metabolic acidosis, treatment is not necessary.
- If treatment is required, the clinician must determine whether to use an ADH inhibitor alone or in conjunction with hemodialysis.
- Two important considerations when determining whether hemodialysis is necessary
 - First concern is the presence of toxic metabolites such as formate. Although these metabolites cannot easily be measured directly, the presence of a metabolic acidosis suggests that some of the parent compound has already been metabolized to a toxic metabolite, and dialysis should be employed.

- Second consideration is the duration of time needed to eliminate the toxic alcohol without dialysis.
 - Half-life of methanol is approximately 2 days when ADH is inhibited.
 - If the initial serum concentration is 200 mg/dL, about 6 days in an ICU may be necessary to reach a concentration of 25 mg/dL.
 - In contrast, if dialysis were performed, the patient may require only a day of hospitalization, depending on the reason for ingestion of the alcohol.
- Two ADH inhibitors available are fomepizole and ethanol.
 - Though more expensive, fomepizole is the treatment of choice.
 - Fomepizole is administered by empiric weight-based dosing, whereas ethanol infusion requires serum concentrations to be obtained frequently.
 - Fomepizole does not cause CNS or respiratory depression.
 - Fomepizole is given as a 15 mg/kg IV loading dose, followed in 12 hours by 10 mg/kg every 12 hours for 48 hours.
 - If continued dosing is required, the infusion rate should be increased to 15 mg/kg.
 - When fomepizole is unavailable, ethanol should be given IV, or orally if necessary.
 - Loading dose of ethanol is 0.8 g/kg over 20 to 60 minutes, followed by an initial infusion of 100 mg/kg/hour.
 - The goal of ethanol therapy is to maintain an ADH inhibitory concentration of 100 mg/dL.
 - Serum ethanol concentration should be obtained frequently and the rate adjusted accordingly.
- Hemodialysis is performed for patients with concentrations of methanol >25 mg/dL or ethylene glycol >50 mg/dL when toxic metabolites are shown to be present

(indicated by metabolic acidosis), or when ADH inhibition alone would require an unreasonable amount of time.

- ADH blockade should continue during hemodialysis; fomepizole should be dosed every 4 hours; and ethanol should be administered at a rate of 250 to 350 mg/kg/hour.
- Several hemodialysis sessions may be needed to remove the toxic alcohol, depending on the initial concentration.
- Symptoms of isopropanol can usually be managed with fluids and supportive care alone, although rarely, hemodialysis may be indicated.
- Folate is a cofactor in the conversion of formic acid to a nontoxic metabolite, and thiamine and pyridoxine assist in transforming toxic metabolites after ethylene glycol poisoning.
 - Therefore, 1 to 2 mg/kg of folic acid given every 4 to 6 hours in the first 24 hours of methanol poisoning
 - Thiamine hydrochloride (100 mg IM or IV) and pyridoxine (100 mg/day IV) administered for ethylene glycol poisoning
- Reasonable to administer sodium bicarbonate to a target pH of 7.2 to shift the equilibrium from formic acid to the less toxic formate

CHOLINERGIC COMPOUNDS

Mechanism of Toxicity

- Acetylcholine is the neurotransmitter found throughout the parasympathetic nervous system, in the sympathetic nervous system at the level of the ganglia and sweat glands, and at the neuromuscular junction (Fig. 30.3).

FIGURE 30.3. Sympathetic and parasympathetic nervous system. (Adapted with permission from Clark RF. Insecticides: organic phosphorous compounds and carbamates. In: Flomenbaum NE, Goldfrank LR, Hoffman RS, et al., eds. *Goldfrank's Toxicologic Emergencies*. 8th ed. New York: McGraw-Hill; 2006:1447–1459.)

- *Cholinergic syndrome* describes the condition of excess acetylcholine characterized by the sum of the parasympathetic, somatic, and sympathetic effects.
- Cholinergic compounds are used as medications, pesticides, and weapons.
- In 2005, the AAPCC received reports of 10 fatalities and 62 major effects related to organophosphate and carbamate insecticides.
 - World Health Organization estimates at least 1 million unintentional poisonings and 2 million suicide attempts annually worldwide from these insecticides.
- Acetylcholine is inactivated in the synapse by acetylcholinesterase (AChE).
- Inhibition of AChE causes an excess of the neurotransmitter in the synapse.
- Two most important classes of AChE inhibitors
 - The carbamates—inactivate AChE by carbamylation
 - The organic phosphorous compounds—inactivate AChE by phosphorylation
 - Carbamates and organic phosphorous compounds both are absorbed by ingestion, by inhalation, and through skin.
- Some generalizations can be made about the two classes.
 - Organic phosphorous compounds have a greater delay to onset of action.
 - After ingestion, peak concentrations reported at 6 hours
 - Many organic phosphorous agents activated in the liver
 - Resulting in a further delay to peak action
 - Many of the carbamates have peak concentrations within 40 minutes of ingestion.
 - Organic phosphorous compounds are generally very lipophilic.
 - Redistribution from fat allows measurable serum concentrations for up to 48 days.
 - Carbamates may be almost completely eliminated within days.
 - Organic phosphorous compounds exhibit peripheral and CNS effects, whereas the carbamates do not readily cross into the CNS.
 - Most important
 - Organic phosphorous compounds exhibit “aging” whereby the reversible inhibition of AChE becomes permanent.
 - Aging can take minutes to days, depending on the particular compound.
 - Carbamates, in contrast, spontaneously hydrolyze from the active site of AChE and do not age.
- ICU admission is required for those with respiratory compromise, hemodynamic instability, or the need for administration of large amounts of atropine.

Clinical Manifestations

- Diagnosis is often established by recognition of the muscarinic signs.
 - Includes salivation, lacrimation, urination, defecation, bradycardia, bronchorrhea, and bronchospasm
- Acetylcholine initially acts as an agonist.
 - In excess, acetylcholine becomes an antagonist at the neuromuscular junction, producing weakness, fasciculations, and paralysis.
 - Stimulation of nicotinic receptors at the sympathetic ganglia produces tachycardia and mydriasis.

Management

- The first management priorities involve the following:
 - Securing the airway when necessary
 - Decontaminating the patient’s skin to protect caregivers and prevent further absorption
 - After initial stabilization, administering atropine
 - Tachycardia is not a contraindication to atropine.
 - The goal is reversal of the muscarinic symptoms.
 - Titrate to effect the resolution of bronchospasm and bronchorrhea.
 - The initial dose of 1 mg IV atropine (0.05 mg/kg in children) can be doubled every 2 minutes until muscarinic signs are controlled.
 - There is variation in amount of atropine required, ranging from one to hundreds of milligrams.
- If CNS anticholinergic toxicity develops prior to resolution of peripheral muscarinic signs
 - The peripherally acting antimuscarinic agent, glycopyrrrolate, may be given.
 - Initial dose is 1 mg IV and then titrate to symptomatic relief.
 - A common clinical pitfall is to interpret froth from the patient’s mouth as a sign of cardiogenic pulmonary edema and respond with fluid restriction.
 - On the contrary, cholinergic-poisoned patients have large volume losses from diaphoresis and bronchorrhea.
- Oximes are used to supplement antimuscarinic therapy.
 - Improve both muscarinic and nicotinic signs, primarily by restoring activity to phosphorylated AChE
 - Will not restore activity once aging has occurred, so must be administered early
 - Recommended for both organic phosphorous compounds and carbamates because oximes may have salutary effects after carbamate poisoning and because the toxic agent in question is not always known with certainty
 - Even in carbaryl poisoning, adequate atropinization overcomes any deleterious effect of pralidoxime.
 - Pralidoxime (2-PAM) is the oxime most frequently available in the United States.
 - Administer 1 to 2 g IV over 30 minutes (20–40 mg/kg in children, to a maximum of 2 g).
 - Significant poisoning may require a continuous infusion of 500 mg/hour (10–20 mg/kg/hour in children, up to adult dose).
- Diazepam should be administered to patients severely poisoned by organic phosphorous compounds.
 - Although human data are not available, animal studies show a survival benefit possibly unrelated to the GABAergic effects of diazepam.
 - Severely poisoned patients will require endotracheal intubation.

Diagnostic Studies

- AChE inhibitor poisoning is a clinical diagnosis.
 - RBC cholinesterase and butyrylcholinesterase are inhibited by carbamates and organic phosphorous compounds.
 - Activity may remain depressed after clinical signs and symptoms have resolved.
 - These tests may have a clinical role in mild cases when the diagnosis is unclear.

- Electromyography may be a sensitive indicator of toxicity before clinically apparent symptoms have occurred.

Delayed Manifestations

- In the acute setting, the physician should be vigilant for recurrence of cholinergic signs after apparent resolution and for a distinct form of toxicity called the *intermediate syndrome*.
- *Intermediate syndrome*
 - Syndrome is so named because it occurs after acute, but before delayed, toxicity that may occur 24 to 96 hours after organic phosphorous poisoning.
 - The syndrome consists of upper-body weakness, cranial nerve palsies, and areflexia.
 - Syndrome appears to be self-limited but can last up to 30 days and be severe enough to require intubation.
 - Continue pralidoxime infusion at 500 mg/hour when this diagnosis is considered.
 - Organic phosphorous compounds are very lipophilic; redistribution from fat stores may result, causing delayed toxicity days after apparent resolution.
 - Considered discharge when the patient has been asymptomatic without additional treatment for 1 to 2 days.

CYANIDE

Mechanism

- Cyanide salts are widely available and may be used in suicidal or homicidal poisoning.
- Jewelers, laboratory workers, and industrial workers have ready access to cyanide.
 - Relationship to these industries may be an important historical clue.
- Cyanide poisoning should also be considered in all fire victims.
 - Cyanide is released when certain synthetic and natural fibers undergo combustion.
- Cyanide poisoning most frequently occurs after the ingestion of a cyanide salt or inhalation of the gas hydrogen cyanide.
 - In both forms, cyanide is rapidly absorbed.
 - Most important toxic effect of cyanide is inhibition of cytochrome oxidase of the electron transport chain.
 - Despite the presence of oxygen, cells cannot offload electrons from nicotinamide adenine dinucleotide (NADH) to oxygen, and generate ATP, resulting in anaerobic metabolism and producing lactic acid.
- Small quantities of cyanide are detoxified by the enzyme, rhodanese.
 - Rhodanese catalyzes the transfer of sulfur from thiosulfate, yielding thiocyanate.
 - Poisoning results when this system is overwhelmed by large concentrations of cyanide.

Clinical Manifestations

- History may be very helpful in establishing diagnosis.
- Cyanide poisoning should be considered in anyone who rapidly loses consciousness after ingestion or inhalational exposure.
- Signs and symptoms resemble those of hypoxia, with no cyanosis.
 - Headache
 - Lethargy
 - Seizures
 - Coma

Management of Cyanide Poisoning

- Requires treatment before laboratory confirmation is available
 - As soon as considered
 - 100% oxygen should be administered.
 - IV access should be established.
 - Fluids should be given.
 - Remainder of treatment depends on the route of exposure.
 - Symptoms of cyanide poisoning are similar to those associated with hypovolemia or carbon monoxide poisoning.
 - Diagnosis is difficult to establish with certainty.
 - Laboratory studies will show a lactic acidosis.
 - Plasma lactate concentration >8 mM/L in patients with clinical suspicion of poisoning was 94% sensitive and 70% specific for cyanide toxicity.
 - The cyanide antidote kit consists of amyl nitrite, sodium nitrite, and sodium thiosulfate.
 - Nitrites derive their efficacy by generating methemoglobin, which has a greater affinity for cyanide than cytochrome oxidase.
 - If reduced oxygen-carrying capacity suspected (due to anemia or carboxyhemoglobinemia), omit nitrites.
 - Avoid nitrites in patients after smoke inhalation.
 - Such individuals may not tolerate further compromise in their oxygen distribution associated with an increase in methemoglobin.
 - Amyl nitrite is a volatile liquid.
 - Ampule encasing is broken and held in front of the patient's mouth for 15-second intervals with 15-second breaks.
 - Once IV access is established, sodium nitrite can replace the amyl nitrite.
 - Sodium nitrite is administered 10 mL IV in adults (0.2 mL/kg in children).
 - In 2 hours, the dose can be repeated at half the initial dose.
 - A methemoglobin concentration should be obtained 30 minutes after nitrite administration: target concentration of 20% to 30%.
 - Sodium thiosulfate, the final component of the kit, functions by providing substrate to rhodanese, facilitating conversion of cyanide to thiocyanate.
 - Dose is 50 mL in adults and 1.65 mL/kg in children.
 - Drug may be repeated in 2 hours at half the initial dose if symptoms persist.
 - Hydroxocobalamin
 - ◻ Available in the United States shortly
 - ◻ Combines with cyanide to form cyanocobalamin (vitamin B₁₂)
 - ◻ Synergistic with thiosulfate
 - ◻ Hydroxocobalamin should be given IV at 70 mg/kg (to a maximum of 5 g) in a separate infusion site from thiosulfate.

CYANIDE, THIOCYANATE, AND NITROPRUSSIDE

- Nitroprusside contains an iron molecule coordinated to five cyanide molecules and one molecule of nitric oxide.
- Cyanide molecules slowly liberated after nitroprusside is infused
 - Usually at a rate that can be detoxified by endogenous pathways
- Risk factors for accumulation of cyanide are:
 - Prolonged infusion
 - High infusion rate
 - Poor nourishment
- If diagnosis suspected
 - Discontinue infusion.
 - Administer hydroxocobalamin and thiosulfate.
- More likely complication of nitroprusside use is thiocyanate toxicity.
 - Thiocyanate causes no symptoms at low concentrations.
- Cleared renally
 - Bioaccumulation occurs in patients with impaired renal function.
- Symptoms are as follows:
 - Delirium
 - Hallucinations
 - Seizures
 - Rash
- Serum thiocyanate concentrations checked after 48 to 72 hours of infusion in the following:
 - Patients receiving $>2 \mu\text{g/kg/minute}$ nitroprusside
 - Those with renal insufficiency
 - Discontinue infusion if thiocyanate concentration is $>10 \text{ mg/dL}$.
 - Dialysis effective for thiocyanate accumulation.
 - Reserve for the most severely compromised patients.

METHEMOGLOBIN

Mechanism

- Results from the formation of “dyshemoglobin”
 - Caused by inappropriate oxidation of heme iron
- Normally, iron in deoxyhemoglobin remains in the reduced ferrous state: Fe^{2+} .
 - Heme is available to bind oxygen.
 - After oxygen binds, iron assumes the oxidized ferric state: Fe^{3+} .
- Methemoglobin is formed normally in small quantities when hemoglobin iron moiety is exposed to oxidative stress.
 - Methemoglobin is converted to the ferric state in the absence of binding oxygen.
 - It is unable to bind oxygen and increases the affinity of normal hemoglobin for oxygen.
 - Result of methemoglobin formation is as follows:
 - Decreased oxygen delivery
 - Leftward shift in the oxygen dissociation curve
 - Low-level methemoglobin production may be a protective mechanism against oxidant damage to erythrocytes.
 - Major mechanism of methemoglobin reduction is catalyzed by enzyme, methemoglobin reductase (cytochrome b_5 reductase), using NADH generated from the Embden-Meyerhof glycolytic pathway.
- Congenital methemoglobinemia
 - Rare condition caused by methemoglobin reductase deficiency
 - Enzyme also relatively deficient until approximately 4 months, making infants prone to methemoglobin formation
- Most individuals with methemoglobinemia treated and discharged from ED
 - May require ICU admission when it recurs after initial treatment
 - Either from continued absorption of an inducer or
 - Continued metabolism of a drug to a methemoglobin inducer

Clinical Manifestations

- Diagnosis commonly confirmed by co-oximetry
 - May be established presumptively based on symptoms and signs and via pulse oximetry
- Symptoms of methemoglobinemia those associated with hypoxia
 - Severity of symptoms determined by concentration of methemoglobin and the patient's underlying comorbidities
 - At low concentrations (0%–15%), patients may be asymptomatic.
 - At moderate concentrations (20%–50%), patients may manifest decreased exercise tolerance and dyspnea.
 - At high concentrations (50%–70%), metabolic acidosis, seizures, and coma result.
 - Concentrations greater than 60% or 70% can cause death in previously healthy individuals.
- Cyanosis, an important physical examination finding, occurs when methemoglobin concentration is 1.5 g/dL .
 - This corresponds to a concentration of 10% in an individual with a total hemoglobin concentration of 15 g/dL .
 - In contrast, 5 g/dL of deoxyhemoglobin is required to produce cyanosis, corresponding to an oxygen saturation of 66% in the same patient.
 - Thus, patients who are cyanotic from methemoglobinemia will not appear as ill as those who are cyanotic from impaired oxygenation.
- Pulse oximetry aids in diagnosis before co-oximetry has been obtained.
 - Methemoglobin interferes with pulse oximetry somewhat predictably.
- Pulse oximetry reads absorbance of light at 660 nm and 940 nm, so chosen because they are the best to distinguish the absorption spectra of oxyhemoglobin and deoxyhemoglobin.
 - Based on the ratio of absorption between the two wavelengths, the pulse oximeter uses an algorithm to estimate the percentage of total hemoglobin as oxyhemoglobin.
 - Methemoglobin has greater absorption than either oxyhemoglobin or deoxyhemoglobin at those wavelengths.
 - When present in modest concentrations, the pulse oximeter will no longer be able to meaningfully calculate oxygen saturation.
 - In the clinical setting, methemoglobin does consistently generate readings between 70% and 90%.

- SaO_2 derived from arterial blood gas analysis is not measured in the same fashion as SpO_2 , and will not reflect the methemoglobin concentration.
 - SaO_2 is a calculated saturation based on the pO_2 and should be normal in the setting of methemoglobinemia.
 - Difference between the SpO_2 and SaO_2 may suggest methemoglobinemia.

Methemoglobin Inducers

- Acquired methemoglobinemia is most frequently seen after drug exposure.
 - It can also be found in infants without drug exposure who are ill with a metabolic acidosis or diarrhea.
 - Drugs associated with methemoglobin formation are extensive.
 - Dapsone, nitrites, nitrates, benzocaine, and sulfonamides are consistently implicated in producing methemoglobinemia (Table 30.5).

TABLE 30.5

COMMON ETIOLOGIES OF METHEMOGLOBINEMIA

Hereditary

Hemoglobin M

Cytochrome b_5 reductase deficiency

Acquired: medications

Amyl nitrate

Benzocaine

Dapsone

Lidocaine

Nitric oxide

Nitroglycerin

Phenacetin

Phenazopyridine

Prilocaine

Quinones

Sulfonamides

Acquired: other xenobiotics

Aniline dye derivatives

Butyl nitrite

Chlorobenzene

Fire

Food adulterated with nitrites

Food high in nitrates

Isobutyl nitrite

Naphthalene

Nitrate

Nitrite

Nitrophenol

Nitrous gases

Silver nitrate

Trinitrotoluene

Well water (nitrates)

Pediatric

Reduced nicotinamide adenine dinucleotide (NADH) methemoglobin reductase activity in infants (<4 mo)

In association with low birth weight, prematurity, dehydration, acidosis, diarrhea, and hyperchloremia

Adapted with permission from Price D. Methemoglobin inducers. In: Flomenbaum NE, Goldfrank LR, Hoffman RS, et al., eds. *Goldfrank's Toxicologic Emergencies*. 8th ed. New York: McGraw-Hill; 2006:1734–1745.

- It is not entirely clear why some individuals develop methemoglobinemia after exposure to these drugs and others do not.
- There is clearly a dose-response effect, and host factors such as coexisting medical illness and metabolic variables play a role in methemoglobin development.

Management of Methemoglobinemia

- When cyanosis is recognized and methemoglobinemia is considered
 - Administer 100% oxygen by nonrebreather mask.
 - Unless patient is asymptomatic, methylene blue should be administered IV, 1 to 2 mg/kg over 5 minutes.
 - Methylene is reduced by nicotinamide adenine dinucleotide phosphate to leukomethylene blue.
 - Leukomethylene blue, in turn, reduces methemoglobin to hemoglobin.
 - Clinical improvement is seen within minutes of administration.
 - Because the medication itself has a blue color, SpO_2 may transiently worsen.
 - Repeat dose of methylene blue may be required if the methemoglobin concentration is high or if there is ongoing oxidative stress.
- Some recommend against giving methylene blue, an oxidizing agent, to individuals with glucose-6-phosphate dehydrogenase (G6PD) deficiency.
 - Patients with this condition suffer from hemolytic anemia when exposed to drugs that create oxidative stress.
 - Because G6PD is required to activate methylene blue, a deficiency in the enzyme may lead to a lack of efficacy of the antidote.
- Administration of methylene blue is appropriate when clinically indicated unless there is a strong history of G6PD deficiency.
 - In these cases, hyperbaric oxygen or exchange transfusion should be considered.
 - If the G6PD-deficient patient presents with severe methemoglobinemia, methylene blue should be administered and the patient monitored closely for hemolysis.

Dapsone-induced Methemoglobinemia

- Both dapsone and its hydroxylamine metabolites are responsible for methemoglobin formation.
 - Cytochrome P450 conversion of dapsone to these metabolites inhibited by cimetidine
 - Cimetidine administered IV, 300 mg every 6 hours, to these patients

CARBON MONOXIDE

Mechanism

- The AAPCC received more than 16,000 reports of carbon monoxide (CO) exposure, including 176 major effects and 66 fatalities.
- These figures underestimate morbidity and mortality from carbon monoxide, considered the leading cause of poisoning death in the United States.

- CO is as follows:
 - Hemotoxin
 - Neurotoxin
 - Cardiac toxin
 - Inhibitor of cytochrome oxidase
 - CO binds to hemoglobin with greater affinity than does oxygen and causes a leftward shift of the oxyhemoglobin dissociation curve.
 - This causes a decrease in the delivery of oxygen to cells.
 - Although the formation of carboxyhemoglobin can impair oxygen delivery sufficiently to cause mortality, inhibition of oxygen delivery does not fully explain why carboxyhemoglobin concentrations of 50% are often fatal whereas a similar degree of anemia might be well tolerated.
 - Formation of carboxyhemoglobin is inadequate to explain the chronic cardiac and neurologic sequelae of CO.
 - CO inhibition of cytochrome oxidase persists for days after carboxyhemoglobin concentration has normalized
 - CO is associated with damage to the brain endothelium, resulting in lipid peroxidation.
 - CO also binds to myoglobin with high affinity, making it a direct skeletal and cardiac muscle toxin.
- CO results from the incomplete combustion of carbonaceous fuels.
 - It is tasteless, odorless, and colorless.
 - Initial clue to the presence of CO in the home may be the alarm from a CO detector.
 - Methylene chloride, an important source of CO that is not a product of combustion, is hepatically metabolized to CO by the liver.
 - Methylene chloride is used as a paint stripper and can be absorbed dermally, inhalationally, or by ingestion.
 - Unlike other sources of CO poisoning, where carboxyhemoglobin begins to decline as soon as the patient is removed from the exposure, peak carboxyhemoglobin concentration will occur hours after exposure to methylene chloride as the parent compound is metabolized to CO.
- CO poisoning does not usually require ICU admission.
 - ICU admission necessary only for the following:
 - patients who are comatose or obtunded
 - patients with signs of cardiotoxicity
 - patients with significant burns or other comorbidities

Clinical Manifestations

- Initially complaints are of headache, nausea, and dizziness.
 - CO poisoning may be misdiagnosed as a viral illness.
 - Diagnosis should be considered when more than one person in a home presents with the same symptoms.
- Alteration in mental status, coma, seizures, and syncope are signs of severe poisoning.
 - Indicators of tissue hypoxia, such as tachypnea, tachycardia, and ECG changes, may be seen.
 - CO can cause dysrhythmias or an acute myocardial infarction (MI).
- Intensity of signs and symptoms is related to duration and severity of exposure and comorbid conditions.

- Pulse oximetry will interpret carboxyhemoglobin as hemoglobin: SpO₂ will be falsely normal.
- Diagnosis of CO poisoning
 - Aided by obtaining the carboxyhemoglobin concentration, which can be taken from either a venous or arterial sample
 - Normal carboxyhemoglobin concentration less than 5%
 - In smokers, may be up to 10%
 - Carboxyhemoglobin concentrations are an indicator of exposure but do not correlate with degree of toxicity.
 - With delay from exposure to measurement of carboxyhemoglobin, the concentration loses further value as a clinical tool.
 - More likely if the patient has been receiving supplemental oxygen, which decreases the half-life of carboxyhemoglobin the level will have decreased.

Chronic Sequelae

- For survivors of an acute CO exposure, there may be significant chronic neurologic and cardiovascular effects.
 - Delayed neurologic sequelae follow the resolution of initial symptoms.
 - Sometimes days to weeks later
 - Include dementia, movement disorders, and memory impairment

Diagnostic Studies

- In patients with chest pain, shortness of breath, palpitations, or neurologic deficits indicating severe exposure
 - ECG should be performed.
 - Serum cardiac markers should be obtained.
 - Pregnancy status should be determined in women of child-bearing age.
 - Elevated serum cardiac markers during moderate and severe acute toxicity predict long-term mortality.
 - Pathophysiology of chronic cardiovascular effects of carbon monoxide poisoning probably involves CO poisoning of cardiac myoglobin but needs further study.
- Within 12 hours of exposure, loss of consciousness occurs, and changes on a computed tomography (CT) scan of the brain may be seen.
 - Findings include the following:
 - Symmetric, low-density changes in the globus pallidus, putamen, and caudate nuclei
 - Normal CT scan a good prognostic indicator
 - A negative CT within 1 week of admission associated with good outcome

Management

- When diagnosis is considered, administer 100% oxygen.
 - Obtain carboxyhemoglobin concentration.
 - Without supplemental oxygen, the half-life of carboxyhemoglobin in blood is 4 to 6 hours.
 - With oxygen, it ranges from 1 to 2 hours.
- Most important decision is whether to administer hyperbaric oxygen (HBO).
 - HBO decreases the half-life of carbon monoxide even more rapidly than 100% normobaric oxygen, but this is not clinically important.

- Value of HBO is its potential to decrease morbidity, not mortality.
- Specifically, HBO may reduce delayed neurologic sequelae by preventing brain lipid peroxidation and regenerating CNS cytochrome oxidase after CO exposure.
- The use of HBO for CO poisoning is controversial.
 - Large randomized clinical trials report mixed results.
 - All of the trials conducted to date have limitations, and the ideal trial may never be performed because of the ethical concerns of randomizing patients to nonhyperbaric therapy.
 - In light of the demonstrable benefit of HBO and the relative safety of the therapy, we recommend HBO in patients with moderate to severe poisoning as early as safely possible.
 - Delay greater than 6 hours may associated with worse outcome.
 - Indications for HBO are as follows:
 - Ayncope, coma, seizure, or any other hard neurologic findings
 - Signs of cardiac ischemia or dysrhythmias
 - Carboxyhemoglobin >20%

Pregnancy and Carbon Monoxide

- Because fetal circulation relies on maternal oxyhemoglobin for oxygenation, any disturbance in maternal oxygen delivery will be magnified in the fetus.
- Fetal hemoglobin has less affinity for CO than adult hemoglobin, but there is a high incidence of fetal CNS damage and spontaneous abortion after severe maternal poisoning.
- Pregnant women with lesser exposures have normal pregnancies and deliver healthy children.
- All prospective trials of HBO have excluded pregnant women, but we recommend treating these patients similarly to those who are not pregnant.

CAUSTICS

Mechanism

- Chemicals that produce damage during contact with tissues
 - Generally acid or alkali
 - Commercially available as toilet bowl cleaners, drain cleaners, and other products
 - Commonly encountered alkalis include the following:
 - Ammonium hydroxide (ammonia)
 - Sodium hydroxide (lye, found in drain cleaners)
 - Hydrochloric acid and sulfuric acid, which are both used as drain cleaners, with the latter used in automobile batteries as well
 - Alkali drain cleaners accounted for more than 3,677 reported exposures in 2005, more than any other caustic chemical. Of these, 46 were major and 5 fatal.
 - Damage caused by caustics is determined by pH, quantity, duration of contact, and the titratable alkaline (or acid) reserve.
 - Ingested caustics can potentially produce damage to the oropharynx, esophagus, stomach, and respiratory tract.

- Acid and alkali produce different injuries.
 - Alkaline exposure produces dissociated OH^- ion, resulting in fat saponification, membrane dissolution, and cell death—a process known as liquefactive necrosis.
 - Acid exposure releases H^+ ions, producing an eschar and desiccation, a process referred to as *coagulation necrosis*.
 - Both acid and alkali produce stomach and esophageal injury.
- Esophageal burns can be described by a commonly used classification system.
 - Grade I burns demonstrate hyperemia without ulceration.
 - Grade II burns demonstrate ulcers but do not damage periesophageal tissues.
 - Grade II lesions are subdivided into IIa (noncircumferential) and IIb (circumferential) lesions.
 - Grade III describes burns with deep ulceration and damage to surrounding tissues.
 - Classification of the burn predicts chronic sequelae.
 - Grade IIb and III injuries may heal with strictures and dysphagia and may perforate.
 - When esophageal perforation is suspected, or when there is airway injury, patients are admitted to the ICU.

Clinical Manifestations

- Lack of oral burns does not exclude significant esophageal injury.
 - Presence of oral lesions does not guarantee visceral burns.
- Physical examination after caustic ingestion can be deceiving.
 - Visceral burns present in 37.5% of patients without oral burns and 50% of patients with oral burns.
 - Drooling, odynophagia, and abdominal pain are common findings after significant caustic exposure.
 - Abdominal pain or tenderness occur in fewer than half of patients with gastric injury.
 - Pulmonary aspiration may lead to coughing and respiratory distress.
 - Absorption of acid from the stomach may cause acidemia after ingestion.
 - Alkalis are not systemically absorbed in consequential amounts.
 - Metabolic acidosis may be present if significant injury has occurred.

Management

- Endoscopy should be performed in all adult patients presumed to have significant exposures to establish the severity of the burn.
 - If endoscopy is normal, the patient can be safely discharged.
 - Patients with severe injury are rapidly stabilized and referred for surgical care before their condition worsens.
 - Endoscopy should be performed as early as possible, ideally within 12 hours.
 - Wound strength is weakest between 5 days and 2 weeks after ingestion, when the perforation risk is greatest.
 - Exception to universal endoscopy may be a subset of pediatric exposures.

- No serious esophageal injuries are found in patients who lacked stridor or the combination of vomiting and drooling.
- Presence of endoscopic evidence of perforation mandates immediate surgery.
 - Other indications for operative repair include the following:
 - Pleural effusions
 - Ascites
 - Serum pH <7.2
- With grade I injury, the patient can be started on a soft diet and the diet advanced as tolerated.
- Presence of grade II esophageal burns with gastric sparing warrants placement of a nasogastric tube under direct visualization.
- More severe injury may require parenteral nutrition or a jejunostomy.
- Silicone rubber esophageal stents have been used to prevent stricture.
- Administer antibiotics that cover anaerobic bacteria and gram-positive and gram-negative aerobic organisms when perforation considered.
 - Piperacillin/tazobactam are appropriate choices as are levofloxacin and clindamycin.
- Corticosteroids are recommended to help prevent scarring and stricture formation in grade II lesions.
 - Most recent meta-analysis could not find a benefit for the administration of corticosteroids following exposure to caustics.

HYDROFLUORIC ACID

Mechanism

- Hydrofluoric acid (HF), a weak acid, has no important tissue-corrosive properties.
 - HF dissolves metal oxides and glass, making it useful in rust removal and glass etching.
 - HF is stored in plastic, not glass.
- HF is an important dermal, ophthalmic, pulmonary, and systemic toxin.
 - HF penetrates deeply into tissues before dissociating into protons and fluoride ions.
 - Protons cause some damage.
 - Most important toxic effects result from fluoride ions binding the divalent cations calcium and magnesium.
 - This leads to neuropathic pain and cell death.
- HF ingestions and exposures resulting in electrolyte abnormalities require ICU admission.

Clinical Manifestations

- Clinical syndrome distinct from the caustic agents and requires specific therapy.
 - In small dermal exposures, HF produces severe pain with limited dermal findings.
 - Large exposures by any route, including dermal, can produce severe hypocalcemia and death.
- Most unintentional HF exposures are dermal.

- Severity of HF exposure is determined by the duration of exposure, concentration, and extent of surface area exposed.
 - Low fluoride concentration solutions may cause severe pain beginning hours after the exposure.
 - Physical examination is unremarkable.
 - Area that appears normal or merely mildly erythematous may be extremely painful.
 - High-concentration industrial preparations may cause immediate pain, with hyperemia and ulceration.
 - Ophthalmic exposures result in pain, chemosis, and damage to conjunctiva and corneal epithelium.
- Most consequential effects of HF poisoning are systemic.
 - Dermal exposures to concentrated HF covering only 2.5% body surface area have resulted in systemic toxicity.
 - Typical fatal dermal exposures are larger.
 - Lengthening of the QRS and QT intervals or presence of peaked T-waves may be early indicators of toxicity.
 - Proximal cause of death is usually dysrhythmias; ventricular fibrillation and sudden cardiac arrest are described.

Management

- Most important concern in small dermal injuries is pain control.
- Mainstay of therapy is calcium gluconate.
 - Derives its efficacy from binding fluoride ions.
 - Calcium chloride should be used only topically, as extravasation causes tissue damage.
 - Analgesics and regional anesthesia are not contraindicated.
 - Calcium has the advantage of halting tissue damage in addition to providing pain relief.
 - After decontamination with water, calcium gluconate gel should be applied to the injured area.
 - If hands involved, gel can be held in contact by placing it in a sterile glove and putting the glove on the hand.
 - Gel is prepared by mixing 25 mL of 10% calcium gluconate in 75 mL of water-based lubricant.
 - If wound is located where compartment syndrome is not a concern, 0.5% calcium gluconate can be injected intradermally, 0.5 mL/cm².
 - If these techniques fail to give relief
 - There is a role for careful use of intra-arterial calcium gluconate.
 - Obvious advantage of this route is that calcium can be administered directly and by continuous infusion to affected area.
 - Add 10 mL of 10% calcium chloride to 40 mL of 0.9% sodium chloride and infuse over 4 hours.
 - Nasogastric tube should be carefully placed, and any material in the stomach should be aspirated and followed by instillation of a calcium solution.
 - Benefits of this practice are not established, but it seems reasonable.
 - IV calcium and magnesium should be given liberally, and electrolytes should be obtained hourly.
 - One gram calcium gluconate contains 4.5 mEq of elemental calcium.
 - One gram calcium chloride contains 13.6 mEq.
 - Both calcium salts can produce vasodilation and dysrhythmias when administered too quickly.

- IV calcium should be administered no faster than 0.7 to 1.8 mEq/minute.
- Dysrhythmias should be expected in severely poisoned patients.
- Place defibrillator pads on the patient and perform continuous cardiac monitoring.
- In animal models, quinidine was protective after lethal doses of IV fluoride.
- When systemic toxicity occurs, electrolyte abnormalities are most severe in the first several hours of toxicity.
 - If no signs or symptoms of systemic toxicity for 24 hours, transfer to lower level of care.

ANTIDIABETIC AGENTS

Mechanism

- Diabetes is characterized by an inability to maintain normal blood glucose concentration due to deficiency of insulin, resistance to insulin, or a combination of both.
- Medications used to treat diabetes are collectively known as *antidiabetic agents*.
- Subset of these drugs is properly called *hypoglycemic agents*.
 - Hypoglycemics include insulin and those drugs that promote the release of endogenous insulin.
 - Hypoglycemic agents and antidiabetic agents are not synonymous, because many diabetic medications (metformin, thiazolidinediones) cannot produce hypoglycemia.
- In 2005, the AAPCC received reports of 8,695 exposures to sulfonylureas and biguanides, including 244 major exposures and 28 deaths.
- The antidiabetics are diverse, but there are some important generalizations.
 - Sulfonylureas, meglitinides, and thiazolidinediones are very highly protein-bound and thus not amenable to extracorporeal removal.
 - Insulin and metformin are completely renally eliminated.
 - Most of the sulfonylureas have active hepatic metabolites with urinary excretion of both active metabolites and the parent drug.
- Most important pharmacokinetic parameter of the hypoglycemics is duration of action.
 - Duration of action of insulin and the sulfonylureas is greatly increased in overdose.
 - In overdose, the formation of depots of the drug in tissues can slow release and greatly prolong the duration of action.
 - Vascularity of the site of injection will also influence the duration of hypoglycemia.
 - Sulfonylureas generally have a duration of action of 12 to 24 hours in therapeutic doses.
 - Chlorpropamide, a first-generation sulfonylurea, may promote insulin release for up to 72 hours.
 - Duration of action is prolonged in overdose, resulting in delayed hypoglycemia.
 - Meglitinides, intended to prevent postprandial hyperglycemia, induce insulin release for only 1 to 4 hours.
 - Appears likely that duration of action would be increased in overdose.

Clinical Manifestations

- Most important signs and symptoms of the aptly classified hypoglycemics are manifestations of decreased serum glucose.
- Diagnosis of hypoglycemia is established by interpreting a serum glucose concentration in the context of a patient's clinical status.
 - Threshold for symptoms of hypoglycemia ranges between 78 mg/dL in poorly controlled diabetics and 53 mg/dL in nondiabetics.
- Manifestations of hypoglycemia can be classified as either autonomic or neuroglycopenic.
 - Autonomic symptoms include tremor, diaphoresis, hunger, and nausea.
 - Neuroglycopenic features of hypoglycemia can manifest as almost any conceivable neurologic deficit, including the following:
 - Coma
 - Agitation
 - Seizure
 - Hemiplegia
 - Mild confusion
 - Autonomic symptoms, which precede neuroglycopenic symptoms, serving as a warning of hypoglycemia
 - Autonomic symptoms may be blunted or absent in diabetics or patients taking β -adrenergic antagonists.
- Less clinically important—electrolyte abnormalities
 - Hypokalemia
 - Hypomagnesemia
 - Hypophosphatemia
 - Reported more frequently in very large insulin overdoses
- Metformin does not produce hypoglycemia itself but is often formulated with drugs that do, such as glipizide or glyburide.
- Metformin and its biguanide predecessor, phenformin, are associated with lactic acidosis by promoting anaerobic metabolism and inhibit lactate metabolism.
 - Lactic acidosis is rare but is more likely in the setting of liver disease, renal insufficiency, heart failure, other acute illness, or acute overdose.
 - Hepatotoxicity is reported from therapeutic use of thiazolidinediones and acarbose.

Management

- Rapid bedside serum glucose concentration is obtained when hypoglycemia is considered.
 - If diagnosis is established, 1 g/kg IV dextrose should be given.
- Children should receive 25% dextrose solution and infants 10% dextrose solution.
- When normal mental status is restored, patient should be fed.
 - Each 50-mL vial of 50% dextrose supplies 100 kcal of short-lived simple carbohydrate.
 - A meal will supply hundreds of “sustained-release” kilocalories.
- Glucagon should not be administered unless IV access is delayed and the patient cannot be fed.
 - Glucagon will not be effective in patients with depleted glycogen stores.

- Recurrent insulin-induced hypoglycemia should be treated with a dextrose infusion.
 - 10% to 20% solution and titrate to maintain glucose in a normal range
 - 5% dextrose solution inappropriate for glucose maintenance
- Octreotide, a somatostatin analog, is indicated for hypoglycemia following sulfonylurea use.
 - It is given subcutaneously, 50 μg every 6 hours (4–5 $\mu\text{g}/\text{kg}/\text{day}$ in divided doses in children).
 - Dextrose alone might not be sufficient to manage sulfonylurea-induced hypoglycemia.
 - This drug class potentiates endogenous β -islet cell insulin release, supplemental dextrose will induce more insulin release, with transient corrections and subsequent recurrence of hypoglycemia.
 - Octreotide inhibits the β -islet cell calcium channel, inhibiting sulfonylurea-induced insulin release.
 - No significant adverse effects result from short-term octreotide use.
 - Octreotide should be continued for 24 hours.
 - After octreotide is discontinued, the patient should be observed for 24 hours.
 - Limited data in the literature regarding meglitinide toxicity
 - Mechanism of action similar to the sulfonylureas, the meglitinides are shorter acting
 - Less likely to produce recurrent hypoglycemia but no data to support this assumption
- Metformin-associated lactic acidosis should be considered in the following:
 - Patients taking an overdose
 - Children exposed to more than one or two tablets
 - Patients who take metformin therapeutically and also have renal insufficiency, hepatic insufficiency, heart failure, or another acute illness
- Diagnosis is established by obtaining a serum chemistry, lactate concentration, and serum pH.
 - Primary therapy is supportive.
 - Role of bicarbonate in metformin-associated lactic acidosis is unclear; supplemental bicarbonate should be used to maintain the pH above 7.1.
 - Metformin is highly protein bound, but hemodialysis can be used to correct refractory acidosis.
- Adults and children should be observed for 24 hours, even in the absence of hypoglycemia.
- Patients who present with hypoglycemia from long-acting forms of insulin should be observed for 24 hours.

NATURAL TOXINS

Plants

- In 2005, 76 major outcomes resulting from plant exposure were reported to the AAPCC.

Belladonna Alkaloids

- Plants such as jimsonweed (*Datura stramonium*) contain numerous anticholinergic compounds.
 - These are used recreationally, often in the form of teas, for their hallucinatory effects.
- Toxicity is identified by the presence of anticholinergic symptoms: tachycardia; hyperthermia; dry, flushed skin; urinary retention; and agitation.
- One hundred jimsonweed seeds contain nearly 6 mg of atropine and similar alkaloids.
- In addition to supportive care, physostigmine can be given when the diagnosis is relatively certain, administered 1 to 2 mg IV slowly over 5 minutes.
 - Physostigmine should be discontinued and the diagnosis reconsidered if cholinergic symptoms develop.
 - If there is improvement or no change in the patient's condition, physostigmine can be readministered after a 10- or 15-minute delay.

Nicotine and Nicotineline Alkaloids

- Nicotine poisoning occurs from inhaled, transdermal, and ingested nicotine.
 - Dose of 1 mg/kg can be lethal in an adult.
 - A cigarette contains 13 to 30 mg of nicotine, most not delivered to the smoker.
 - Largest portion of the nicotine is pyrolysed but not inhaled.
 - 5 to 7 mg of nicotine remains in the cigarette butt, a potentially lethal dose for a child.
 - Workers handling tobacco can be poisoned from nicotine as well.
 - Signs and symptoms of nicotine toxicity result from activation and then inhibition (from overstimulation) of nicotinic receptors:
 - GI signs include nausea, vomiting, and diarrhea.
 - Early cardiovascular toxicity involves hypertension from nicotinic stimulation of the sympathetic ganglia, but hypotension eventually occurs.
 - Most important signs and symptoms result from nicotinic agonist effects at the neuromuscular junction. Early toxicity causes fasciculation, which gives way to paralysis.
- Management is supportive.
 - Vasoactive agents may be necessary to maintain blood pressure.
 - Intubation may be indicated to support respiration during paralysis.

Cicutoxin

- Cicutoxin is found in *Cicuta* spp. such as water hemlock.
 - Toxin is found throughout the plant, which is often eaten by adults who misidentify it as wild parsley, turnip, or parsnip.
 - Mechanism of cicutoxin poisoning is unclear.
 - Early symptoms are primarily GI and begin soon after ingestion.
 - Later, cicutoxin can cause status epilepticus, renal failure, and rhabdomyolysis.

Sodium Channel-altering Plants

- Aconitine, from *Aconitum* spp., opens sodium channels, increasing cellular excitability.
- Increased sodium influx delays repolarization, which in turn delays conduction.
 - Slow conduction of peripheral nerves can lead to decreased sensation, weakness, paralysis; in the CNS, seizures.
 - Vagal and cardiac myocyte sodium channel effects lead to bradycardia, atrioventricular blockade, increased automaticity, or asystole.

- Aconitine is found in *Aconitum napellus* (monkshood) and Chinese herbal remedies.
- Management is supportive.
 - GI decontamination should be performed.
 - Cardiac complications have been successfully managed with ventricular assist device.

Mushrooms

- Forty-six major outcomes and six deaths from mushroom ingestions were reported to poison control centers in 2005.
- Vast majority of mushroom exposures do not result in significant morbidity, and most of the fatalities that occur are caused by only a few of the many mushroom species in North America.
- Identification of mushrooms is challenging and best left to the mycologist.
- Each of the clinically important toxic mushrooms causes a distinct clinical syndrome that should be identified.
- **GI toxin-containing mushrooms:** Most reported exposures are to mushrooms containing gastrointestinal toxins.
 - Most notable clinical feature of ingestion of these mushrooms is the development of vomiting and diarrhea within several hours of ingestion.
 - Mushrooms that cause GI symptoms within 6 hours belong to this category and usually do not cause life-threatening symptoms.
 - Early onset of vomiting after exposure to GI toxin-containing mushrooms clinically differentiates them from the cyclopeptide-containing mushrooms.
 - Treatment of exposure to these mushrooms is supportive, and symptoms are generally self-limited.
 - These mushrooms rarely lead to toxicity requiring ICU admission.
- **Cyclopeptide-containing mushrooms:** Three of five fatalities from mushrooms in 2004 were related to cyclopeptide-containing mushrooms.
 - Mortality from these mushrooms is high.
 - Most prominent member of this group is *Amanita phalloides* and other *Amanita* spp.
 - *Amanita phalloides* contains numerous cyclopeptides.
 - Most important are a group called the amatoxins, which are heat-stable and present in lethal concentrations in mushrooms as small as 20 g.
 - **Clinical manifestations and management:** Amatoxins cause endocrine, renal, and CNS injury, but the hepatic effects are the most consequential.
 - Patients are asymptomatic for the first few hours after ingestion.
 - Within 5 to 24 hours, patients develop watery diarrhea.
 - Hepatic toxicity is evident on day 2 with elevations in bilirubin, AST, and ALT.
 - Signs of fulminant hepatic failure such as encephalopathy and coagulopathy follow.
 - Hypoglycemia results not just from hepatic failure but from direct pancreatic toxicity.
 - Cyclopeptides may also cause decreased levels of thyroid hormone and increased calcitonin.
 - Patients do not seek help until symptoms develop; it is common for patients to present to a health care facility with volume depletion and early hepatic injury.
- Good supportive care and prevention of secondary complications are the keys.
 - Activated charcoal should be administered 1 g/kg every 2 to 4 hours to adsorb any toxin remaining.
 - No data support its use in *Amanita* poisoning, but NAC effectively treats hepatic failure from other hepatotoxins, such as acetaminophen.
 - Administer NAC IV, according to the acetaminophen protocol: 150 mg/kg over 45 minutes, 50 mg/kg over 4 hours, and 100 mg/kg over 16 hours. Continue the final infusion until the patient expires, definitively recovers, or receives liver transplant.
 - Silibinin, extracted from milk thistle, improved hepatic markers and mortality in a dog model of *Amanita* poisoning but was not beneficial in a meta-analysis of human studies.
 - In light of its experimental benefits, recommend orally administered silibinin, 20 to 50 mg/kg/day.
 - Silibinin is not a Food and Drug Administration–approved drug but is available at health food stores.
 - High-dose penicillin had some effectiveness in a dog model of *Amanita* poisoning, possibly by blocking hepatocyte uptake of amatoxin.
 - Therapy includes IV penicillin G, 1 million units/kg/day in divided doses.
- The criteria for liver transplantation have not been clearly established.
- Some consider transplantation for those with encephalopathy and prolonged PT, persistent hypoglycemia, metabolic acidosis, increased serum ammonia, aminotransferases, and hypofibrinogenemia.
- **Gyromitrin-containing mushrooms:** These are found throughout the United States and contain gyromitrin (*N*-methyl-*N*-formyl hydrazine), which is hydrolyzed to monomethylhydrazine (MMH).
 - MMH inhibits the formation of pyridoxal-5'-phosphate (PLP), an enzyme cofactor synthesized from pyridoxine (vitamin B₆).
 - PLP is a cofactor for glutamic acid decarboxylase, the enzyme in the CNS that converts glutamate to GABA.
 - Inhibition of PLP by monomethylhydrazine results in excessive excitation relative to inhibition.
 - **Clinical manifestations and management:** The initial phase of toxicity, occurring 5 to 10 hours after ingestion, is manifest by nonspecific clinical features including nausea, vomiting, diarrhea, and headache, and ultimately leads to intractable seizures.
 - Ingestions of *Gyromitra* spp. should receive activated charcoal, 1 g/kg.
 - Seizures may not respond to benzodiazepines alone.
 - If *Gyromitra* spp. ingestion is considered or if a patient presents with seizures after mushroom ingestion, pyridoxine 70 mg/kg IV should be given.
 - This serves as substrate for pyridoxine phosphokinase, allowing some PLP to be generated despite inhibition by MMH.
 - **Allenic norleucine-containing mushrooms:** The nephrotoxic *Amanita smithiana* contains the amino acid toxins allenic norleucine (amino-hexadienoic acid) and possibly 1–2-amino-4-pentynoic acid.
 - All known exposures to these mushrooms have occurred in the Pacific Northwestern United States.

- These mushrooms are important exceptions to the “rule” that mushrooms that cause early GI toxicity do not cause significant end-organ damage later.
- **Clinical manifestations and management:** Initial symptoms, which include nausea, vomiting, diarrhea, and abdominal cramping, may begin within an hour of ingestion.
 - Most important clinical features of toxicity develop later.
 - Acute renal failure, indicated by elevations in blood urea nitrogen and creatinine, manifest 4 to 6 days after ingestion.
 - Activated charcoal should be administered when patients present after ingesting mushrooms from the Pacific Northwest.
 - Management of nephrotoxicity is supportive.
 - Patients who required hemodialysis underwent the procedure two to three times per week for approximately 1 month.
- **Orellanine- and orellanine-containing mushrooms:** *Cortinarius orellanus*, found in North America, contains the toxin orellanine, which is converted by photochemical degradation to another toxin, orellanine.
 - Orellanine and orellanine are important causes of mushroom-induced nephrotoxicity.
 - Orellanine is activated by the P450 system.
 - Molecules generate oxidative damage by sustained redox cycling.
 - **Clinical manifestations and management:** Symptoms begin 24 to 36 hours after ingestion.
 - Headache, chills, polydipsia, nausea, and vomiting have been reported.
 - Early laboratory findings of hematuria, leukocyturia, and proteinuria indicate interstitial nephritis.
 - Later, renal failure develops, characterized histologically by tubular damage and fibrosis of tubules with relative glomerular sparing.

- Hepatotoxicity is uncommon.
- Management is supportive.
 - Administer activated charcoal if patients present early.
 - Some patients will rapidly improve, whereas others require chronic hemodialysis.

TREATMENT REFUSAL

- Patients with toxicologic emergencies are often suicidal and self-destructive and may have an altered level of consciousness.
 - We have an ethical obligation to our patients to allow them to guide their own treatment.
 - This may mean the patient will decide against the physician’s recommendation.
 - To refuse care, the patient must demonstrate the capacity to understand his or her condition and the implications of treatment refusal.
 - Refusal must be voluntary in the absence of a medical or psychiatric condition precluding the ability to make such a decision.
 - The hospital has the right to physically restrain a person who has an altered level of consciousness for the purpose of evaluation and intervention.
 - There is potential for legal liability whenever the medical staff physically restrain a patient, retain a patient against his or her will, or allow a patient to refuse a life-saving therapy.
 - Staff can reduce liability by thoroughly documenting the patient’s decision-making process and by involving psychiatric consultation in determining the patient’s capacity.
 - When in doubt, the physician should consult the hospital’s legal department.

CHAPTER 31 ■ SUBSTANCE ABUSE AND WITHDRAWAL: ALCOHOL, COCAINE, OPIOIDS, AND OTHER DRUGS

INTRODUCTION

- Ethanol, illicit drugs, and prescription drugs used for non-medical purposes are significant medical and social problems.
- The 2005 National Survey on Drug Use and Health found that 22.7% of Americans, or 55 million individuals, were binge drinkers.
 - Includes 16 million heavy drinkers (five or more drinks on the same occasion at least 5 different days in the prior 30 days).

- Pain relievers were used nonmedically by 4.7 million Americans, and 3.5 million used stimulants or cocaine.
- Casual or habitual use of these drugs contributes to acute and chronic illness.
 - Also underlies many forms of injury, including vehicular accidents, falls, near-drowning, thermal injuries, homicide, and suicide.
 - Other critical illnesses may be impacted by either substance use or substance withdrawal.

ETHANOL

Mechanism

- Alcohol abuse and alcoholism (a dependence on alcohol) are major social, economic, and public health problems throughout the world.
- Alcoholism is the third leading cause of death in the United States.
 - Reduces life expectancy by 10 to 12 years
 - Men who imbibe more than 14 drinks per week or 4 drinks at one time or women who have more than 7 drinks per week or 3 drinks at one time are at risk for alcohol abuse and dependence.
- Ethanol is rapidly absorbed unaltered from stomach and small intestine.
 - Presence of food (especially milk and fatty foods) in the stomach delays absorption.
 - Presence of water enhances absorption.
 - Primarily metabolized in the liver
 - Less than 10% is excreted by the lungs or kidneys or through the skin.
 - Several hepatic enzyme systems independently metabolize ethanol to acetaldehyde.
 - Primary degradation pathway is in the hepatic cytosol by alcohol dehydrogenase, with nicotinamide adenine dinucleotide as a cofactor.
 - Acetaldehyde generated by this process is in turn metabolized through the Krebs cycle to carbon dioxide and water with 7 kcal/g liberated.
 - Most people can metabolize about 150 mg ethanol/kg body weight/hour.

Acute Toxicity

- Common features of acute ethanol intoxication are shown in Table 31.1.
- Intoxication with ethanol depends on the rate of rise of the blood alcohol level and the length of time the level is maintained.
 - Blood alcohol levels of 20 to 30 mg/dL are often associated with a mild euphoria, delayed reaction time, decreased inhibition, and alteration in judgment.
 - Most exhibit gross intoxication at levels above 150 mg/dL.
 - Obtundation often develops at levels above 300 mg/dL.
 - Death may result from respiratory depression, aspiration, or cardiovascular collapse when levels exceed 400 to 500 mg/dL.
- Ethanol is a sedative-hypnotic drug and exerts its primary effects on the central nervous system (CNS).

Assessment and Treatment of Acute Intoxication

- Treatment of acute ethanol intoxication is primarily supportive.
- Careful examination is needed to detect complications.
 - First priority is assessment and stabilization of the airway and ventilation.

TABLE 31.1

CLINICAL MANIFESTATIONS OF ALCOHOL INTOXICATION

Central nervous system

Decreased inhibition
Slowed reaction time
Visual disturbance
Incoordination
Slurred speech
Diplopia
Nystagmus
Lethargy, stupor, coma

Cardiovascular

Vasodilation
Cardiac dysrhythmias
Myocardial depression

Respiratory

Hypoventilation
Aspiration

Metabolic

Hypoglycemia
Electrolyte abnormalities
Hypophosphatemia
Hypomagnesemia
Acid-base disturbance
Respiratory acidosis
Metabolic alkalosis (vomiting)
Metabolic acidosis (alcoholic ketoacidosis)

Gastrointestinal

Gastritis
Increased incidence of peptic ulcer
Pancreatitis
Alcoholic hepatitis

Hematologic

Suppression of all bone marrow cell lines

Other

Suppression of antidiuretic hormone (diuresis)
Increased sweating
Altered temperature regulation

- Respiratory rate, depth of respirations, SpO₂, mental status, gag reflex, and presence of vomitus should be rapidly evaluated.
- Arterial blood gas analysis should be obtained if hypoventilation is a concern but is not obvious on clinical examination.
- Intubation is indicated in the obtunded or comatose patient who is unable to protect his or her airway and when aspiration has occurred or is likely.
- Positive pressure ventilation should be instituted to correct alveolar hypoventilation and hypoxemia.
- With altered mental status, 50 to 100 mg of thiamine and 25 g of glucose should be administered intravenously.
 - If the patient responds to the administration of glucose or if blood glucose levels are low, a continuous infusion of glucose should be given.
 - Intravenous (IV) naloxone may be administered if concomitant opioid use is suspected.
- Hypotension should be treated initially with volume resuscitation.

- Gastrointestinal (GI) bleeding should be considered in the hypotensive patient, and further assessment may include a rectal examination and insertion of a nasogastric tube.
- GI decontamination is of limited utility because the majority of alcohol is already absorbed.
 - Ethanol is not adsorbed by activated charcoal, but charcoal may be administered if ingestion of other toxic drugs is suspected.
- Hypothermia, fluid, electrolyte, and acid-base disturbances are corrected, depending on the clinical presentation.
- Creatine phosphokinase level is warranted in the patient with trauma or prolonged muscle compression to evaluate for rhabdomyolysis.
- Ethanol blood level may be helpful in documenting the severity of intoxication and estimating the duration of impairment.
 - A low ethanol level in the setting of a patient with a depressed level of consciousness should prompt an evaluation for other etiologies.
- Chest x-ray is often necessary to assess for evidence of aspiration or other complications such as pneumonia.
- Consider obtaining computed tomography of the head if there is any suspicion of subdural hematoma or other intracranial injury.
- Hemodialysis has been used in cases of massive ethanol ingestion.
- Chronic alcoholic may also develop alcoholic ketoacidosis.
 - Typically preceded by binge drinking followed by a period of abstinence for 1 to 3 days with nausea, vomiting, and insufficient nutrient intake.
 - Liver produces excessive ketones in response to starvation, results in an anion gap acidosis.
 - Pancreatitis is frequently present in these patients.
 - Blood glucose may be low or high in this setting but is rarely above 300 mg/dL unless chronic glucose intolerance is present.
 - Condition responds to volume replacement and administration of glucose.
 - Insulin is not needed.
 - Thiamine administered before glucose to avoid precipitation of acute beriberi and Wernicke–Korsakoff syndrome.
- Prevention of alcohol withdrawal syndromes has been shown to improve morbidity and mortality and shorten hospital and intensive care unit length of stay.
- Four stages of alcohol withdrawal have been described, but symptoms are a continuum of neuropsychiatric and hemodynamic manifestations (Table 31.2).
- A key distinction is to determine whether the patient has an intact or altered sensorium.
- Benzodiazepines act as an alcohol substitute to dampen the excitatory neuronal activity, and additional benefits include prevention of seizures and delirium tremens.
 - Choice of benzodiazepine in hospitalized patients may depend on severity of hepatic dysfunction, desired duration of action, and available routes of administration.
 - All benzodiazepines are effective when appropriate doses are used.
 - Fixed dosing and symptom-triggered regimens have been used effectively.
 - Fixed dosing may be more appropriate in critically ill patients until other conditions have stabilized.
 - Treatment duration beyond 7 days is seldom required.
- All patients with alcohol withdrawal should receive supportive measures in addition to pharmacologic intervention.
 - Thiamine (vitamin B₁) should be given IV or orally to prevent Wernicke encephalopathy.
 - Magnesium sulfate may be needed to correct hypomagnesemia.

Seizures

- Chronic excessive alcohol ingestion depresses central α and β receptors and potentiates the inhibitory neurotransmitter γ -aminobutyric acid (GABA).
- Brain adapts with a functional increase in N-methyl D-aspartate (NMDA) receptors part of an excitatory system.
- When alcohol consumption stops, excess excitatory receptors and removal of GABA-mediated inhibitory effects contribute to the hyperadrenergic state seen in alcohol withdrawal.
- Alcohol withdrawal syndromes occur during the initial period of abstinence.
 - In hospitalized patients, symptoms of alcohol withdrawal may occur in up to 40% of those who drink excessive amounts of alcohol.
- Approximately 5% to 10% of patients with untreated mild alcohol withdrawal symptoms progress to seizures.
- Those with several detoxification admissions are at higher risk of seizures than patients with fewer detoxification admissions.
 - This association has been termed the “kindling effect”—accumulation of multiple episodes lowers the seizure threshold.
- Most alcohol withdrawal seizures are brief and self-limited in duration.
 - Usually generalized tonic-clonic but focal seizures may also occur.
 - Multiple seizures (two to six episodes) occur in approximately 60% of patients and within a 12-hour period.
 - May be difficult to distinguish withdrawal seizures from a pre-existing seizure disorder or new onset of a nonalcohol-related seizure.
 - Other causes such as hypoglycemia, metabolic abnormalities, trauma, infection, and other drug intoxication must be considered.
 - CT scan of the head should be obtained for new-onset seizure, persistent neurologic deficits, or evidence or suspicion of trauma.
 - Alcohol withdrawal seizures can be terminated with benzodiazepines.
 - The risk of a recurrent seizure is 13% to 24%.
 - Lorazepam (2 mg) significantly reduces the risk of recurrent seizure.
 - Phenytoin has no effect.
 - Fewer than 3% of patients develop status epilepticus, and they should be treated with benzodiazepines or propofol. Phenytoin is not as effective.

Alcohol Withdrawal

TABLE 31.2
STAGES OF ALCOHOL WITHDRAWAL AND TREATMENT

Symptoms	Time frame ^a	Treatment
Tremulousness Hyperactivity, tremor Diaphoresis, nausea Mild tachycardia, hypertension Clear sensorium	Onset within hours Peak 10–30 h Subside in ~40 h	Benzodiazepines (oral or IV) Supportive measures Fluid and electrolytes PRN Quiet environment Thiamin, folate, vitamins
Seizures	Onset 6–48 h Peak 13–24 h	Lorazepam 2–4 mg IV; repeat as needed Diazepam 10–20 mg IV Supportive measures as above
Hallucinations Auditory Visual Tactile	Onset 8–48 h May last 1–6 d	Benzodiazepines (oral or IV) Supportive measures as above
Delirium tremens Coarse tremors, agitation Altered sensorium (delusions, hallucina- tions, confusion)	Onset 60–96 h	Benzodiazepines IV as needed Diazepam Lorazepam Midazolam Alternative treatments Propofol Barbiturates β -blockers
Fever, tachycardia Hypertension Circulatory collapse		

^aTime after last drink.

Delirium Tremens

- DTs are most severe manifestation of alcohol withdrawal and should be cared for in intensive care unit setting.
 - Untreated DT carries a mortality of 15% but declines to 1% if treated.
 - Accumulation of multiple prior withdrawal episodes leads to more severe DT with each episode.
 - DT patients have more severe autonomic hyperactivity than milder stages of withdrawal and manifest delirium that may fluctuate.
 - Fluid requirements may be increased due to increased insensible losses (fever, diaphoresis) and lack of oral intake.
 - High-dose IV benzodiazepines (diazepam, lorazepam, midazolam) administered at frequent intervals or as a continuous infusion are needed to control the hyperadrenergic symptoms.
 - Individualize dose to achieve light somnolence.
 - Benzodiazepines bind at the GABA—benzodiazepine receptor, and once these receptors are saturated, additional drug cannot bind.
 - Propylene glycol diluent in benzodiazepines may result in a lactic acidosis with prolonged administration
 - Daily dose reductions of 25% can be initiated after the second or third day of treatment.
 - Propofol infusions may be useful for patients who are refractory to benzodiazepines.

- Dual activity similar to alcohol (GABA agonist and NMDA antagonist properties) that may explain its efficacy.
- Other sedative-hypnotic drugs such as paraldehyde and barbiturates are effective in treating DT but are not commonly used.
- Neuroleptic agents are inferior to benzodiazepines and should not be used as single agents for treatment of DT.
- Neuromuscular blockers may be considered to control agitation when high-dose sedatives ineffective.
- Cardiac monitoring is necessary to detect arrhythmias early and institute therapy.
 - Torsade de pointes may develop owing to hypomagnesemia or prolongation of the QTc interval and should be treated aggressively with IV magnesium sulfate.
 - Beta blockers may be needed to treat hypertension or tachycardia.
 - Propranolol may worsen delirium.
- Thiamine supplementation (100 mg/day) is recommended for 3 days
- DTs usually last 2 to 5 days.
 - In 5% to 10% of cases, DT lasts longer than a week.
 - Elderly alcoholics have a longer withdrawal period with more symptoms than younger alcoholics.
 - Small percentage of patients remain delirious for several weeks and require continuing treatment.

- After head trauma, a subdural hematoma can evolve subacutely in the alcoholic patient.
- Repeat imaging of the brain may be warranted 7 to 10 days into a course of protracted delirium to rule out a slowly accumulating subdural hematoma.

COCAINE

Mechanism

- Cocaine (benzoylecgonine) is an alkaloid derived from leaves of *Erythroxylon coca*.
- Second most commonly used illicit drug and the most frequent cause of drug-related deaths.
- Eighteen- to twenty-five-year-olds are the most common users.
- Cocaine is available in two forms.
 - Cocaine hydrochloride—prepared by dissolving alkaloidal cocaine in hydrochloric acid resulting in a white water-soluble powder, crystals, or granules.
 - This form of cocaine is used intranasally (snorting), orally, or intravenously.
 - Free-base or crack cocaine—heating cocaine hydrochloride in sodium bicarbonate or ammonia makes the hard crystallized cocaine base called crack because of the popping sound it makes when heated.
 - Smoking crack cocaine has become a widespread practice due to the rapid absorption across the alveolar surface.
- Peak effects range from 1 to 90 minutes depending on administration route.
 - Inhalational and IV uses result in the most rapid peak effects and shortest duration of action.
 - Rapidly metabolized by hepatic and plasma cholinesterases and nonenzymatic hydrolysis to ecgonine methyl ester and benzoylecgonine, which are excreted in urine.
 - Urinary excretion of unchanged cocaine ranges from 1% to 15%.
 - Half-lives of most metabolites range from 45 to 90 minutes.
 - Subjective rating of euphoria declines within minutes after constant concentrations are achieved, demonstrating rapid desensitization and acute tolerance.
 - Duration of positive urinary metabolites is somewhat dependent on the assay technique, the activity of plasma cholinesterases, and the duration and dosing of cocaine use.
- Cocaine's lipophilic nature, rapid distribution into and out of the CNS, suggests a highly abusive profile (rush and crash) and increased incidence of kindling.
- Major neurochemical actions of cocaine are as follows:
 - CNS stimulation with release of dopamine
 - Inhibition of neuronal norepinephrine and dopamine uptake, resulting in generalized sympathetic nervous system stimulation
 - Release of serotonin or blockade of serotonin reuptake
 - Inhibition of sodium current in neuronal tissue, resulting in a local anesthetic effect

Toxicity

- Numerous morbidities have been associated with acute and chronic cocaine use (Table 31.3).

TABLE 31.3

CLINICAL MANIFESTATIONS OF COCAINE USE

Anesthetic effects

Localized numbness
Central neuronal depression
Coma

Central nervous system

Euphoria
Alertness
Tremor
Sleeplessness
Paranoia
Psychosis
Headache
Seizures
Stroke
Transient ischemic events
Intracerebral hemorrhage
Cerebral vasculitis
Cognitive dysfunction

Cardiovascular

Tachycardia
Arrhythmias
Hypertension
Myocardial ischemia and infarction
Myocarditis
Aortic dissection or rupture
Sudden death
Cardiomyopathy
Atherosclerosis
Vasculitis

Renal

Induction of renal atherogenesis
Renal failure
Renal infarction
Scleroderma renal crisis

Respiratory

Pulmonary edema
Pulmonary hypertension
Respiratory arrest
Pulmonary vascular occlusion, pulmonary infarction
Pneumothorax
Pneumomediastinum
Hemoptysis

Gastrointestinal

Mesenteric ischemia, infarction
Gastrointestinal perforations

Metabolic

Weight loss
Hyperthermia
Rhabdomyolysis

Other complications

Nasal mucosal injury
Nasal septal perforation
Chronic rhinitis
Deep venous thrombosis
Dystonic reaction
Skin ischemia

Obstetric

Spontaneous abortions
Abruptio placentae
Intrauterine growth retardation
Prematurity

Diagnosis of Acute Intoxication

- Patients with cocaine intoxication may present with a variety of primary complaints such as altered mental status, chest pain, syncope, palpitations, seizures, or attempted suicide.
- Characteristic findings of CNS stimulation such as agitation, mydriasis, sweating, hypertension, and tachycardia often present.
- Effects of other drugs, the presence of complications, and delays in presentation may obscure typical sympathomimetic manifestations.
- Other conditions such as meningitis, encephalopathy, epilepsy with status, and thyrotoxicosis may mimic cocaine intoxication.
- Confirmation of acute or recent cocaine exposure is made by urine toxicology testing.

Treatment for Acute Intoxication

- Benzodiazepines the pharmacologic agents of choice for control of cocaine-induced agitation.
 - Agitation and psychosis of cocaine overdose usually can be managed with titrated doses of IV diazepam, 5 to 20 mg; lorazepam, 2 to 4 mg; or midazolam, 5 to 10 mg slowly.
 - Haloperidol not recommended as a first-line agent because of the lack of experimental support and potential to lower the seizure threshold.
 - Adequate hydration and correction of electrolyte abnormalities important.
- **Cardiovascular:** No large clinical trials have evaluated treatment strategies for cocaine-associated ischemia
 - Treatment of cardiac toxicity is directed at reversing physiologic effects that cause ischemia or arrhythmias.
 - Aspirin should be administered as an antiplatelet agent for suspected myocardial ischemia unless there is evidence of cerebral hemorrhage.
 - Oxygen may help to limit myocardial ischemia.
 - Benzodiazepines and nitroglycerin are considered first-line agents for relief of chest pain, but small clinical studies have yielded conflicting results on the benefit of combining the agents.
 - Alpha blockers such as phentolamine are recommended as a second-line treatment for unrelieved pain, but rarely.
 - β -blockers in the management of myocardial ischemia are debated.
 - Concern of worsening vasospasm or hypertension due to unopposed stimulation of α receptors
 - Most patients with cocaine-associated chest pain will not have infarction.
 - Managed in chest pain or observation units similar to other chest pain patients.
 - Low-risk patients with normal cardiac markers can be risk-stratified safely with stress testing.
 - Therapy for cocaine-induced myocardial infarction should consist of oxygen, aspirin, and nitroglycerin as required for pain relief.
 - If pain persists, patients are candidates for reperfusion therapy.
 - Primary percutaneous angiography is preferred in patients with evidence of ST-elevation myocardial infarction.
 - Thrombolytic therapy has been safely used in cocaine-associated myocardial infarction and may be considered if invasive reperfusion not available.
- Arrhythmias associated with cocaine use are usually transient. Standard therapy should be considered for sustained arrhythmias unresponsive to control of pain and agitation.
- Sustained hypertension in acute cocaine intoxication is not common due to the short physiologic effects of the drug.
 - IV labetalol is a reasonable option if the blood pressure needs to be lowered due to its α - and β -blocking effects.
 - Cocaine-intoxicated patients should be considered to have acute elevations in blood pressure, and there should be little concern about cerebral hypoperfusion with immediate lowering of blood pressure to normal levels.
- **Central nervous system:** Seizures induced by cocaine are best controlled with IV benzodiazepines.
 - Other standard antiepileptics can be added for refractory cases.
 - Neuromuscular blocker use warrants continuous EEG monitoring.
 - Interventions for ischemic strokes associated with cocaine use should be carefully considered.
 - Etiology may involve vasoconstriction as well as thrombosis; the decision to use thrombolytic agents in patients presenting within 3 hours of symptom onset may be more difficult.
 - Vascular imaging may be helpful.
 - Blood pressure is not usually severely elevated, but if sustained hypertension is present, current guidelines should be followed for lowering blood pressure.
 - Neurosurgical consultation should be sought for intracranial hemorrhages to evaluate for possible interventions.
 - Patients with subarachnoid hemorrhage should be evaluated for vascular malformations that may be treatable.
- **Pulmonary:** Most pulmonary toxicities associated with cocaine are managed with usual care or supportive care.
 - Bronchospasm and asthma should be treated with inhaled β -agonists and corticosteroids if indicated.
 - Pneumomediastinum can be followed without hospital admission for most patients.
 - Small pneumothoraces may also resolve without intervention.
 - Noncardiogenic pulmonary edema may require supplemental oxygen and mechanical ventilation but resolves within a few days.
- **Hyperthermia/rhabdomyolysis:** Hyperthermia associated with cocaine use should be treated aggressively by rapid cooling.
 - Control of coexisting agitation, psychosis, or seizures is essential.
 - No evidence that pharmacologic agents such as dantrolene are of benefit in cooling patients with life-threatening hyperthermia.
 - Patients with hyperthermia, severe agitation or motor activity, seizures, and obtundation require evaluation for rhabdomyolysis.
 - Aggressive fluid resuscitation to replete the intravascular volume and enhance urine output initiated prior to definitive diagnosis.
 - Serial tests of electrolytes, renal function, and creatine kinases are needed to monitor the severity and response.

- **Body packers/stuffers:** Individuals may ingest packets of cocaine or any illicit drug for the purpose of transport or concealment.
- Body stuffers swallow small amounts of drug (wrapped or unwrapped) in order to avoid arrest.
 - Drugs are not prepared for passage through the GI tract and drug is frequently absorbed.
 - Toxicity is usually mild.
- Body packers swallow larger quantities of drug in multiple packets that are specially prepared for smuggling to withstand transit through the GI tract.
 - Abdominal radiographs often show the location of the packets and allow tracking.
 - Negative result on plain abdominal radiograph does not rule out body packing.
 - Abdominal CT scan may be needed to visualize the packets.
- Most body packers are asymptomatic and can be managed conservatively until the packets have been completely evacuated.
 - Activated charcoal given every 4 to 6 hours can reduce the lethality of oral cocaine.
 - Whole-bowel irrigation may assist with passage of the packets.
 - Body packers with signs and symptoms of drug toxicity, *in vivo* degradation, or gastrointestinal obstruction require emergent surgical intervention.

Cocaine Withdrawal

- Psychological and biochemical dependency on cocaine may be intense.
- Brain becomes dopamine deficient.
- Short period of cocaine abstinence can result in a withdrawal state.
- Clinical effects of cocaine withdrawal include the following:
 - Depression
 - Fatigue
 - Irritability
 - Sleep and appetite dysfunction
 - Psychomotor agitation or retardation
 - Craving for more cocaine
- A period of prolonged somnolence and decreased arousal can occur after binge use of cocaine
 - Often necessitates evaluations to rule out complications associated with cocaine use
 - Supportive environment and professional drug counseling are warranted.

OPIOIDS

Mechanism

- Opioids include all drugs with morphine-like properties and/or that bind to opioid receptors.
- At least five opioid receptors with various physiologic roles, including analgesia, ventilatory depression, drug dependence, bradycardia, dysphoria, hallucinations, sedation, and miosis

TABLE 31.4

CLASSIFICATION OF OPIOID AGENTS

Opioid agonists
Natural opium derivatives
Codeine
Morphine
Semisynthetic opioids
Heroin
Hydrocodone
Hydromorphone
Oxycodone
Synthetic opioids
Diphenoxylate
Fentanyl
Levorphanol
Loperamide
Meperidine
Methadone
Propoxyphene
Tramadol
Pure opioid antagonists
Nalmefene
Naloxone
Naltrexone
Agonists–Antagonists
Butorphanol
Nalbuphine
Pentazocine

- Classified as receptor agonists or antagonists, or combined because they stimulate one type of receptor and antagonize another (Table 31.4)
- Opioid dependence characterized by repeated self-administration of the drug and encompasses physiologic dependence and addictive behavior.
- Exposure to opioids causes neural changes that produce tolerance, dependence, and withdrawal.

Toxicity

- All opioids are associated with toxicity.
 - Most fatal overdoses occur with IV administration.
 - Diagnosis of opioid toxicity made by characteristic clinical findings, exposure history, qualitative toxicology assay, and response to naloxone.
 - Qualitative urine assays may not detect all opioid derivatives (e.g., fentanyl).
- Opioid intoxication is characterized by a clinical syndrome of depressed level of consciousness, respiratory depression, and miosis.
 - Manifestations are variable depending on the drug used and presence of other drugs or alcohol.
 - Miosis is not seen with meperidine and propoxyphene toxicity.
 - The primary toxic manifestations of opioids are mediated by the μ and κ receptors in the brain, which cause CNS depression.
 - Common clinical effects of these drugs are shown in Table 31.5.

TABLE 31.5**CLINICAL MANIFESTATIONS OF OPIOID INTOXICATION****Central nervous system**

Analgesia
Apathy
Lethargy
Seizures
Coma
Ventilatory depression
Nausea
Emesis
Miosis

Respiratory

Histamine release—bronchospasm
Pulmonary edema

Cardiovascular

Arteriolar and venous dilation
Preload reduction
Hypotension

Gastrointestinal

Decreased peristalsis
Decreased hydrochloric acid secretion
Constipation

Other

Histamine release—urticaria, pruritus
Muscle rigidity (fentanyl)
Urinary retention

- The most worrisome feature of CNS depression is hypoventilation.
 - Tidal volume decreases first, then respiratory rate falls.
- Seizures may be associated with meperidine, propoxyphene, and tramadol toxicity or result from hypoventilation and hypoxemia due to other opioids.
- Arteriolar and venous dilatation with opioid use can precipitate preload reduction, a fall in cardiac output, and hypotension.
- Opioid-induced release of histamine from mast cells can precipitate bronchospasm, urticaria, and pruritus.
- Other respiratory complications include the following:
 - Aspiration of gastric contents
 - Noncardiogenic pulmonary edema
 - Asthma exacerbation (heroin)
 - Pulmonary hypertension
 - Acute respiratory distress syndrome
 - Septic pulmonary emboli
- IV-injected illicit opioids may be mixed with microcrystalline cellulose, talc, or cellulose.
 - These are capable of producing angiothrombosis and a foreign-body granulomatous reaction in the lung.
- Decreased GI peristalsis and increased ileocecal and anal sphincter tone are responsible for the constipation frequently seen with opioid use.
- Urinary retention may be caused by increased detrusor muscle tone.
- Local infections, endocarditis, and other systemic infections are especially common in the IV user.

Treatment for Acute Intoxication

- The most common cause of death in opioid overdose is ventilatory failure.
 - Immediate priority in acute opioid intoxication is airway management and ventilation.
 - If reversal of respiratory depression cannot be accomplished quickly with naloxone, intubation may be necessary.
 - Naloxone, a pure opioid antagonist, reverses all of the opioid-induced CNS and ventilatory depressant effects.
 - Dose required to reverse opioid effects depends on the amount and type of opioid administered.
 - Initial dose of naloxone is 0.4 to 2 mg; the lower dose should be administered initially in patients suspected of chronic addiction to avoid precipitating acute withdrawal symptoms.
 - We dilute 0.4 mg in a total of 10 mL, resulting in a concentration of 40 mcg/mL and administer 1 to 2 mL at a time, initially.
 - Additional doses of naloxone can be given based on the patient's response.
 - Can be administered intramuscularly, by sublingual injection, or through an endotracheal tube
 - Goal of therapy is to restore adequate spontaneous respirations rather than complete arousal.
 - CNS depression not reversed by 20 mg of naloxone, alternate causes should be aggressively addressed.
 - Hypoglycemia
 - Hypothermia
 - Head trauma
 - Close observation of the patient after naloxone administration is warranted because its effects last approximately 60 to 90 minutes.
 - May require repeated bolus injections of naloxone or a continuous infusion to maintain adequate respirations, particularly with long-acting opioids.
 - Infusion dose is one-half to two-thirds of the initial naloxone dose that reversed respiratory depression given hourly.
 - Isotonic fluids should be administered for hypotension due to opioids.
 - Noncardiogenic pulmonary edema is usually self-limited (24–36 hours) and managed with supportive care that may include intubation and mechanical ventilation.
 - Seizures unresponsive to naloxone should be treated with IV benzodiazepines.
 - Refractory seizures may suggest either body packing or another complication.
 - Potential for acetaminophen toxicity should be considered in patients ingesting opioids formulated with acetaminophen.

Acute Opioid Withdrawal

- Chronic administration of exogenous opiates is thought to lead to diminished endogenous opioid peptides.
 - When exogenous opiates discontinued, opioid withdrawal may occur.
 - The clinical manifestations of opioid withdrawal are outlined in Table 31.6.

TABLE 31.6**CLINICAL MANIFESTATIONS OF OPIOID WITHDRAWAL****Early**

Yawning
Lacrimation
Rhinorrhea
Sneezing
Sweating

Intermediate

Restless sleep
Piloerection
Restlessness
Irritability
Anorexia
Flushing
Tachycardia
Tremor
Hyperthermia

Late

Fever
Nausea
Vomiting
Abdominal pain
Diarrhea
Difficulty sleeping
Muscle spasm
Joint pain
Involuntary ejaculation
Suicidal ideation

- Onset of symptoms varies with the drug abused.
 - Within 6 to 12 hours of the last dose with short-acting opioids such as heroin
 - Within 36 to 48 hours with long-acting opioids such as methadone
- Withdrawal is rarely life threatening and usually does not require intensive care.
- If necessary to control withdrawal symptoms
 - Most opioids in sufficient dosage will alleviate symptoms.
 - Methadone, buprenorphine, and clonidine have been used to treat acute opioid withdrawal.
 - Methadone and buprenorphine have been used to treat opioid addiction chronically.
 - Methadone can cause constipation, respiratory depression, dizziness, sedation, nausea, and diaphoresis.
 - Oral buprenorphine is restricted in the United States to qualified physicians who treat opioid dependence.
 - Has low toxicity in high doses, partly because its μ -antagonistic effects limit the opioid effects of sedation, respiratory depression, and hypotension
 - Is more effective than clonidine and similar to methadone for management of opioid withdrawal
 - Clonidine is used to suppress the autonomic effects of opioid withdrawal.
 - Doses of 0.1 to 0.3 mg orally can suppress the signs and symptoms of opiate withdrawal within 24 hours and shorten acute withdrawal reactions by 3 to 4 days.
 - Side effects are hypotension, drowsiness, dry mouth, and bradycardia.

Heroin Body Packers

- Heroin body packers should be managed similar to cocaine body packers (preceding section).
- If evidence of systemic absorption from leaking packets, treat opioid toxicity with a continuous infusion of naloxone.

AMPHETAMINES AND DERIVATIVES**Mechanism**

- Amphetamines, methamphetamines, and similar derivatives are the most commonly abused CNS stimulants along with cocaine.
- Usually abused for the euphoric effects or to enhance performance.
 - Amphetamines by increasing release and inhibiting reuptake of dopamine and serotonin in the brain.
 - Minor chemical substitutions enhance drug's hallucinogenic properties.
- Production of these drugs from readily available ingredients in clandestine laboratories has resulted in increased supply throughout the United States.
 - Methamphetamine can be made from common ingredients such as rock salt, paint thinner, lantern fuel, battery acid, lye, ammonia, lithium, ether, rubbing alcohol, iodine, and cold medicines containing pseudoephedrine.
- Methamphetamine in a crystalline form (commonly called ice, crank, glass, or crystal) one of the most popular drugs in this class.
 - Can be orally ingested, smoked, snorted, or injected IV
 - An amphetamine-like drug, 3,4-methylenedioxymethamphetamine (MDMA), is a designer drug (commonly known as Ecstasy, XTC, or MDMA) that acts simultaneously as a stimulant and hallucinogen.
 - Results in greater serotonin release in the brain with inhibition of serotonin reuptake
 - Most amphetamines are detected on qualitative urine toxicology assays but a negative result does not rule out amphetamine intoxication or abuse.

Toxicity

- Drugs cause release of catecholamines, which result in a sympathomimetic/adrenergic syndrome.
 - Compared to cocaine, the “high” and physiologic effects last longer (hours to several days depending on the agent used).
- Clinical presentation is characterized by tachycardia, hyperthermia, agitation, hypertension, and mydriasis.
- Hallucinations (visual and tactile), hypervigilance, and acute psychoses (often paranoia) are frequently observed.
 - MDMA leads to increased verbosity and sociability.
 - MDMA use is associated with bruxism that is often countered by sucking on a pacifier or lollipop.
 - Often associated with behaviors resulting in trauma and risky sexual encounters.

- Acute adverse medical consequences are similar to those seen with cocaine abuse (preceding discussion).
- Long-term use of these drugs may result in dilated cardiomyopathy and “meth mouth.”
 - Meth mouth refers to a pattern of oral signs and symptoms of methamphetamine abuse, thought to include rampant caries and tooth fracture, leading to multiple tooth loss and edentulism.
 - Burn injuries from methamphetamine laboratory explosions are associated with a higher incidence of inhalational injury and greater use of critical care resources.
- Complications of MDMA use are usually a result of the drug effects and nonstop physical activity.
 - Effects of MDMA last 4 to 6 hours.
 - Medical complications include the following:
 - Hyperthermia
 - Hyponatremia
 - Rhabdomyolysis
 - Seizures
 - Renal failure
 - Arrhythmias
 - Syncope
 - Cerebral infarction/hemorrhage
 - Hepatotoxicity
 - Serotonin syndrome
 - Death

Management

- Primarily supportive
 - Gastric lavage is not recommended because absorption after oral ingestion is usually complete when patients present.
 - Activated charcoal may be considered if a recent oral ingestion is known to have occurred.
 - Careful assessment for complications should be made, including measurement of core temperature, obtaining electrocardiogram, searching for evidence of trauma, and evaluating laboratory data for evidence of renal or hepatic dysfunction and rhabdomyolysis.
 - IV hydration for possible rhabdomyolysis is warranted in individuals with known exertional activities pending creatine phosphokinase results.
 - Patients should be placed in a quiet, calm environment, and benzodiazepines, often in high doses, are used for controlling agitation.
 - Haloperidol is reserved for patients with inadequate response to benzodiazepines.

Withdrawal

- Acute withdrawal from amphetamines is similar to cocaine.
- Symptoms include fatigue, depression, anxiety, motor retardation, hypersomnia (followed by insomnia), increased eating, and drug craving.
 - Although uncomfortable, the manifestations are not dangerous.
 - Patients may become suicidal during withdrawal and should be evaluated for this possibility.
 - Symptoms may persist for months.

γ -HYDROXYBUTYRATE

Mechanism

- γ -Hydroxybutyrate (GHB) is a naturally occurring metabolite of GABA found in the brain.
 - Commonly a drug of recreational abuse
 - One of several agents characterized “date rape” drug.
 - Promoted to build muscle, improve performance, produce euphoria, and enhance sleep.
 - Available as a colorless, odorless liquid with a mild salty taste easy to mask in drinks.
 - GHB absorbed from stomach within 10 to 15 minutes.
 - Readily crosses the blood–brain barrier where it interacts with GHB and γ -aminobutyric acid type B (GABA_B) receptors
 - Stimulatory effects occur from resulting increased dopamine levels in the brain and sedative effects by potentiation of endogenous opioids
- γ -Butyrolactone (GBL), also known as 2(3H)-furanone-dihydro, and 1,4 butanediol (BD), also called tetramethylene glycol, are abused with the same adverse effects as GHB.
 - Both agents are metabolized systemically to GHB.

Acute Toxicity

- Manifestations of GHB toxicity are dose-related and include the following:
 - Agitation
 - Coma
 - Seizures
 - Respiratory depression
 - Vomiting
 - Other effects include amnesia, tremors, myoclonus, hypotonia, hypothermia, decreased cardiac output, and bradycardia.
 - Dose of 20 to 30 mg/kg can produce euphoria and sleepiness and coma may result from doses of ≥ 40 to 60 mg/kg.
 - Concomitant use of ethanol results in synergistic CNS and respiratory depressant effects.
 - Deaths attributed to GHB and related agents usually result from respiratory depression, hypoxemia, or aspiration.
- GHB is not routinely detected by urine toxicology assays but can be detected in plasma or urine by gas chromatographic-mass spectrophotometric techniques.
 - Rapid clearance precludes detection beyond 12 hours after a dose.
 - Diagnosis is usually determined by the clinical course and history of exposure elicited after the patient recovers.
 - Hallmark of GHB intoxication is rapid onset of toxicity and sudden, rapid recovery rather than gradual recovery seen with ethanol or benzodiazepine intoxication.

Assessment and Treatment of Acute Intoxication

- No antidote for GHB, GBL, or BD toxicity.
- Primary management for ingestion of these drugs is supportive care with particular attention to airway protection.

- In some cases, intubation and mechanical ventilation are required.
- Gastric lavage and activated charcoal are not warranted because of the small amounts involved and the rapid absorption.
- Naloxone and flumazenil are of no benefit.
- Atropine may be needed for symptomatic bradycardia.
- Mild intoxication may be observed in the emergency department and released after symptoms resolve.
 - Rapid recovery of consciousness from an obtunded condition in a few hours is frequently observed.
 - Patients requiring intubation and mechanical ventilation can be expected to resolve within 2 to 96 hours unless complications such as aspiration or anoxic injury have occurred.
 - Concomitant use of alcohol may prolong the CNS depression.
 - Physostigmine reported to awaken patients with GHB intoxication, its use is not recommended.

γ -Hydroxybutyrate Withdrawal

- Sedative withdrawal syndrome after high-dose frequent use (every 1–3 hours) of GHB, GBL, and BD has been described.
 - Mild symptoms such as anxiety, insomnia, nausea, vomiting, and tremors begin within 6 hours of the last dose.
 - May progress to severe delirium with autonomic instability (usually mild) requiring hospitalization and sedation.
 - Patients may experience auditory, visual, and tactile hallucinations.
 - Symptoms requiring treatment may be as long as 2 weeks.
 - Benzodiazepines are the initial choice for management and high doses may be required.
 - Propofol and barbiturates have also been used successfully.

PHENCYCLIDINE

Mechanism

- Phencyclidine (PCP) is a psychoactive drug used as a hallucinogen that can be administered by oral ingestion, nasal insufflation, smoking, or IV injection.

- A dissociative agent that blocks the NMDA receptors leading to an inhibition of sensory perception.
- Sympathomimetic effects result from inhibition of norepinephrine and dopamine reuptake.

Clinical Manifestations

- Signs and symptoms reported with PCP use are variable depending on the route of abuse, susceptibility of the user, and concomitant drug use
- Behavioral effects of PCP include coma, catatonia, psychosis, and confusion.
 - Agitation may be intermittent and unexpected.
 - Misperception of reality can lead to violent behavior, risk-taking behavior, and accidents resulting in trauma.
 - Nystagmus (horizontal, vertical, and/or rotatory) and miosis are characteristic findings with PCP intoxication along with ataxia.
 - Medical complications can include hyperthermia, rhabdomyolysis, and seizures.
 - Dystonic reactions occur rarely.
 - PCP is usually detected on urine qualitative toxicology tests.

Management

- Includes control of agitation using a quiet, nonstimulatory environment and benzodiazepines as needed
 - Haloperidol may be beneficial for frank psychosis.
 - Physical restraints are often needed until adequate sedation is achieved.
 - Tachycardia and hypertension, if present, usually respond to control of agitation.
- Activated charcoal does adsorb PCP, but most patients present after GI absorption is complete.
- Urinary acidification enhances PCP excretion but is not recommended.
- Possibility of rhabdomyolysis should be evaluated, and early fluid therapy should be considered while awaiting test results.

CHAPTER 32 ■ ENVENOMATION

SNAKES NATIVE TO THE UNITED STATES

General

- The United States has two broad categories of venomous snakes.
 - First, and less common, is the coral snake, members of the family Elapidae, with two general and several species.
 - The only venomous snake in North America that is not a pit viper, does not have “cat eye”-shaped pupils, and a rather small head.
 - Only 1% to 2% of all U.S. snakebite envenomations involve coral snakes, yet this small number accounts for a somewhat disproportionate amount of human morbidity and mortality.
 - Secondly, the pit vipers account for about 95% of U.S. snakebites.
 - Members of the family Crotalidae and comprise rattlesnakes, water moccasins, and copperheads.
 - Pit vipers are composed of three genera and numerous species.
 - They have two heat-sensing pits approximately halfway between their nostrils and eyes.
 - Because of their considerable venom apparatus, they appear to have heads significantly larger than one might expect, given the size of their bodies.
 - Remaining 2% to 3% of all U.S. snakebites are inflicted by exotic venomous snakes.
 - Identification of offending animals should be done if possible but without undue risk of further bites to the victim or others.
 - U.S. pit viper and coral snake antivenoms are polyvalent, so it is only necessary to identify a snake to the family level.
 - Identification charts are available, and experts such as local herpetologists may be consulted in certain cases.

Coral Snake Envenomation

General

- Rather small and brilliantly colored secretive reptiles
- Often found around newer housing projects and may be encountered in one's garden or yard
 - Not aggressive, supporting stories that children may play with them for hours to days without being bitten
 - Cannot open their mouths as widely as the pit vipers, so they typically bite only at the tips of fingers or the webbed space between the thumb and first finger

- Envenomation requires hanging on to this small anatomic part for 10 to 30 seconds to work venom into the skin, an activity most victims will not tolerate.
- Several nonpoisonous distant look-alikes with which it is sometimes confused
 - Coral snake (in the United States) has a black nose, with alternating rings of red, yellow (sometimes white), and black encircling the entire body of the snake.
- Coral snake envenomation is complicated by the fact that, in direct contradistinction to pit viper envenomation, there is little or no local tissue damage.
 - Characteristic triad of immediate local pain, swelling, and discoloration characteristic of pit viper envenomation does not develop.
 - However, it is possible to misconstrue a serious bite from a coral snake as one from either a “dry bite” by a venomous snake or a bite by a nonvenomous snake.
 - Can lead to an unfortunate outcome

Symptoms and Manifestations

- Symptoms may be delayed up to 12 hours.
 - Dangerous and can progress rapidly should they occur
 - Observe patients for 24 hours to determine whether an envenomation has occurred.
- Venom chiefly neurotoxic so signs and symptoms are declared in approximately the following ascending order and frequency:
 - Mild numbness in the bitten extremity
 - Euphoria, often precipitously followed by cranial nerve symptoms
 - Diplopia being the one that the patient most often first notices.
 - Distinct flat dysarthria (similar to patients with myasthenia gravis) is the one that health care professionals usually first notice.
 - Stridor
 - Inability to swallow
 - Finally, respiratory arrest may rapidly ensue.
 - During progression from dysarthria to respiratory arrest, aspiration pneumonia is extremely common and constitutes one of the major morbidities and mortalities of coral snake envenomation.
 - Should cranial nerve involvement be noted to develop, prophylactically and preemptively intubate to protect airway.
- Lacking the large fangs characteristic of pit vipers, this snake's puncture wounds are notoriously not prominent.
 - Squeeze the bite site: One may see minute, pinpoint accumulations of blood welling up from the tissue, indicating that the teeth of the coral snake have successfully entered the subcutaneous tissue, allowing venom deposition.
 - Triad of risk factors, if any two are present, warrant strong consideration for the infusion of three to five vials of antivenom:

- Snake is positively identified as a coral snake.
- History of the snake “hanging on” the bitten site for at least 15 to 30 seconds
- One can observe pinpoint of blood after applied pressure to the bitten area.
- Typically do not administer antivenom for the presence of only one feature of this triad, but typically observe the patient for about a day.
- Natural history of duration of respiratory arrest is approximately 7 to 10 days before the effects of the venom naturally abate.
 - Mentation is not affected.
 - Patient is totally flaccid.
 - Long-term sequelae after either successful treatment or the natural history of the envenomation syndrome may include several months of dysesthesias and paresthesias in bitten extremity but generally fade after several months to a year.

Antivenom Administration

- Antivenom Wyeth (Antivenin [*Micrurus fulvius*] [equine origin]) is no longer being manufactured.
- Present statements and future predictions on how to treat envenomation by coral snake difficult
- If antivenom can be procured, if symptoms deemed either imminent or present, three to five vials of the antivenom given IV about every 8 to 12 hours until symptoms stop progressing.
- Single treatment is usually sufficient.
- If symptoms develop ≥ 1 hour before antivenom administration
 - Notoriously difficult to reverse the neurologic blockade
 - Repeated administration of antivenom futile and probably unwise
- Antivenom, prepared in Mexico (Coralmyx, Bioclon) available in emergencies
 - Call regional poison center (1.800.222.1222) to assist in acquisition, as most products in the United States are held by zoos.

Pit Viper Envenomation

General

- ***Crotalus***: The family Crotalidae consists of three genera found within the United States. The largest genus, composed of some 15 to 20 species and subspecies, is *Crotalus*, the rattlesnakes.
 - Most serious bites those of the eastern diamondback rattlesnake (*Crotalus adamanteus*) and the western diamondback rattlesnake (*Crotalus atrox*)
- ***Sistrurus***: Two other species of rattlesnakes in the genus *Sistrurus*. *Sistrurus catenatus* (also known as the massasauga) is mostly encountered in the upper Midwest from western Pennsylvania and New York across to Michigan and Iowa.
 - *Sistrurus miliarius* (also known as the pygmy rattlesnake) is seen chiefly in Florida and up into the Atlantic coast states.
- Bites are characterized by a very low morbidity and virtually zero mortality.
 - Antivenom used only occasionally (approximately 10% of the time).

- ***Agkistrodon***: The third genus of the family Crotalidae is *Agkistrodon*.
 - The copperhead (*Agkistrodon contortrix*) is the most common pit viper from Georgia up through the Atlantic Coast states. Antivenom administered to only 0% to 11% of victims.
 - *Agkistrodon piscivorus* (water moccasin) is also in the Atlantic Coast states, in Florida, and westward through Alabama and Mississippi and into eastern Texas. Neither species of *Agkistrodon* is extremely venomous. Bites characteristically cause significant edema but virtually no mortality. Antivenom used in only about 25% of victims of water moccasin envenomations.
 - Chiefly for patients either at the extremes of age or with significant comorbidities

Range of Venom Effects

- Bites from these species of pit vipers vary enormously.
 - Variability of the virulence is due to the variability of the venom.
 - Individual members of a species, kept over time, display variability in their venom pattern.
 - Important when one considers the antivenom that is currently available. CroFab (Crotalidae polyvalent immune Fab [ovine] [FabAV], Therapeutic Antibodies, Inc., Nashville, TN) is a mixture of Fab fragments prepared from purified immunoglobulins produced by sheep repeatedly injected with venom from one of the following four snakes: *Crotalus atrox*, *Crotalus adamanteus*, *Crotalus scutulatus*, or *Agkistrodon piscivorus*.
 - Fab fragments from all four preparations are then mixed together to produce a polyvalent mixture.
 - Variable degrees of immunogenicity and responses from the sheep.
 - Not all venom components will be neutralized to exactly the same degree.

Symptoms and Manifestations

- A near-immediate onset of a symptom triad occurs in victims of pit viper envenomation.
 - Pain
 - Swelling
 - Discoloration
- Digestive enzymes such as phosphatases, hyaluronidases, proteinases, phospholipases, and other substances dissolve connective tissue and proteins, and attack nerve endings.
- Edema is largely brought about by disruption of the endothelium of capillaries and lymphatics due to a variety of proteins that directly attack the endothelial integrity of the microcirculation.
- Lack of pain, swelling, and discoloration usually indicate that the victim is one of the 15% to 30% of pit viper victims in which the reptile did not inject venom.
- So-called “dry bites” do not require antivenom.
 - Some patients may be envenomated by a pit viper, fail to have any local signs, yet may be clearly ill as attested by their profuse weakness, fasciculations, diaphoresis, hypotension, nausea, vomiting, diarrhea, mental status alterations (which include confusion and stupor), and the oft-mentioned “metallic taste” experienced by several victims.

- This occurs in approximately 5% to 10% of envenomations.
 - Attributed to injection of the venom more or less directly into a vessel or a muscular bed rich in capillaries such that venom goes more directly into the circulatory system.

Clinical and Laboratory Findings

- Coagulopathic findings—clinical and laboratory—are of great interest to those who treat pit viper envenomations.
 - Laboratory coagulation defects are far most pronounced within the *Crotalus* genus and rarely encountered in the *Agkistrodon* and rarely, if ever, in the *Sistrurus* genera.
- Laboratory coagulation abnormalities due to a thrombin-like enzyme that has been referred to as crotalase.
 - Enzyme rapidly, efficiently, and partially cleaves fibrinogen by cleaving the B-peptide off the β -subunit, as does thrombin.
 - Neither cleaves the A-peptide from the α -subunit nor activates factors V, VIII, or XIII
 - This partially clotted fibrinogen forms a loose gel that is exquisitely sensitive to any proteolytic activity, so visible thromboses or organ manifestations of systemic thromboses are not encountered.
 - Crotalase neither activates platelets nor consumes anti-thrombin III.
 - Crotalase does not activate plasminogen directly (i.e., *in vitro* or *in vivo*) but does so indirectly, most likely by release of endothelial-secreted tissue plasminogen activator.
 - Plasma levels of tissue plasminogen activator spike in a reflex response to the deposition of the partially formed fibrin on the endothelial surface, and a brisk fibrinolysis occurs.
 - Essentially, the total body fibrinogen complement (some 15 g) is nearly totally converted into fibrin degradation products (FDPs) within an hour.
 - Crotalase is necessary in only extremely small amounts to totally defibrinogenate an adult human, resulting in plasma fibrinogen levels <50 mg/dL.
 - Coagulation end point (visible fibrin clot) of routine coagulation tests, such as prothrombin time (PT) and partial thromboplastin time (PTT) so impaired that many interpret this as the blood being “incoagulable.”
 - Thrombin generation via the intact coagulation cascade is **totally retained** save for the lack of the visible clot.
 - Intact thrombin generation serves to afford intact hemostasis, despite incoagulable *in vitro* PTs and PTTs.
 - Defibrinogenation syndrome is reversed by the administration of fibrinogen in the form of approximately 8 to 10 units of cryoprecipitate.

Postmortem Findings

- Death from American pit viper envenomation is rare, and full autopsies are even rarer.
- In 16 deaths of about 1,000 cases of North American envenomations reported up to 1989
 - Central nervous system edema and hemorrhage were reported in a few cases.
 - Cerebral hemorrhage was deemed the cause of death in only one.

- Mortality rate from severe, complicated rattlesnake envenomation was approximately 1.4%.
- Most common cause of death was progressive shock leading to multiorgan failure and death hours to a few days later.

Prehospital Treatment

- The key to good and effective therapy with minimal chance of loss of life, limb, or function is prompt transportation to a medical care facility.
- Initial scene management
 - Prevent further bites
 - Calm the patient
 - If successful transport is anticipated within an hour, it is probably best to forgo any local therapy other than to gently splint the bitten extremity, keeping it at or slightly below heart level, and transport the patient.
 - Topical cold packs may provide some relief of severe pain.
 - Incising or excising the wound, the application of electrical currents, or other traumatic manipulations are contraindicated.
 - Suction devices remove at best 2% of the venom load, are likely to be clinically insignificant, and, if used, should not delay transport.
 - The use of a tourniquet with pressure sufficient to impede either arterial or venous flow is contraindicated.
 - A lymphatic constriction band (ideally a blood pressure cuff inflated to 15 to 25 mm Hg, a band that allows a finger to pass easily beneath) or a properly applied pressure immobilization bandage may be considered if there are immediate life-threatening effects or a prolonged (>1 hour) transport time.

Hospital Treatment

- Approximately 5,000 to 10,000 bites occur in the United States each year.
- Death from envenomation by North American pit vipers occurs only about five to 10 times (0.1%) per year, representing approximately a 99.9% survival rate.
- Table 32.1 outlines the essentials of appropriate management of such patients.

Immediate Management

- **Confirm the bite:** Confirm that the patient was bitten by a snake and, particularly, a venomous snake.
 - With the exception of coral snake envenomation, this usually includes the presence of puncture wounds.

TABLE 32.1

INITIAL EVALUATION AND DIAGNOSTIC POINTS

- Confirm patient was bitten by a venomous snake; determine snake species if possible.
- Evaluate for local signs of envenomation:
 - Pain
 - Swelling
 - Discoloration
- Evaluate for systemic signs of envenomation:
 - Alterations in vital signs, nausea, vomiting, diarrhea
 - Fasciculations
 - Coagulation abnormalities
 - Altered mental status

TABLE 32.2

CLINICAL CHARACTERISTICS OF ENVENOMATION THAT POTENTIALLY AID IN IDENTIFICATION OF OFFENDING *CROTALUS* SPECIES

Common name	Scientific name	Distribution	Neurologic symptoms	Coagulopathic findings	Rhabdomyolysis
Eastern diamondback	<i>Crotalus adamanteus</i>	Southeastern United States	+	Prolonged PT/PTT; minimal thrombocytopenia	+
Canebrake	<i>Crotalus horridus atricaudatus</i>	Eastern United States	Nil	Nil	++++
Mojave	<i>Crotalus scutulatus</i>	Desert southwest United States	+++	Nil	++++
Timber	<i>Crotalus horridus horridus</i>	Eastern United States	Nil	Prolonged PT/PTT; moderate to severe thrombocytopenia	Nil

PT, prothrombin time; PTT, partial thromboplastin time.

+ = usually minimally present; ++ = usually moderately present; +++ = usually extensively present; ++++ = always present.

- Not uncommon to see snakes with one fang or even three or four, as their fangs mature and move forward, replacing one another with time.
- Vast majority of patients will have the prompt triad of pain, swelling, and discoloration confined to the bite site almost within minutes of the event but up to 2 hours later in unusual cases.
- **Determine the genus and species:** Next, one should try to determine the family and/or genus and species of snake if at all possible.
 - Majority of victims know precisely that they were in the same area as a venomous snake and the snake's common name.
 - Another 25% to 30% will bring the snake to the health care facility in conditions ranging from badly mutilated to quite alive.
 - Several online links, such as <http://www.pitt.edu/~mcs2/herp/SoNA.html>, are available to assist identification.
 - One can occasionally augment identification of an offending snake by the symptom complex its bite produces (Table 32.2).
 - Prognosis generally species dependent but also related to the time to presentation, time to antivenom administration, the health of the host, and other factors.
- **Determine systemic signs and manifestations:** Assuming the patient does have signs of local envenomation, next in order is to determine whether there are any systemic signs of envenomation.
 - No one dies of local envenomation but only from systemic manifestations.
 - Systemic symptoms such as nausea, vomiting, diarrhea, and diaphoresis and fasciculations—particularly in *Crotalus* envenomations—portend the possibility of a more serious outcome.
 - Many coagulation abnormalities seen in *Crotalus* envenomations are often spectacular in their laboratory manifestations.
 - Altered mental status to include a noticeable stupor and a metallic taste is often reported in serious envenomations.
- **Assign degree of severity:** In attempting to assign a degree of severity from mild to moderate to severe, one must recognize

- That the envenomation syndrome is progressive
- Evaluation is ongoing and time-dependent
- The *rate of change* in signs, symptoms, and other manifestations is important
 - Not only in grading the severity of the bite but in grading the effect—or lack of effect—of the administration of antivenom

Antivenom Administration

- Indications for the use of antivenom vary.
 - Severe envenomations are often apparent by the time they arrive at emergency care, primarily because of the rapidity with which the venom initially gains entry into the circulatory system.
 - In our experience, it is quite rare to see one progress from moderate envenomation to severe envenomation.
 - Severely envenomated patients may be considerably hypotensive with lethargy, nausea, and vomiting, and require immediate and aggressive therapy (Table 32.3).
 - Suggested therapy is outlined in Table 32.4.
 - At least one large-bore intravenous access site must be obtained and blood drawn for a variety of tests.
 - It is useful to outline the leading edge of proximal progression of the swelling with some type of ink pen.
 - In this manner, one can observe whether the swelling is progressive. Whereas some relatively slow progression is tolerated—particularly if one elects not to treat the patient or if antivenom is not immediately available—more rapid swelling, particularly with concomitant systemic symptoms, usually justifies prompt and aggressive therapy.
 - In a situation involving our native reptiles, antivenom is not administered to patients who have no envenomation.
 - About 10% to 15% of people with minimal envenomation, half of those patients with moderate envenomation, and all patients with severe envenomation are administered antivenom.
 - There are several reasons for not administering antivenom to all, or nearly all, victims:
 - The extremely low mortality rate of envenomation by snakes native to the United States

TABLE 32.3

SEVERITY OF ENVENOMATION BY PIT VIPERS

Grade	Frequency	Initial findings	FabAV vials in first 24 h
No envenomation	15%–30%	No local, systemic, or laboratory abnormalities 2 h after bite	0
Minimal envenomation	20%–40%	Local and slowly progressive swelling without systemic or severe laboratory abnormalities	0–6
Moderate envenomation	20%–40%	Rapidly progressive local swelling; systemic symptoms of nausea, vomiting, diarrhea, diaphoresis, fasciculations, moderate hypotension, and moderate hemostatic abnormalities, but without bleeding	6–18
Severe envenomation	5%–10%	Severe systemic symptoms as above plus severe hypotension and lethargy; severe hemostatic abnormalities and possible bleeding	12–24 or more

- The—admittedly very low—rate (<0.01%) of serious and mild (14%) allergic reactions
- The modest rate (15%) of serum sickness–like late reactions (occurring typically 8–12 days after administration) to FabAV
- The cost of antivenom treatment can easily exceed \$50,000.
- Antivenom is more efficacious the earlier it is administered.
 - If the decision made to employ the drug, do it promptly.
 - Control of the envenomation syndrome is adjudged by the slowing, or preferably the cessation, of progressive local swelling.
- Hemorrhagic bleb formation at the site of the bite is *not* an important sign in and of itself, although it generates much attention.
 - These should be left alone or, if one thinks that bursting is imminent, the blebs should be topically sterilized and lanced.
- Compartment syndromes seen very rarely.
 - Indications for surgical intervention are justified by pressure measurements in only about 1% to 2%.
 - Reliable signs of compartment syndrome are total lack of function and exquisite pain of the muscles contained

within a compromised compartment and often an intense hardness of the site.

- The mainstay for treatment for North American pit viper envenomation is ovine FabAV for bites in both adults and children.
 - The Fab portions of sheep immunoglobulins are made by enzyme cleavage and elimination of the Fc fragment and by further enzymatic cleavage of the resulting F(ab')₂.
 - Pretreatment skin or conjunctival testing is neither required nor recommended prior to the administration of FabAV.
- Some species of snakes, particularly the timber rattlesnake (*Crotalus horridus horridus*), have a principle in their venom that causes significant thrombocytopenia, which is resistant to reversal by antivenom therapy.
 - If platelet counts are significantly falling and/or are <10,000 to 20,000 cells/μL
 - Administration of (additional) antivenom and infusion of platelets may be indicated.
 - With most Crotalid envenomation, there is a mild thrombocytopenia in the range of 50,000 to 150,000 cells/μL that is thought to be due to passive entrapment of platelets within the previously described soft fibrin network and does not support diagnosis of disseminated intravascular coagulation (DIC).
 - Platelet count often will rebound within the day as the soft fibrin network is quickly cleaved by endogenously generated plasmin.

TABLE 32.4

SUMMARY OF THERAPEUTIC MEASURES FOR PIT VIPER ENVENOMATION

- Obtain IV access and administer crystalloid as indicated.
- Obtain CBC, PT, PTT, and platelet count every 6–12 h.
- Estimate severity of envenomation:
 - Species of snake
 - Age, health status of victim
 - Rate of progression of signs/symptoms
- Administer FabAV per Table 32.3.
- Follow rate of progression of signs/symptoms after FabAV administration.
- Determine tetanus vaccination status.
- Seek consultation from experts or a poison center (1.800.222.1222), especially if less experienced in treating snake envenomation.

CBC, complete blood count; PT, prothrombin time; PTT, partial thromboplastin time.

Surgical Procedures

- Surgical procedure for the wound is rarely indicated.
- Antibiotics are generally not employed, as they are of questionable assistance, and their routine use is not recommended.
- Tetanus vaccination status should be ascertained as being up to date.

Observation

- Best to have the extremity clearly visible so as not to compromise the evaluation
 - No covering dressings or wraps are recommended.
 - Once the patient is at the hospital and receiving antivenom, the extremity should be elevated above the level of the heart.
 - Monitoring is usually best performed in the ED.

- Subsequent admission to the intensive care unit (ICU) may be needed, although ICU therapy should not be considered a standard of care.
- Usual length of hospitalization required is 4 to 6 days.
- For up to 24 hours, we often observe patients—either in the emergency department or in the hospital—who are deemed to have no envenomation or mild envenomations and who do not receive antivenom because of the very high incidence of concurrent inebriation, which would allow for the possibility of inadequate history or incomplete evaluation and follow-up.

Prognosis

- Nearly all North American pit viper bites result in some near-instantaneous local tissue destruction.
 - Should not be expected to be totally absent or to resolve, even with the very best and most rapid care
- Most edema and swelling that does occur after antivenom treatment lasts only for a month or two, with longer recovery times seen in older or debilitated patients.
- In general, there is a total return of function to the bitten extremity.
 - Some patients can experience mild stiffness, atrophy, and weakness for up to a year or more.
- Patients who are bitten by snakes tend to continue their risky behavior, resulting in the finding that re-envenomation is not rare.

SNAKES NONNATIVE TO THE UNITED STATES

Major Problems

- The severity and spectrum of effects in envenomation varies widely.
 - Life-threatening effects may be seen, and fatalities do occur.

Epidemiology

- About 3,000 snake species in the world
 - Fewer than 300 are dangerous to humans.
 - Venomous reptiles include the families Atractaspididae, Colubridae, Crotalidae, Elapidae, Helodermatidae, and Hydrophiidae.
 - Between 40 and 50 nonnative snake envenomations occur yearly in the United States.
 - Certain families, genera, and species are more commonly encountered.
 - Cobras (family Elapidae) account for one-third of all nonnative venomous snake exposures, and 86% of Elapids
 - *Naja naja*, *Naja nigricollis*, and *Ophiophagus hannah* are the most commonly involved Elapid species.
 - Viperids account for 46% of all nonnative venomous snake exposures.
 - *Bothrops*, *Bitis*, and *Lachesis* genera accounting for 33%, 19%, and 11% of these, respectively.
 - *Bothrops goodmanni*, *Bothrops schlegeli*, *Bitis gabonica*, and *Lachesis mutus* the most commonly encountered viperid species.

- Almost one-third of nonnative envenomations develop major to moderate symptoms and signs of disease, and are admitted to an ICU.
 - Case fatality rate of approximately 1% is significantly greater than in native snakebites
 - Males are involved in 84% of bites, a percentage similar to that in native bites.
 - Almost 15% are ages 17 years or less, and approximately 7% are ages 5 years or younger, most likely as a result of private collections in home settings.
 - Potential penalties for possession of venomous animals in some jurisdictions may result in the withholding of critical information.
 - A qualified herpetologist should be consulted for the identification of nonnative snakes that are otherwise unidentified.
 - Presence of a puncture and typical appearance of the site, progression of findings, and consistent laboratory abnormalities of a snakebite, indicate the possibility even with no history.

Pathophysiology

- The venom glands of poisonous snakes are modifications of salivary glands.
- The venom of a single snake is a complex mixture of enzymes, nonenzymatic proteins and peptides, and other substances.
- Some of these components may be found in all venomous snakes, with mixed clinical effects. The most important deleterious components of snake venom are shown in Table 32.5.
- Elapid venoms vary widely among species but contain more neurotoxins and cardiotoxins, resulting in various expressions of nerve and cardiac toxicity.
 - Sea snakes have venom similar to elapids.

Diagnosis and Monitoring

- **Size and species:** In general, larger snakes contain and deliver more venom.
 - Fatal envenomations may result from juvenile snakes.
- **Quantity injected:** As many as 30% of Crotalid bites and 50% of Elapid bites may result in no envenomation.
 - When venom is injected, the amount may be reduced by poor penetration of the fang or high tissue pressures, as in fingertips.
 - Volume of available venom may also be reduced by recent previous feedings.
- **Bite location:** Tissues and anatomic areas with a low capacity for swelling or which are functionally important, such the fingers or hand, are particularly at risk of both short- and long-term impairment.
 - Destructive effects of proteolytic enzymes may directly damage tissues.
 - Tissue pressures may be significantly elevated, and vascular compromise may occur.
 - Lower-extremity bites may damage venous valves and produce long-term dependent edema.
 - Decreased mobility and mobilization after a bite may predispose to deep venous thrombosis or other morbidities.

TABLE 32.5

SOME COMPONENTS OF SNAKE VENOM

Component	Viperid	Elapid	Effect
Proteinases	+++	+	Tissue destruction; hematologic effects
Hyaluronidase	++	++	Hydrolyzes connective tissue stroma; promotes spread
Cholinesterase	+	++	Catalyzes hydrolysis of acetylcholine
Phospholipase A ₂	+++	+	Hemolysis; may potentiate neurotoxins; myonecrosis
Phosphodiesterase	+	+++	Unknown
Neurotoxins	+	+++	Flaccid paralysis; muscle fasciculation
Cardiotoxins	+	+++	Depolarizing; depression; rhythm disturbances

+ = usually minimally present; ++ = usually moderately present; +++ = usually extensively present.

- **Age and health of the victim:** Those at greatest risk of morbidity and mortality include patients with long delays to treatment, those with significant comorbid conditions, and those at the extremes of age.
 - Because of smaller body mass, children receive a relatively greater dose of venom.
- **Symptoms and manifestations:** As snakes can, to some extent, control whether and how much venom to deliver and as other factors may affect the quantity and specific components available and delivered, it is difficult to make an *a priori* determination of the clinical potential of the envenomation.
 - **Local effects:** Snake venom that produces local effects causes pain and edema at the bite site, erythema, ecchymosis, and occasional bleb formation. Later, the increased membrane permeability and cellular destruction produced by proteases result in spreading edema both distally and proximally and may cause tissue necrosis.
 - If there is concern for elevated tissue or compartmental pressures, they should be measured directly (Stryker Intra-Compartmental Pressure Monitor System, Stryker United Kingdom; COACH Transducer, MIPM GmbH, Mammendorf, Germany).
 - Local venom effects will respond to adequate amounts of antivenom with cessation of progression of proximal edema and reduced tissue pressures.
 - Locally acting venom components are usually exhausted by 24 to 36 hours.
 - Resulting tissue injury may continue to develop over days to weeks.
 - Starting on the second day after envenomation, the clinical appearance of the bitten extremity, with increased heat and inflammation of the lymphatics, may be difficult to distinguish from an infective process.
 - **Hematologic effects:** Coagulation alterations result from proteases acting on various parts of the coagulation cascade and may occur singly or in any combination.
 - Fibrinogenolysis may occur, resulting in decreased levels of fibrinogen and increased levels of fibrin degradation products.
 - Platelet inhibition, aggregation, or consumption may occur with abnormal function and/or decreased platelet counts.
 - Intravascular hemolysis has also been reported with some snake venoms.
 - The coagulation defects may result in local or systemic bleeding, including life-threatening hemorrhage.
 - Laboratory tests, including a complete blood count (CBC) with platelet count, PT/INR, PTT, fibrinogen, and fibrin degradation products (or d-dimers)
 - Most patients who will develop hematologic abnormalities will demonstrate them within 1 to 2 hours, although early use of antivenom may mask this finding.
 - Normal hematologic values at 6 hours suggests an absence of such effects.
- **Neurologic effects:** These may result from Atractaspid, Elapid, Helodermid, Hydrophiid, or Viperid envenomations.
 - Clinical effects can include sweating, numbness, paresthesias, convulsions, coma, muscle fasciculation, muscle weakness, and respiratory arrest.
 - Respiratory muscle paralysis is the primary cause of death with most Elapid and Hydrophiid venoms.
 - Coma may be secondary to hypovolemia or to a direct effect of the toxin.
 - Neurologic effects may develop rapidly, with respiratory arrest occurring within 15 to 30 minutes, but also may be delayed by many hours.
 - Measures such as the application of a pressure immobilization bandage (PIB) may also delay the onset of neurotoxicity.
 - Once neurologic effects occur, they may progress very rapidly.
 - Patients should be observed for a sufficient period of time, and preparations to manage the airway should be readily available.
 - Both antivenom and cholinergic agonists will generally stop the progression of effects and have been reported to result in either dramatic or more rapid improvement than would otherwise be expected.
 - Extubation criteria are based on standard tests of respiratory sufficiency.
 - **Nonhematologic systemic effects:** Type I hypersensitivity reactions to venom (IgE or non-IgE mediated) with or without hypotension may occur; incidence is approximately 1%.
 - Characterized by wheezing, urticaria, laryngeal edema, and/or hypotension
 - Airway compromise from laryngeal edema may also occur
 - Incidence of type I hypersensitivity to antivenoms varies from <5% to 25%.
 - Other systemic findings common in snakebites are nausea, vomiting, diaphoresis, and pulmonary edema, especially in more severe cases.

- Usually resolve in response to antivenom and rarely persist beyond the immediate postbite period.
- Type III hypersensitivity reactions—“serum sickness”—may occur in any patient who has received antivenom and are the result of circulating immune complexes.
- Usually occur between 5 and 21 days after receiving antivenom and vary widely in incidence by antivenom utilized, from less than 5% to 100%

Diagnosis

- The diagnosis of snakebite may be a clinical one and should be suspected in any unknown presentation with any of the foregoing clinical manifestations.
- Immunoassays and bioassays have been used to identify various snake venoms in tissue within endemic areas; these are not available in the United States.
- A local zoo or aquarium may be of assistance in identifying the snake.

Management

- The management of clinically significant snake envenomation can be divided into first aid, specific antivenin therapy, and supportive therapy (Table 32.6)

TABLE 32.6

DIAGNOSTIC PEARLS

- Up to 30% of Viperid and 50% of Elapid bites do not result in envenomation.
- Signs and symptoms of envenomation may be delayed by many hours.
- Identification of the snake to the species level is required for antivenom selection.
- Viperid venoms usually produce (a) local tissue injury and (b) hematologic abnormalities and may also include (c) cardiovascular effects and (d) neurologic effects.
- Elapid venoms usually produce (a) neurologic toxicity, progressing to respiratory muscle paralysis, and may also include (b) local tissue injury and (c) hematologic abnormalities.
- Type I hypersensitivity reactions (anaphylaxis) may occur to venom or antivenom.
- Anaphylaxis, cardiotoxins, or fluid loss may produce hypotension.
- Local tissue injury may result in severe swelling, pain, and elevated tissue and/or compartmental pressures. Functional impairment, necrosis, and tissue loss may occur.
- Hematologic effects include impairment or consumption of platelets, fibrinogenolysis, hypofibrinogenemia, prolongation of PT/PTT, procoagulant effects, and other abnormalities, either singly or in combination; also, significant bleeding may occur.
- Neurologic effects include diplopia, ptosis, fasciculations, respiratory muscle paralysis, and arrest. Viperids may cause weakness but usually not respiratory compromise.
- Other venom effects include tachycardia, nausea, vomiting, diaphoresis, and anxiety.
- Wound infection is uncommon, documented in fewer than 5% of cases.
- Local effects may continue or recur for the first 24–36 h, and hematologic effects may continue or recur for up to 3 wk.

PT, prothrombin time; PTT, partial thromboplastin time.

TABLE 32.7

PREHOSPITAL MANAGEMENT

- A pressure immobilization bandage (PIB, a crepe bandage wrapped at lymphatic pressure tension from the distal to proximal aspects of an extremity) or lymphatic constriction band (a blood pressure cuff inflated to 15 to 25 mm Hg) will retard progression of venom into the general circulation.
- Prehospital management is indicated with Elapids; in Viperids with early, severe, systemic effects; and possibly when there are long transport times
- The bitten body part should otherwise be kept gently splinted, slightly below heart level. It may be lowered further if systemic effects are seen, and elevated for excessive swelling.
- At least one large-bore IV should be initiated.
- The offending snake should be identified to the species level, if possible.
- If available, antivenom should accompany the patient.
- The victim should be rapidly transported by emergency medical services to a health care facility.
- Contraindicated management approaches
 - Arterial or venous tourniquets
 - Incision, excision, heat, cold, electricity, or other local wound manipulations
 - Suction devices, which are not effective and should not delay transport to definitive care

- **Online antivenom index:** Initiation of efforts to obtain the appropriate antivenom should not wait until symptoms or signs develop; should be done immediately
 - The online antivenom index is a resource for determining the appropriate antivenom(s) for any given snake and maintains a continuously updated listing of zoo antivenom stocks and contact information; accessible by regional poison centers (1-800-222-1222).
- **First aid:** In general, the patient should get away from the snake, and the snake should be secured by a qualified individual (Table 32.7).
 - Pre-existing medical information, information regarding the biting species, and any available antivenom should be transported with the patient.
 - Bitten body part should be splinted to slow the passage of venom into circulation.
 - With envenomations from known neurotoxic snakes, generally the Elapids and sea snakes, the application of a PIB (a wide crepe bandage wrapping the entire extremity from distal to proximal at lymphatic compression pressures) or a lymphatic constriction band (i.e., a blood pressure cuff inflated to 15–25 mm Hg) has been shown to slow central compartment spread of venom and reduce the risk of out-of-hospital respiratory arrest, and thus should be routinely employed.
 - Hypotension, airway compromise, or other signs of a severe type I hypersensitivity reaction are examples of appropriate indications for the use of a PIB or lymphatic constriction band in a Viperid bite.
 - Prior to arrival at a hospital and administration of antivenom, the bitten area should be kept at or slightly below the level of the heart.
 - Dependent position may be used if rapid, severe systemic effects are occurring.

TABLE 32.8**HOSPITAL BITE SITE AND WOUND MANAGEMENT**

- If previously applied, a pressure immobilization bandage (PIB) or lymphatic constriction band (LCB) should not be removed until antivenom is being administered or a decision has been made to observe without antivenom.
 - Wash the bite site, apply antibiotic ointment, leave it otherwise uncovered, and provide tetanus immunization updating as needed.
 - Once antivenom has been initiated, or a decision has been made not to administer it, keep a bitten extremity elevated with periodic assessment of edema (and tissue pressures if indicated), and monitor for development or progression of systemic symptoms.
 - Management of progressive tissue edema and elevated tissue or compartmental pressures is by adequate amounts of antivenom and elevation, if tolerated.
 - Frankly necrotic tissue should be debrided.
 - There is little to no role for dermatomy or fasciotomy.
- Transport to a health care facility should be by paramedic ambulance.
 - Initiation of two, large-bore intravenous lines is a sensible precaution.
 - **Hospital care:** Basic wound care should be provided, including updating the tetanus status. After period of observation—8 to 24 hours—depending on the species of the snake, if the victim demonstrates no signs or symptoms of envenomation, release from the hospital (Tables 32.8 through 32.10).
 - **Surgical management:** Frankly devitalized tissue, usually becoming evident several days following an envenomation, should be debrided.
 - Because high concentrations of venom have been found in blisters overlying the bite area, unroofing these should be considered.
 - Fasciotomy or dermatomy have been advocated for compartment syndrome or tense tissue edema potentially affecting blood flow.

TABLE 32.9**HOSPITAL ANTIVENOM MANAGEMENT**

- Antivenom is the definitive management of snake envenomation, when it is available.
- Antivenom for an exotic species can be located via the Online Antivenom Index. Poison centers (1-800-222-1222) can assist.
- When available, species-specific antivenom should be used.
- Skin testing is indicated if recommended by the manufacturer.
 - Skin tests are neither sensitive nor specific to predict hypersensitivity reactions.
 - A positive reaction does not preclude antivenom administration.
 - Skin testing should not delay administration of antivenom in a life- or limb-threatening envenomation.
- Exotic antivenoms are imported under Investigational New Drugs licenses and, if used, appropriate reports need to be made to the hospital's institutional review board (IRB) and the Food and Drug Administration (FDA).

TABLE 32.10**HOSPITAL SYMPTOMATIC MANAGEMENT**

- Hypotension
 - May be due to a type I hypersensitivity reaction to venom or to antivenom, cardiotoxins, or fluid loss.
 - Management is with Trendelenburg positioning, crystalloid fluid expansion, pressors, anaphylaxis treatments (epinephrine, H₁ and H₂ blockers), and antivenom (if believed to be secondary to venom).
 - Neurologic effects
 - Should be managed with antivenom and mechanical airway support as needed.
 - Cholinergic agonists, such as neostigmine, may be used as adjunctive or substitute managements of muscle weakness in some Elapid envenomations.
 - Hematologic effects
 - Severe or multicomponent abnormalities are managed primarily with antivenom.
 - Blood products are reserved for clinically significant hemorrhage and are given with additional antivenom if needed.
 - Some effects (e.g., platelet aggregation) may be readily reversed, while other processes (e.g., fibrinolysis) may be stopped, with components returning to normal levels by their natural replenishment.
 - Other systemic effects are managed with symptomatic and supportive care.
 - Parenteral opioids may be required for pain.
 - Recurrence of local and/or hematologic venom effects may occur.
 - Patients at high risk should be closely monitored, especially after discharge.
 - Additional antivenom should be considered for recurrent local effects in the first 24 h or recurrent severe or multicomponent hematologic abnormalities.
- **Other supportive therapies:** These include basic wound care and updating tetanus status.
 - Ventilatory support and hemodialysis may be necessary for pulmonary and renal complications of severe envenomation.
 - Corticosteroids may be used for hypersensitivity reactions to venom or antivenom.
 - Antibiotics are indicated for documented infection or in the presence of frank necrosis.
 - **Hypersensitivity reactions:** If a type-I hypersensitivity reaction develops, the antivenom infusion should be stopped.
 - Anaphylactoid reactions are primarily related to rate of infusion, and stopping the infusion often results in rapid improvement.
 - Anaphylactic reactions (i.e., those IgE-mediated) are often dramatic and continue to progress after the infusion has been stopped.
 - Standard managements should be used. If symptoms persist, the patient should be treated with H₁ (e.g., diphenhydramine, 50 mg IV) and H₂ (e.g., ranitidine, 50 mg IV) blockers. Wheezing may respond to β -adrenergics by nebulizer (e.g., albuterol). If there is hypotension or laryngeal edema, epinephrine, either subcutaneously or intravenously, should be considered.
 - Antivenom should be withheld until the reaction has subsided and then a determination made whether to restart it.

TABLE 32.11

POSTDISCHARGE MANAGEMENT

- Physical therapy may be helpful in minimizing the extent and duration of functional impairment.
 - Type III hypersensitivity reactions (“serum sickness”):
 - They usually develop between 5 and 14 d following antivenom administration.
- The incidence varies from fewer than 5% to greater than 80% of cases depending on the antivenom, host, and other factors.
- Nonsteroidal anti-inflammatory drug analgesics and antihistamines are usually sufficient for symptomatic care.
- Severe reactions may have renal involvement and require steroids and, in rare cases, rehospitalization.
- Patients with significant hematologic abnormalities, especially those treated with Fab antivenoms, may be at risk of recurrent effects after discharge.
 - Close follow-up is necessary for at least 2 to 4 d to detect recurrence.
 - Consider readministration of antivenom for clinical bleeding or multicomponent or severe hematologic abnormalities, especially with comorbid conditions.

◦ If restarted, the patient should receive pretreatment with H_1 and H_2 blockers and the infusion begun more slowly.

- **Postdischarge considerations:** Desirable to see patients at least once post discharge to monitor for persistent or recurrent hematologic effects if indicated or tissue injury and its sequelae.
 - To refer for physical or occupational therapy in order to maximize functional recovery
 - Patients should also be cautioned about the possible risk of sensitization to snake venoms or antivenoms regarding possible future envenomations (Table 32.11).

SPIDERS AND SCORPIONS

Spiders

- In the United States, only two groups of spiders are typically considered medically significant.
- These are the widow or *Latrodectus* spiders and the brown spiders belonging to the *Loxosceles* genus.

Widow Spiders (*Latrodectus* Genus)

- Widow spiders, including the well-known black widow, belong to the *Latrodectus* genus
 - Widow spiders are found throughout most of the country but are most common in the southeast, with the black widow (*Latrodectus mactans*) believed to cause most envenomations.
 - The female black widow, more harmful to humans than the male, as her fangs are longer and better able to penetrate human skin, has a shiny black round abdomen and a characteristic bright red hourglass marking on her underside.
 - Considered shy spiders and can be found in dark, secluded areas such as under leaf litter
 - All widow spiders worldwide are believed to have similar venom characteristics and similar clinical symptoms.

- **Pathophysiology:** The primary component of widow spider venom that causes human clinical effects is α -latrotoxin.
 - Binds to neuronal tissue and causes neurotransmitter release in at least two ways:
 - Binds to and helps form ion channels, which allow calcium and other ions to leak, causing a calcium-dependent release of neurotransmitter
 - Binds to the latrophilin receptor on neuronal tissue, and causes a calcium-independent release of synaptic vesicles
- **Diagnosis:** Diagnosis is primarily clinical and historical, as there are no laboratory tests to confirm envenomation.
 - Bite victims will recall a painful pin pricklike bite, but the bite can be painless.
 - Historically are associated with outhouse use
 - Can also occur when dressing or putting on shoes, especially if they are left outside, or even while in bed
- **Clinical effects—local:** Can produce mild local irritation
 - Bite is classically described as two small punctures with a small area of erythema surrounding a minimally blanched area centrally, producing a “halo” or “target” effect.
 - Local injection of venom is not believed to cause necrotic wounds.
 - Superinfection is uncommon.
- **Clinical effects—systemic:** The more medically significant effects after widow envenomation are the constellation of systemic symptoms known as *latrodectism*
 - Symptoms begin within an hour after the bite.
 - Local muscle cramps can progress to involve larger muscle groups, spreading continuously from the site of the bite.
 - Abdominal muscles can be involved, leading to abdominal rigidity that can imitate the peritoneal signs of a perforated viscus and which may result in an incorrect diagnosis in the young child or uncommunicative adult.
 - Priapism
 - Compartment syndrome
 - Elevations in creatine kinase
 - Myocarditis
 - Hypertension has been reported and could be life threatening in susceptible populations.
- **Management:** Though the *Latrodectus* venom is very potent, the volume of venom is minuscule.
 - No role for tourniquets, incision, or excision at the venom injection site
 - Initial control of pain and muscle contraction should be accomplished through administration of opiates and benzodiazepines.
 - IV calcium has not been shown to provide significant benefit and is no longer considered a first-line agent.
 - An antivenom specific to *L. mactans* is available ([*L. mactans*] Black Widow Spider Antivenin, Equine Origin, Merck & Co., Inc).
 - Risk of hypersensitivity reactions, including anaphylaxis and serum sickness
 - Use of antivenom is controversial.
 - Most would agree that when dealing with patients in the extremes of age, pregnant patients, or those with intractable muscle cramping and pain, the use of antivenom should be strongly considered.
 - The dose for adults or children is the contents of one restored vial (2.5 mL) of antivenom.
 - Can be given as an intramuscular injection but is typically administered as a slow IV infusion

- Can be redosed if needed, but one vial of antivenom is usually sufficient
- Evidence for cross-reactivity of antivenoms produced to various *Latrodectus* species, including a purified F(ab')₂ antivenom produced in Australia to the red-backed spider (*Latrodectus hasselti*) by CSL Limited and which possesses an improved safety profile compared with the U.S. product
 - This antivenom is not currently approved for use in the United States; consultation with a regional poison center (1-800-222-1222) can be beneficial.
- **Follow-up:** Unless antivenom is administered, in which case monitoring for serum sickness should be arranged, there are no long-term sequelae expected from a widow spider envenomation.

Brown Spiders (*Loxosceles* Genus)

- *Loxosceles* spiders are found primarily in the southern half of the United States.
- *Loxosceles reclusa* species (“brown recluse”) is the most common and medically important in the United States.
- Considered shy spiders, hiding in woodpiles and dark corners, only biting when threatened
 - More common in warmer months and are often presumed to occur when a spider is caught next to skin by clothing or linens
- **Pathophysiology:** Venom from *Loxosceles* spiders is a complex mixture of cytotoxic components that indirectly cause impressive, delayed local symptoms and have the potential for causing human systemic toxicity.
 - Hyaluronidase in the venom causes significant tissue destruction, allowing spread.
 - Sphingomyelinase D in *Loxosceles* venom is believed responsible for the dermal inflammation seen after bites.
- **Diagnosis:** Because the bite is usually painless and thus unnoticed at the time, unless a *Loxosceles* bite is witnessed and positive identification of the spider occurs, the diagnosis is typically a historical and clinical one.
 - The necrotic wounds found with *Loxosceles* spider bites can mimic numerous other common cutaneous conditions, such as bites by other spiders or other insects, soft-tissue bacterial infections, or a vasculitis.
 - Broad differential, including these, as well as conditions such as erythema nodosum, pyoderma gangrenosum, pyogenic granuloma, and herpes infections, should be reviewed before a necrotic wound is attributed to a *Loxosceles* spider in the absence of a known bite.
 - Positive laboratory identification by ELISA or hemagglutination is possible to confirm *Loxosceles* envenomation in research settings but is not at this time clinically useful.
- **Clinical effects—local:** Unlike the widow spiders, the majority of clinical effects seen from *Loxosceles* spiders are a result of local tissue injury.
 - Characteristic necrotic wounds are described as having a “red, white, and blue” appearance.
 - Local tissue inflammation occurs over the first day after envenomation, causing skin erythema.
 - In the center of this reddened skin, a small necrotic or “blue” area develops that is surrounded by a halo of blanched tissue appearing gray or “white.”
 - Often the wound is not noted until it begins to cause significant pain or the necrotic area becomes prominent.
- **Clinical effects—systemic:** Rarely, a *Loxosceles* spider bite can lead to a clinical syndrome known as *systemic loxoscelism*.
 - Cases, many of them in children, begin as low-grade febrile illness with arthralgias and other nonspecific symptoms.
 - Within 24 to 48 hours after the bite, these symptoms can progress to a potentially life-threatening illness characterized by hemolysis and shock.
 - Systemic loxoscelism should be in the differential of unexplained hemolysis associated with shock.
- **Management:** Many pharmacologic and surgical treatments have been proposed in the management of the necrotic dermal wounds associated with *Loxosceles* spiders, but none has been proven to have significant effects in preventing or reversing damage.
 - Early attempts to “core” out affected areas to prevent venom spread result in poor wound healing and worsened scarring.
 - Systemic loxoscelism should be treated with symptomatic and supportive care.
 - Aggressive fluid resuscitation
 - Blood product transfusion
 - Vasopressor use

Nonnative Spiders

- The funnel web spiders (*Hadronyche* and *Atrax* spp.), native to Australia, and the banana spider (*Phoneutria* spp.), native to South America, are considered far more dangerous than the native *Latrodectus* and *Loxosceles* spiders.
- These can be found through collectors or as accidental stowaways in goods transported internationally.
 - The funnel web spider venom contains a potent neurotoxin that can cause fasciculations, weakness, and autonomic instability, with coma and pulmonary edema complicating the clinical course.
 - An antivenom available in Australia has been successfully used in severe envenomations.
- The South American spiders belonging to the genus *Phoneutria* have a neurotoxic venom that can cause pain and neurologic and gastrointestinal symptoms and shock and pulmonary edema in severe cases.
 - An equine antivenom is available in South America.
- Antivenoms may be located in the United States through the Online Antivenom Index, with the assistance of a regional poison center (1.800.222.1222).

Scorpions

- In United States, only one medically significant species of scorpion, *Centruroides exilicauda* (formerly *Centruroides sculpturatus*)
 - Found in the southwestern United States, primarily in southern Arizona, it is commonly known as the bark scorpion.
- Stings occur by the tail, with the venom containing neurotoxins and other components.
 - Pediatric patients are at greatest risk of having clinically significant symptoms associated with such a scorpion sting.
 - Symptoms can be minor with only some local paresthesias but, for some, symptoms can be severe, including cardiac manifestations such as tachycardia and hypertension, neurologic manifestations such as roving eye movements and agitation, and respiratory manifestations, including tachypnea and stridor.
- Cholinergic symptoms such as hypersalivation have also been reported.

- Treatment options in the past have included a goat-derived antivenom, limited to use within the state of Arizona.
- No longer produced, however, and existing supplies are rapidly dwindling.
- A F(ab')₂ antivenom is currently in clinical trials.
- Continuous midazolam infusion, ventilatory support, and otherwise supportive and symptomatic care are current mainstays of treatment.
- Atropine for excessive cholinergic signs has been recommended.

MARINE ANIMALS

Stingray

- Eleven different species of stingray are found in U.S. waters, seven of which are found in the Atlantic Ocean.
- Have long, sharp, serrated barbs along the dorsal surface of their tails, which can cause significant tissue damage and death, even without envenomation
- The tail barbs are covered in an integumentary sheath that covers two ventrolateral venom glands.
- Their venom is a complex mixture that includes phosphodiesterase, nucleosidases, and serotonin.

Clinical Effects

- Burning pain at the wound site typically intensifies with time, and local symptoms may last up to 48 hours.
- Venom can cause initial vasodilation and edema at the bite site, then vasoconstriction with hemorrhagic necrosis of tissue, and inflammatory infiltrate.
- Cardiac conduction abnormalities ranging from bradycardia to atrioventricular nodal blocks with dysrhythmias and cardiac arrest from asystole have been reported.
- Venom effects also include nausea/vomiting/diarrhea and abdominal pain and ataxia, seizure, coma, hypotension, and respiratory distress.

Treatment

- Treatment is symptomatic and supportive.
- Radiographic imaging and local wound exploration are necessary to evaluate for retained foreign body in the wound.
- Tetanus prophylaxis should be administered if needed.
- Prophylactic antibiotics to cover marine microorganisms should be considered, as secondary bacterial infections are common.
- Pain control with narcotic analgesia is often required.
- Immersion of the limb in hot water (110°F, 43°C) may aid in pain relief.
- Care should be taken to not produce thermal injury.
- Consider an observation period of at least 4 hours to ensure that symptoms do not progress to systemic effects.

Scorpaenoidea

- Group is composed of a number of venomous fish, and is the most common marine source of human envenomation, both in the wild and in home aquaria.
- Found in the warm waters of the Gulf of Mexico and Florida Keys, as well as the Pacific, including around Hawaii, and the Indian Ocean

- Includes
 - Lionfish (*Pterois*)
 - Zebrafish (*Danio*)
 - Scorpionfish (*Scorpaena*)
 - Stonefish (*Synanceja*)
- Venom apparatus is a collection of spines along the body of the fish, each composed of paired venom glands covered by an integumentary sheath.
- Dorsal spines are typically the most numerous and can inject the most venom.
- Venom of the fish in this phylum is a complex mixture, and most contain significant amounts of inflammatory mediators such as thromboxane and prostaglandins.
 - The chemical makeup and potency of venom vary by species within this group, and clinical effects range from very severe (stonefish) to mild (lionfish).
 - Stonefish is by far the deadliest of this group; however, outside of zoos, educational institutions, and private aquaria, it is not likely to be encountered in the United States. It lives in the temperate and warm waters of the Australian and Indo-Pacific and east African coast.
 - Lionfish, zebrafish, and scorpionfish although not found wild in U.S. coastal waters, are a favorite of exotic fish collectors, and stings can result from pets kept in home aquaria.

Clinical Effects

- Majority of reported stings occur on hands and fingers, followed by local, excruciating pain.
- Local swelling common, with few reported vesicular lesions at the bite site
- Systemic symptoms are much less commonly reported but include nausea, sweats, chest and abdominal pain, and rarely hypotension.
- Local effects, especially numbness, may persist long after the sting, and often wounds are very slow to heal, usually resulting in granulomatous and fibrous scarring.

Treatment

- Treatment is primarily by symptomatic and supportive care.
- Exception is the stonefish, for which there is an antivenom.
 - Can be located by contacting a regional poison center (1.800.222.1222)
- Good wound care is also essential.
 - Spines may break off during envenomation, and the wound should be closely inspected for any retained foreign body.
 - Immersion of the limb in nonscalding hot water (110°F, 43°C) may aid in pain relief.
 - Unroofing of any blisters that form at the envenomation site is indicated as the vesicle may contain venom and contribute to persistent effects.
 - Tetanus immunization or booster should be administered as needed.
 - Antibiotics should be given if secondary infection develops.

Sea Snakes

- Approximately 50 species of sea snakes in several subfamilies
- Found primarily in the warm tropical waters of the Indo-West Pacific

- None are found in the Atlantic Ocean or Caribbean Sea.
- Envenomations are likely the result of such snakes being kept in zoos or academic institutions or kept by private collectors.
- Venom is similar to Elapid venom, with neurotoxicity—and potentially respiratory arrest—as the primary clinical effect. See the earlier section, **Snakes Not Native to the United States**, for management considerations.

Invertebrates

- Five phyla—Cnidaria, Porifera (sponges), Echinodermata (sea urchins, starfish), Mollusca (octopi and cone snails), and Annelida (bristle worms)—constitute the venomous invertebrates.
 - More than 10,000 species in the phylum Cnidaria (formerly Coelenterata), and several hundred are dangerous to humans.
 - Includes jellyfish (class Scyphozoa), the Portuguese man-of-war and other sea hydroids (class Hydrozoa), and the sea anemones and fire corals (class Anthozoa)
 - All possess envenoming apparatus in the form of nematocysts.
 - In jellyfish and hydroids, nematocysts are primarily on the tentacles, and each tentacle can contain thousands.
 - Each nematocyst is a spiral-coiled dart-like structure within venom sacs. Venom is injected when the barb penetrates the flesh of its prey.
 - Nematocysts that have become detached from the tentacle, tentacles of dead jellyfish, or detached tentacles can all still cause envenomation upon contact.
 - The Portuguese man-of-war (*Physalia physalis*) is found in the Atlantic waters off the southern coast of the United States, especially from July through September.
 - Actually a complex colony of multiple hydroids
 - Body is pale blue and bell or bottle shaped and the tentacles may grow to more than 100 feet in length.
 - Venom is especially complex and also contains neurotoxins.
 - The severity of the sting depends on the organism, the number of successful discharges, and the composition of the venom.
 - Like the majority of venoms, Cnidaria venoms are complex mixtures of many substances.
 - Commonly found chemicals include histamine, serotonin, alkaline and acid phosphatases, proteases, hyaluronidase, nucleosidases, hemolysins, and inflammatory mediators, among others.
- sure to another organism in the same genus, although the responsible organism has not yet been identified
 - With envenomation by the Portuguese man-of-war
 - Immediate intense local pain at the sting site, with development of large, linear, erythematous welts where tentacles have contacted the skin
 - Often leave significant scarring
 - Systemic effects include nausea and vomiting, headache, and myalgias and may progress to muscle weakness, respiratory distress, and cardiovascular collapse in severe envenomations.
 - Intense pain and occasional paralysis caused by many stings from this jellyfish can result in drowning.
 - Multiple stings can be fatal.
 - Fire coral (*Millepora*) is not a true coral, rather a relative of fresh water hydra, but has nematocysts to envenomate its prey.
 - Stings cause local burning pain, urticaria, and intense pruritus.
 - Wheals may take weeks to heal completely and may leave hyperpigmented scars.
 - Scyphozoa contain the “true” jellyfish, including the deadly box jellyfish (*Chironex fleckeri* or sea wasp), which is not found in U.S. waters, and is present here in zoo, institutional, and possibly private collections only.
 - Usually found in tropical climates of the Indian and Pacific Oceans, including the coastal waters of Australia
 - Box jellyfish is so named because of its four translucent panels that roughly form a box.
 - Sting of the box jellyfish is painful and can cause death within minutes.
 - Mortality rate in native settings is 15% to 20%.
 - An antivenom is available and should be stocked by the institutions that house these creatures; antivenom can be located by contacting the regional poison center (1.800.222.1222).
 - Scyphozoa also include sea nettles (*Dactylometra quinquecirrha*), which pose a greater chance of exposure to swimmers of this country.
 - Sting in most cases is a minor annoyance.
 - Systemic symptoms similar to those seen with *Physalia* envenomations have been reported.

Treatment

- Most organisms in this grouping, with the exception of the Portuguese man-of-war, cause only mild local effects in humans.
 - Local effects consist of burning pain at the site of the sting, which may be severe, with swelling, erythema, and possible vesicle formation and ulceration of the area.
 - Regional lymphadenopathy may be seen.
 - Secondary infection and scarring are common.
- Anaphylactoid reactions can occur as well.
- Systemic effects, if any, are mild, but immune reactions such as erythema nodosum and reactive arthritis have been reported.
- Irukandji syndrome is a constellation of both local and systemic symptoms that occur in a delayed fashion after envenomation by an Australian jellyfish (*Carukia barnsi*).
 - Reports of a similar syndrome occurring in swimmers and divers off the coast of southern Florida, likely after expo-
- Swimmers and divers in waters endemic for venomous animals and health care providers caring for victims of envenomations should wear gloves and clothing for personal protection.
- If stung, any nematocysts still on the skin should be inactivated with 5% acetic acid (vinegar) and then removed by “shaving” the area with a dull-edged knife or the edge of a credit card.
 - Shaving cream may aid in the shaving process.
 - Adhesive tape may also be effective at removing unseen nematocysts.
 - Papain meat tenderizer has been reported to improve symptoms and may be used with caution.
 - Alcohol or fresh water may cause the remaining nematocysts to fire and should not be used.
 - A few species’ nematocysts will fire in the setting of acetic acid, including the American sea nettle, the little mauve stinger jellyfish, and the hairy or lion’s mane jellyfish.

- For these few, a slurry of baking soda should be applied for at least 10 minutes over the affected area.
- If tentacles remain attached to the skin, a vinegar or baking soda slurry should be applied, then shaving cream and scraping as for nematocysts to remove the tentacles.
- Many components of the venoms of these organisms are heat-labile, and immersion of the affected area in non-scalding hot water (110°F, 43°C) may aid in pain relief.
- Tetanus prophylaxis should be given as needed.
- Third-generation cephalosporin used for secondary infection
- Pain should be treated with both nonsteroidal anti-inflammatory drugs and opioids as needed.
- Persistent pruritus and swelling should be treated with antihistamines.
- Systemic steroids have not been shown to be of any benefit.

Sea Lice (Seabather's Eruption)

- The prolific time period for the appearance of sea lice is March through June on the southeast coast of Florida.
- Contact dermatitis can develop with exposure to the larvae of sea lice (*Linuche unguiculata*).
- The larvae attach to the fibers in bathing suits and cause a rash in the distribution of the swimwear, thus "seabather's eruption."
- The rash is pruritic, erythematous, and maculopapular and typically resolves spontaneously in hours to days without sequelae.
- Topical treatment with antihistamines and calamine lotion may give relief.

Sponges

- Some sponges contain spicules composed of calcium carbonate and silica, which can cause local irritation and itching of skin upon contact.
- Also known as "skin diver's" or "sponge fisherman's" disease
- The fire, red, and bun sponges also have toxins in their coatings that can cause local irritation, which may be painful and pruritic and produce erythema.
- Pain and paresthesias after contact may persist for weeks.

Treatment

- Remove spicules with adhesive tape or the edge of a dull knife or credit card.
- Washing the area with 5% acetic acid may aid in symptom control.
- Antihistamines and nonsteroidal antiinflammatory drugs may be used for symptom control.

Mollusca

Conus Snails

- Cone shell snails have an ejectable tooth at the end of a long flexible proboscis and envenomate their prey by sinking this tooth deep into the flesh.
- Venom contains primarily neurotoxins that act by ion channel effects.

- **Clinical effects:** Clinical effects include local burning pain, numbness, and paresthesias.
- Systemic effects of perioral paresthesias, cranial nerve palsies, coma, respiratory muscle paralysis, and cardiovascular collapse are reported.
 - Majority of human envenomations are mild and limited to local effects.
 - About 15 deaths have been reported.
- **Treatment:** Treatment is primarily symptomatic and supportive.

Toxic Octopi

- Other marine animals may cause serious, and at times fatal, envenomations.
- Bite of the blue-ringed octopus introduces tetrodotoxin, a potent neurotoxin also found in the puffer fish, and several other neurotoxins, including maculotoxin.
- This organism is of importance, as it may be found in zoo aquaria and the home aquaria of private collectors in the United States.
- The giant monster octopus should not be of concern in the United States.

Clinical Effects

- Clinical effects include local pain, numbness, and paresthesias, which may also involve distant sites such as the lips and tongue.
- Cranial nerve palsies can be seen.
- In severe envenomations, muscle weakness progressing to respiratory paralysis and cardiovascular collapse occurs.

Treatment

- Treatment is primarily symptomatic and supportive care.
- Respiratory and cardiovascular support may be required.
- No antivenom is available.

Echinodermata

- Crown of thorns (*Acanthaster planci*) is found primarily in the Indo-Pacific Oceans.
- Of little concern in the United States except when encountered in zoo, academic institution, and private collector aquaria
- Sharp, rigid spines over the dorsum of the organism can cause deep puncture wounds, even through gloves.
- Venom delivered is a complex mixture of inflammatory mediators, histamine, and others including toxic saponins, with hemolytic and anticoagulant effects.

Clinical Effects

- Local effects predominate, such as burning pain and local hemorrhagic injury.
- Secondary infection and retained foreign body from broken spines are not uncommon.
- Systemic symptoms are rarely reported but may include nausea and vomiting.
- Immersion of the limb in non-scalding hot water (110°F, 43°C) may aid in pain relief, as the venom components are heat-labile.

Sea Urchins

- Many sea urchins have long, sharp spines composed of calcium carbonate that cause local injury, but most are not venomous.
- Deep tissue injury and extension of spines into organs and joint spaces may cause tissue destruction and morbidity from secondary infection.
 - If it is a venom-containing species, the gland is located at the end of the spines and in their pedicellaria (the mouthlike apparatus at the end of a stalk used to gather food).
 - Venom is composed of a mixture of steroid glycosides, serotonin, proteases, and others.

Clinical Effects

- Local pain, erythema, and edema are typically self-limited.
- Partial paralysis of the envenomated limb has been reported with exposure to some species.
- Rare systemic symptoms are noted in the literature.

Treatment

- Affected area should be immersed in nonscalding hot water (110°F, 43°C).
- Oral analgesics
- Local wound care and removal of any embedded spines as needed
- Care is otherwise symptomatic and supportive.

Annelid Worms

- The common bristle worm, found in Floridian and Caribbean waters, causes intense local inflammation with edema, erythema, and urticaria.
- No systemic reactions have been reported, and the toxin is unknown.
- Removal of any bristles adherent to the skin and otherwise simple symptomatic and supportive care are the mainstays of treatment.

SECTION VIII ■ THE SURGICAL PATIENT: PREOPERATIVE, IMMEDIATE POSTOPERATIVE EVALUATION AND TRAUMA

CHAPTER 33 ■ PERIOPERATIVE PULMONARY FUNCTION TESTING AND CONSULTATION

- The **quantification** of pulmonary function has specific applications to clinical medicine in the intensive care unit setting, such as the following:
 - Confirming a clinical **diagnosis** of obstructive versus restrictive ventilatory defects in a patient with respiratory insufficiency or failure.
 - Following the course of the patient's **disease and the response** to treatment.
 - Enhancing **decision making** for patients about to undergo thoracoabdominal surgery.
 - Developing an **anesthetic and postoperative plan** for a patient with pulmonary disease

ROUTINE PULMONARY FUNCTION TESTING

- Although no test is “routine,” there are three types of measurement and assessment of lung function that define the pulmonary status of a patient: (a) **spirometry**, (b) measurement of **lung volumes**, and (c) measurement of lung **diffusing capacity**.

Spirometry

- Spirometry is the most basic technique to assess lung function, and the most valuable.
- The patient is asked to **inhale to total lung capacity (TLC)** and then to **forcefully exhale** into a device that measures volume versus time. The ability to perform a forceful exhalation is key to obtaining an adequate study.
- To ensure that patient effort and cooperation are maximal, the procedure is repeated **three times**, and the spirometric curves are superimposed and compared.
- A patient with pulmonary impairment may have difficulty with this procedure, and an understanding technician is necessary.
- The patient is asked to use a **metered dose inhaler (beta₂ agonist)** and then repeat the forced vital capacity maneuver three more times to assess response to bronchodilators (Fig. 33.1).
- The results are compared to data provided by examining a normal population of men and women and seek to answer two additional questions: whether the patient has an **obstructive** or a **restrictive** physiologic defect.
- **Restrictive defects** are associated with a decrease in the **forced vital capacity (FVC)** of at least 20% of the predicted value.
- **Obstructive defects** are revealed when the ratio of the forced expiratory volume in 1 second (FEV_1) divided by the FVC (the FEV_1/FVC ratio) is $<85\%$. Other indications of obstructive lung disease include (a) the peak expiratory flow rate, a use-

ful assessment in asthmatics, and (b) **maximal midexpiratory flow rate** measured at the midpoint of the FVC. The slope of the line between 25% and 75% of the FVC ($FEF_{25\%-75\%}$) is a better indication of obstructive lung disease due to chronic bronchitis (Fig. 33.2).

- Another method of representing a **maximal forced expiratory maneuver** depicts the FVC versus flow rather than versus time (Fig. 33.3). The forced exhaled volume between TLC and residual volume (RV) is the **maximal expiratory flow curve**. If the patient is asked to fully **inhale** back to TLC once the expiratory maneuver is completed, the flow-volume relationship is referred to as a **flow-volume loop**. This study is especially useful for diagnosing intrathoracic and extrathoracic upper airway obstruction.
- **Maximum voluntary ventilation (MVV)** is a test that involves repeated breaths and vigorous breathing for 10 to 12 seconds. The MVV is reported in liters per minute. Although it is only a rough index, the MMV assesses both **airway status** and respiratory muscle **endurance**.

Lung Volumes

- The lung volume study is completed by once again using the spirometer and coaching the patient to a full respiratory maneuver. Then, after quiet tidal breathing, the patient is asked to exhale to **RV**, then inspire fully to **TLC** and, after a second interval of quiet tidal breathing, fully inspire to TLC and expire to RV. Knowing the functional residual capacity (FRC) from the dilution studies (see below), all of the lung volume compartments can be calculated (see Fig. 33.2).

FIGURE 33.1. Three forced exhalations are performed before and after bronchodilator inhalation to assess immediate response. The maximum measured exhaled volume is FVC. The exhaled volume at 1 second is $FEV_{1.0}$. The $FEV_{1.0}/FVC$ ratio is reduced with an obstructive ventilatory deficit.

FIGURE 33.2. Compartmentalization of lung volume is achieved by noting the volume excursion during tidal breathing and repeated inhalation and exhalation. The functional residual capacity is measured using gas wash-in or wash-out techniques. TLC, total lung capacity; VC, vital capacity; FRC, functional residual capacity; RV, residual volume.

- There are two methods to measure residual volume: the **nitrogen washout** technique and the **inert gas helium** technique.
- RV, FRC, and TLC can be viewed as a system of concentric circles (Fig. 33.4).
- An **obstructive** ventilatory defect is characterized by **hyperinflation**, with a greater effect on RV and FRC than on TLC.
- A **restrictive** ventilatory defect can be either intrinsic or extrinsic. An **intrinsic restrictive** defect is characterized by a concentric reduction (each volume decreases by the same percentage). An **extrinsic restrictive** defect shows a disproportionate loss of volume “off the top” with the major change in TLC. The postoperative patient who has had a surgical procedure in the thorax or upper abdomen shows the latter change in physiology. Though transient, the extrinsic restrictive ventilatory change, especially when superimposed on a patient with obstructive physiology, can be significant.

Diffusing Capacity

- Diffusing capacity studies assess gas transfer at the **alveolo-capillary membrane**.

FIGURE 33.3. The relationship between a recording of flow and volume during a forced vital capacity (FVC) maneuver. ERV, expiratory reserve; FRC, functional residual capacity; IRV, inspiratory reserve; MMEFR, maximal midexpiratory flow rate; PEFR, peak expiratory flow rate; V_T , tidal volume.

- Oxygen is the gas transfer of interest, but making this measurement is difficult because there is always a back pressure or gas tension in the blood that must be compared to alveolar gas.
- This problem can be overcome by introducing a gas that is not normally in the bloodstream, specifically small amounts of **carbon monoxide (CO)**. As CO is not a physiologic gas, this measurement is referred to as the **diffusing capacity**, not **diffusion** capacity.
- The measurement can be made in two ways, and there is controversy over which test gives superior information. The two methods include introducing CO into a breathing circuit and measuring the change in tidal breathing to a steady state and similarly inhaling CO with a single breath.
- If the tissue of an adult lung were microdissected and spread out, it would cover the space of a football field. Thus, one of the reasons for a decrease in diffusing capacity (as opposed to a **thickened alveolar-capillary membrane**) is **loss of effective surface area** for gas transfer. This is a pathognomonic change seen in patients with emphysema.
- When (a) **spirometry**, (b) **lung volumes**, and (c) **diffusing capacity** are all evaluated, there is a characteristic pattern of physiologic changes that identifies patient status and diagnosis, which is important in the care of the perioperative patient (Table 33.1).
- There is value in identifying the patients with obstructive lung disease who have emphysema, as opposed to chronic bronchitis, in assessing and designing postoperative therapy. Table 33.1 summarizes the findings for the various physiologic states.

FIGURE 33.4. Changes in lung volumes with extrinsic and intrinsic restriction ventilatory defects (RVD) are compared to normal. An extrinsic RVD mainly alters the total lung capacity (TLC) with minimal alteration of the functional residual capacity (FRC) and the residual volume (RV). An intrinsic RVD results in concentric reduction of the TLC, FRC, and RV.

TABLE 33.1

PATTERNS OF PULMONARY PATHOLOGY MEASURED BY PULMONARY FUNCTION TESTS

		OVD _E	OVD _{CBR}	OVD _A	RVD _I	RVD _E
Spirometer	FVC	NL or ↓	NL or ↓	NL or ↓	↓	↓
	FEV _{1.0} /FVC	↓	↓	↓	NL or ↑	NL
	BD responder	0	10%	25%	0	0
	TLC	↑	NL or ↑	NL or ↑	↓	↓
	RV/TLC	↑	↑	NL or ↑	N	↓
	DLCO	↑	NL	NL or ↑	↓	NL
	PaO ₂	NL or ↓	↓	NL or ↓	↓	NL or ↓
	PaCO ₂	NL	↑	NL or ↑	NL	NL

OVD, obstructive ventilatory defect; OVD_E, emphysema; OVD_{CBR}, chronic bronchitis; OVD_A, asthma; RVD_I, intrinsic restrictive ventilatory defect; RVD_E, extrinsic restrictive ventilatory defect; FVC, forced vital capacity; FEV_{1.0}, forced expiratory volume at 1 second; BD, bronchodilator; TLC, total lung capacity; RV, residual volume; DLCO, diffusion capacity of the lung for carbon monoxide; PaO₂, arterial partial pressure of oxygen; PaCO₂, arterial partial pressure of carbon dioxide.

Arterial Blood Gas Analysis

- Arterial blood gas analysis is often ordered, but the usefulness is limited to an analysis of trends and diagnosis of underlying chronic disease.
- Prognostic value is limited, and for resectional lung surgery, postoperative arterial blood gases are often improved.

PREOPERATIVE PULMONARY FUNCTION TESTING

Resectional Lung Surgery

- The main indication for lung resection remains the removal of a lung cancer. These patients usually have a history of smoking. Presence of **obstructive lung disease** is not uncommon in these patients.
- Imaging studies have advanced such that the extent of the disease is well documented before surgery. However, until the surgeon explores the chest, the extent of the necessary resection for cure is not known.
- Preoperative evaluation should determine whether the patient can tolerate a pneumonectomy with guidance from pulmonary function testing as outlined in Table 33.2.

TABLE 33.2

PULMONARY FUNCTION INDICATING PHYSIOLOGICAL TOLERANCE FOR SURGERY UP TO AND INCLUDING PNEUMONECTOMY

Pulmonary function	Physiologic tolerance
FVC	50% predicted, or >3.0 L
FEV _{1.0}	2.0 L
FEV _{1.0} /FVC	50%
RV/TLC	<59%
DLCO	50% predicted
MVV	50% predicted

FVC, forced vital capacity; FEV_{1.0}, forced expiratory volume at 1 second; RV, residual volume; TLC, total lung capacity; DLCO, diffusion capacity of the lung for carbon monoxide; MVV, maximum voluntary ventilation.

- If the foregoing criteria are not met and surgical resection, including pneumonectomy, is being considered, the next step is to perform **split-lung function testing** and ascertain the contribution of the right versus the left lung to overall pulmonary function.
- Since the 1970s, the radionuclide **ventilation perfusion lung scans** have been used to determine split-lung function. For example, if the preoperative FEV_{1.0} = 1.6 L, and the scan reveals 60%/40% left lung versus right lung, and the right lung is being considered for resection, then:

$$1.6 \text{ L} \times .60 = .96 \text{ L, the calculated postoperative FEV}_{1.0}$$

- It was observed that the diseased lung often made little or no contribution to overall lung function, and the postoperative lung function was *better* than predicted. Therefore it was suggested that the requirement for the predicted postoperative FEV_{1.0} be lowered from 1.0 L to 800 mL, the level below which they noted respiratory failure and cor pulmonale occurring in the chronic obstructive pulmonary disease patients.

Non-cardiothoracic Surgery

- Whereas quantitative assessment of pulmonary function is useful for **thoracic surgery** patients, there is little evidence to suggest that measurement of pulmonary function should be obtained solely for the purpose of perioperative management of patients undergoing other types of surgery.
- Although certain types of surgery, such as upper-abdominal, non-resectional thoracic, and cardiac surgery, often cause severe alterations in pulmonary function (the FVC may be reduced as much as 50% the first postoperative day), little is added by the pulmonary function tests to the history and physical examination in terms of considering risk.

PREDICTING POSTOPERATIVE PULMONARY COMPLICATIONS

- Postoperative pulmonary complications are usually defined as newly developed **atelectasis**, **pneumonia**, **pulmonary thromboembolism**, and **acute respiratory failure** requiring mechanical ventilation *after* surgery.
- Predicting pulmonary complications cannot be done based solely on the measurement of pulmonary function but needs to include **patient risk factors**.

- The National Veterans Surgical Quality Improvement Program developed a multifactorial risk index for predicting postoperative pneumonia and respiratory failure after major non-cardiac surgery:
 - **Smoking status:** The duration of smoking cessation to achieve benefit appears to be at least 4 weeks, possibly as long as 8 weeks.
 - **Chronic obstructive lung disease**, as defined by history and physical examination (spirometry has not been shown to be useful in prognosis).
 - Measures of **general health status** include the presence/measures of comorbid conditions, functional status, and recent weight loss.
 - **Cognitive impairment** of any etiology
 - **Previous stroke**
 - Type and location of the **anticipated surgical procedure**
 - **Age:** a risk factor when controlled for comorbid conditions
 - **Long-term steroid therapy**
 - **Recent moderate-to-heavy alcohol intake.**
 - **Impaired renal function.**
 - **Large transfusion requirement:** generally >6 units of packed red blood cells, plus other blood products
- The use of **general anesthesia** for surgical procedures and the **duration** (more than 4 hours) have been associated with increased risk of **Postoperative pulmonary complications**. Advances in **anesthesia** technology and skills have allowed investigators to reframe the question. Does the presence of adequate **neuroaxial blockade** during a surgical procedure reduce risk? The anesthetic plan can include spinal anesthesia, epidural anesthesia, combined spinal/epidural anesthesia, and combined light levels of general anesthesia (the “epigeneral”). It does appear that the presence of neuroaxial blockade, either alone or in combination with general anesthesia, is associated with fewer deaths and complications.
- **Postoperative pain management** is an important goal that also enables a patient to complete deep breathing maneuvers.

STRATEGIES TO REDUCE POSTOPERATIVE PULMONARY COMPLICATIONS AFTER NONCARDIOTHORACIC SURGERY

- The general approach has included **cessation of smoking** and an attempt to maximize pulmonary function with the use of **bronchodilators** (both beta-2-agonists and parasympatholytic agents), treatment of underlying **infections** or purulent sputum, and coaching to learn **deep-breathing exercises**. Bronchodilators are continued throughout the anesthetic and surgical procedure.
- *Studies with good evidence:* **lung expansion** interventions including incentive spirometry, deep breathing exercises, and continuous positive airway pressure are useful in preventing PPCs.
- *Studies with fair evidence:* **selective** rather than routine use of **nasogastric tubes**, the use of **short-acting** intraoperative **neuromuscular blocking agents** (e.g., rocuronium vs. pancuronium) is associated with improved outcomes.
- *Studies with conflicting evidence:* Cessation of smoking, use of epidural anesthesia and analgesia, and laparoscopic ver-

sus open abdominal surgery demonstrate conflicting results. As noted above, the presence or absence of neuroaxial blockade—not the anesthetic choice—may be the determining factor. Laparoscopic procedures result in less pain and a lesser reduction in the FVC. Finally, although **malnutrition** is associated with increased risk, routine total enteral or parenteral nutrition may not reduce the risk.

- The value of **preoperative pulmonary function testing** has been repeatedly called into question. Preoperative pulmonary function testing is safe and noninvasive but should not be routinely performed; rather, it should be limited to a specific indication supported by changes in the anesthetic or surgical procedure.

Breathing Patterns

- Normal **tidal breathing** begins at FRC, a point where the tendency for the chest wall to spring outward is balanced by the tendency of the lung to collapse. The balance of these two forces occurs when there is complete apposition of the pleural surfaces. A tidal breath is an energy-transferring mechanism, the reason why exhalation is usually a passive phenomenon returning the lung volume to the normal FRC.
- Patients in respiratory distress alter their **tidal breathing patterns** according to the added load placed on the respiratory system. Patients with a **resistive load** will slow inspiratory or expiratory flows and **diminish the respiratory rate**, in an effort to obtain the best combination of rate and tidal volume/flow, to work against the imposed load. Patients with alterations in **compliance** reach the best combination of rate and tidal volume, which results in a **rapid respiratory rate** and smaller tidal volumes. In the latter patients, tracheal intubation, mechanical ventilation, and the addition of positive end expiratory pressure are used to support the patient.
- The reoccurrence of **rapid, shallow breathing** is used to assess the ability to wean a patient from positive pressure ventilation. The so-called *spontaneous breathing trial* involves watching the patient breathe with very low levels of positive pressure support, presumably enough to overcome the endotracheal tube resistance prior to extubation. Thus, rapid shallow breathing patterns, which can be measured by the rapid shallow breathing index, are used to assess the feasibility of weaning from ventilatory support (see Chapter 95).

SUMMARY

- Pulmonary evaluation is a critical step in managing patients with lung disease who are undergoing elective surgeries or are admitted to the ICU for respiratory insufficiency or failure. It allows confirmation of pathophysiology (restrictive vs. obstructive), follow response to treatment, assist with decision making regarding surgery and anesthesia, and plan for patient education and postoperative course.
- It is still not clear whether risk stratification can be assessed with the use of sophisticated or simple exercise tests and measurements.
- Efforts should be directed to anticipate and correct patient's physiologic response to surgery and improve outcome.

CHAPTER 34 ■ PREOPERATIVE EVALUATION OF THE HIGH-RISK SURGICAL PATIENT

- The perioperative mortality rate for **elective** surgical procedures is low, ranging from 0.001% to 1.9%.
- Age and the **American Society of Anesthesiologist (ASA) physical status classification** systems are good predictors of perioperative complications (Table 34.1).
- **Age >70 years** and **ASA physical status \geq II** are strong predictors of postoperative pulmonary complications.
- The **strength** of the ASA classification is its simplicity and its application to all age groups, medical conditions, and degrees of health. The **weakness** is its inability to distinguish among disorders of different systems and to cumulate risk based on multiple disorders.
- A **multidimensional model** of perioperative risk may be useful, including ASA physical status, surgical risk/invasiveness, physical factors affecting mask ventilation, intubation predictors, and a list of optional risk indicators. The acronym **ASPIRIN** is applied to this model.
- Initial assessment begins with **history and physical examination**. The data obtained from the history and physical examination allow for **preoperative testing based on clinical risk categorization**.
- Following the implementation of the **American College of Cardiology/American Heart Association (ACC/AHA) guidelines** for preoperative cardiac risk assessment allows cardiac testing to be done in a cost-effective manner.

CARDIOVASCULAR SYSTEM

Noncardiac Surgery

Of the approximately 44 million patients undergoing noncardiac surgery in the United States yearly, 30% either have, or

TABLE 34.1

AMERICAN SOCIETY OF ANESTHESIOLOGISTS' PHYSICAL STATUS CLASSIFICATION

Physical status	Definition
I	Healthy patient
II	Mild systemic disease; no functional limitation
III	Severe systemic disease; definite functional limitation
IV	Severe systemic disease that is constant threat to life
V	Moribund patient; unlikely to survive 24 h with or without surgery
VI	Brain-dead patient; organ donor
E	Emergency procedure

are at risk for, **coronary artery disease (CAD)** with a 2.8-fold increase in adverse postoperative cardiac events.

- ACC/AHA Task Force on Practice Guidelines has recommendations on the perioperative cardiovascular evaluation for noncardiac surgery; the update is available at the following Web site: www.acc.org/qualityandscience/clinical/statements.htm
- The ACC/AHA guideline is an eight-step algorithm that incorporates **clinical predictors** based on the patient's history and physical examination, **surgery-specific risk**, and the functional capacity or **exercise tolerance** (Fig. 34.1).
- In the event of an **emergency procedure**, patients should be taken to surgery with no preoperative testing.
- If an elective or urgent procedure is planned, the decision making proceeds down steps 2 and 3 of the algorithm (see Fig. 34.1). If the patient has had a coronary revascularization procedure within the last 5 years with no recurrent symptoms or signs, no further workup is necessary. A cardiac evaluation performed within the last 2 years with no deterioration in cardiac status also negates the need for further workup.
- Steps 5 through 8 of the algorithm (see Fig. 34.1) integrate the **clinical predictor**, **surgery-specific risk**, and the **functional capacity** to determine whether the patient warrants further cardiac workup.
- The presence of major clinical predictors demands intense further workup and may result in delay or cancellation of elective surgery. Intermediate clinical predictors increase the risk of perioperative cardiovascular complications, whereas minor clinical predictors have not been proven to independently increase cardiac risk (Table 34.2).
- The nature and duration of the surgical procedure are strong predictors of cardiovascular morbidity and mortality (Table 34.3).
- Finally, the **functional capacity** of the patient must be evaluated, as it is a strong predictor of perioperative outcome. Functional capacity is expressed in **metabolic equivalents (METs)**, where one MET is 3.5 mL/kg/min of oxygen consumption in a 70 kg, 40-year-old man at rest. Increasing levels of activity correlate with increasing METs, with strenuous sports requiring >10 METs (Table 34.4).
- Inability to perform **at least 4 METs** is associated with increased perioperative cardiac risk.
- Based on the aforementioned **triad of clinical predictors, functional capacity, and surgery-specific risk**, a decision is made regarding whether the patient can proceed to surgery or whether additional investigations to delineate the ischemic burden are required (Table 34.5).
- Delineation of the **ischemic burden** can be broadly achieved by two methods. The first method involves coronary vasodilatation and induction of a "steal" phenomenon by pharmacologic agents, followed by a nuclear imaging technique

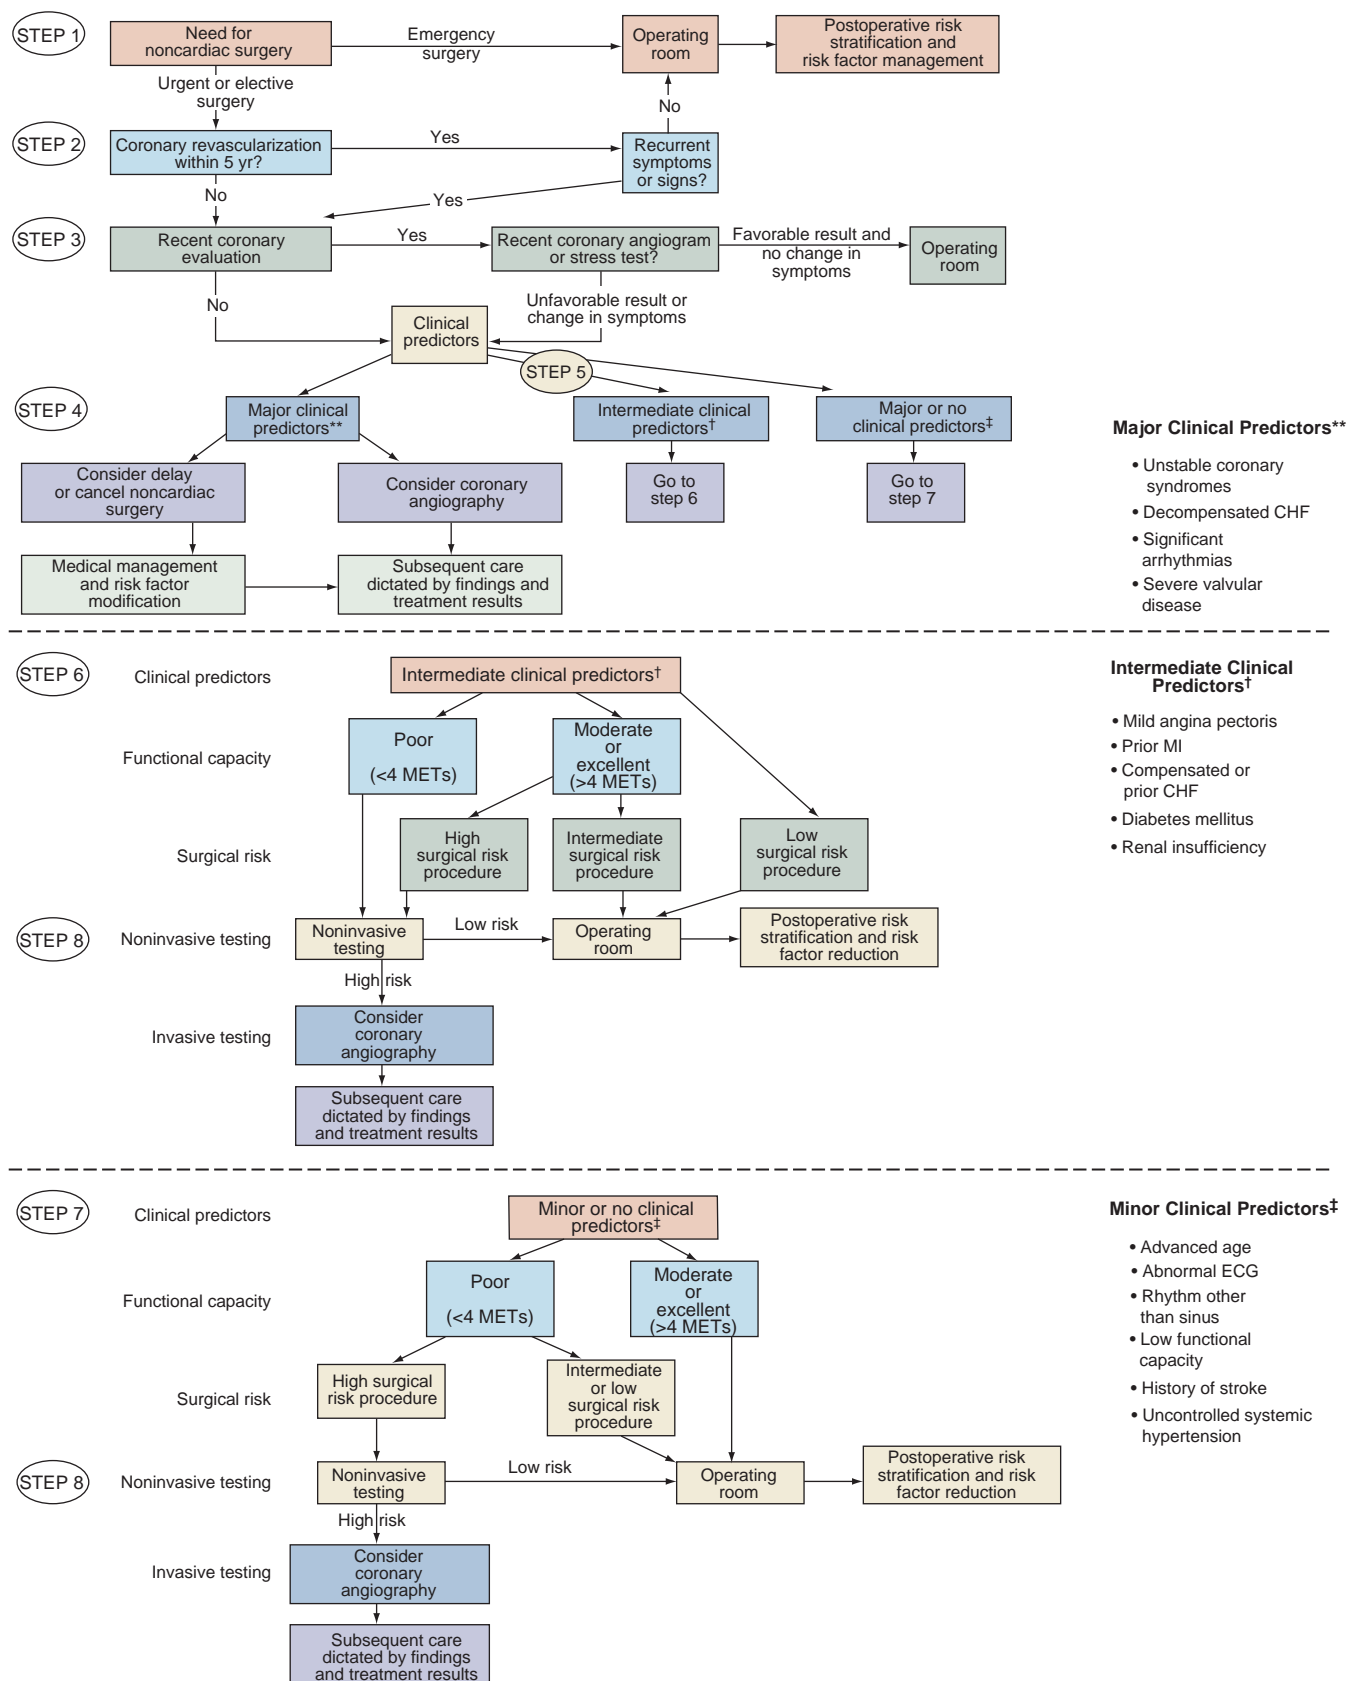

FIGURE 34.1. Stepwise approach to preoperative cardiac assessment. (Reproduced with permission from Eagle KA, Berger PB, Calkins H, et al. ACC/AHA Guideline Update for Perioperative Cardiovascular Evaluation for Noncardiac Surgery: a report of the American Heart Association/American College of Cardiology Task Force on Practice Guidelines [Committee to Update the 1996 Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery]. *Circulation*. 2002;105:1257–1267.)

TABLE 34.2

CLINICAL PREDICTORS OF INCREASED PERIOPERATIVE CARDIOVASCULAR RISK (MYOCARDIAL INFARCTION, CONGESTIVE HEART FAILURE, DEATH)

Major

Unstable coronary syndromes
 Acute or recent MI^a with evidence of important ischemic risk by clinical symptoms or noninvasive study
 Unstable or severe^b angina (Canadian class III or IV)^c
 Decompensated heart failure
 Significant arrhythmias
 High-grade atrioventricular block
 Symptomatic ventricular arrhythmias in the presence of underlying heart disease
 Supraventricular arrhythmias with uncontrolled ventricular rate
 Severe valvular disease

Intermediate

Mild angina pectoris (Canadian class I or II)
 Previous MI by history or pathologic Q waves
 Compensated or prior heart failure
 Diabetes mellitus (particularly insulin-dependent)
 Renal insufficiency

Minor

Advanced age
 Abnormal ECG (left ventricular hypertrophy, left bundle-branch block, ST-T abnormalities)
 Rhythm other than sinus (e.g., atrial fibrillation)
 Low functional capacity (e.g., inability to climb one flight of stairs with a bag of groceries)
 History of stroke
 Uncontrolled systemic hypertension

MI, myocardial infarction; ECG, electrocardiogram.

^aThe American College of Cardiology National Database Library defines recent myocardial infarction as >7 days but ≤1 month (30 days).

^bMay include “stable” angina in patients who are unusually sedentary.

^cCampeau L. Grading of angina pectoris. *Circulation*. 1976;54:522–523.

From Eagle KA, Berger PB, Calkins H, et al. ACC/AHA Guideline Update for Perioperative Cardiovascular Evaluation for Noncardiac Surgery: a report of the American Heart Association/American College of Cardiology Task Force on Practice Guidelines (Committee to Update the 1996 Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery). *Circulation*. 2002;105:1257–1267, with permission.

(dipyridamole-thallium scan). The second method involves increasing myocardial oxygen demand (by exercise stress or pharmacologically with dobutamine) and evaluating electrocardiographic or echocardiographic data for evidence of ischemia.

- The negative-predictive value of both tests is high. However, the positive-predictive value of dobutamine stress echocardiography is higher.
- Once the degree of myocardial ischemia is quantified, patients can either undergo **perioperative medical optimization or revascularization** by either percutaneous coronary intervention or surgery. It is important to note that to obtain benefit from a preoperative coronary intervention, the risk of noncardiac surgery must supersede the **combined risk** of both coronary catheterization and subsequent revascularization procedure.

TABLE 34.3

CARDIAC RISK^a STRATIFICATION FOR NONCARDIAC SURGICAL PROCEDURES

High (reported cardiac risk often >5%)

- Emergent major operations, particularly in the elderly
- Aortic and other major vascular surgery
- Peripheral vascular surgery
- Anticipated prolonged surgical procedure associated with large fluid shifts and/or blood loss

Intermediate (reported cardiac risk generally <5%)

- Carotid endarterectomy
- Head and neck surgery
- Intraperitoneal and intrathoracic surgery
- Orthopedic surgery
- Prostate surgery

Low^b (reported cardiac risk generally <1%)

- Endoscopic procedures
- Superficial procedures
- Cataract surgery
- Breast surgery

^aCombined incidence of cardiac death and nonfatal myocardial infarction.

^bDo not generally require further preoperative cardiac testing.

From Eagle KA, Berger PB, Calkins H, et al. ACC/AHA Guideline Update for Perioperative Cardiovascular Evaluation for Noncardiac Surgery: a report of the American Heart Association/American College of Cardiology Task Force on Practice Guidelines (Committee to Update the 1996 Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery). *Circulation*. 2002;105:1257–1267, with permission.

- Currently, angioplasty is followed by placement of either a bare-metal or a drug-eluting stent; stents reduce both the acute risk of major complications and long-term restenosis rate. After placement of a stent, patients require **antiplatelet therapy** for 1 to 12 months, depending on the type of stent. The presence of antiplatelet therapy adds a new dimension of complexity to the patient presenting for noncardiac surgery after **percutaneous coronary intervention**.
- Elective surgery should be **delayed** for more than **6 weeks** to allow for endothelialization of the stent and discontinuation of antiplatelet therapy. In the event of **urgent surgery** and severe CAD, **angioplasty alone** with no stent placement can be performed. This obviates the need for prolonged antiplatelet therapy and the risk of perioperative bleeding.

Perioperative β -Blockade Therapy

- β -Blockers help to correct the imbalance between **myocardial oxygen demand and supply**. They have additional plaque-stabilizing, antiarrhythmic, anti-inflammatory, and altered gene expression effects.
- There may be a subgroup where there is potential harm with β -blocker use. Insufficient data are available regarding the use of β -blockade therapy in low-cardiac risk patients undergoing intermediate or high-risk surgery.
- Patients on β -blockers at home should be continued on β -blockers. Patients with a positive stress test undergoing vascular surgery should be started on β -blockers (ideally a week before surgery and titrated to heart rate-decreasing effect).

TABLE 34.4**ESTIMATED ENERGY REQUIREMENTS FOR VARIOUS ACTIVITIES**

1 MET	Can you take care of yourself? Eat, dress, or use the toilet? Walk indoors around the house? Walk a block or two on level ground at 2 to 3 mph (3.2–4.8 km/h)?
4 METs	Do light work around the house like dusting and washing dishes? Climb a flight of stairs or walk up a hill? Walk on level ground at 4 mph (6.4 km/h)? Run a short distance? Do heavy work around the house like scrubbing floors or lifting or moving heavy furniture? Participate in moderate recreational activities like golf, bowling, dancing, doubles tennis, or throwing a baseball or football?
>10 METs	Participate in strenuous sports like swimming, singles tennis, football, basketball, or skiing?

MET, metabolic equivalent.

- Although there is debate on the use of perioperative β -blockade use, ACC/AHA 2006 Guideline Update on Perioperative Cardiovascular Evaluation for Noncardiac Surgery: Focused Update on Perioperative Beta-Blocker Therapy has some recommendations until future results from multicenter trials are available (1).

Cardiac Surgery

- There are no standardized definitions for risk thresholds; many of the assessments of statistical risk are based on **odds ratios**. In addition, multiple risk factors frequently coexist, making risk profiling for the individual patient difficult. Steady improvement in cardiac surgical outcomes has been attributed to improving surgical technique, perioperative care, and patient selection.
- Cardiac risk evaluation can be performed by risk assessment tools based on large databases, such as the EuroSCORE and the Society for Thoracic Surgeons database.
- The Society for Thoracic Surgeons database working group has published their analysis of independent risk factors in valvular surgery (Table 34.6).
- **Scoring systems** have a role in predicting both perioperative and long-term mortality and intensive care unit resource use. They provide a framework for identifying and modifying preoperative risk.
- **EuroSCORE** is a compilation of risk factors as weighted by the Parsonnet, EuroSCORE, and Society of Cardiothoracic Surgeons databases. The percentages quoted in Table 34.7

are for *individual* risk factors in each section. Risk factors may be additive and/or synergistic.

Preoperative Risk Modification for Cardiac Surgery

- Preoperative risk modification involves **optimization of comorbidity** and limiting cardiopulmonary bypass–related myocardial injury.

Comorbidity

- **Renal dysfunction and failure** are significant risk factors in both valvular and coronary artery bypass graft (CABG) surgery. Increase in plasma creatinine of one-and-a-half times from baseline with short periods of oliguria may carry a 90-day mortality of 8%. Patients with **cardiogenic shock or an emergent indication** for surgery often have acute renal failure; these patients have a high risk of death perioperatively with a mortality above 40%.
- Survival rates at 8 years in dialysis-dependent patients were 45.9% for CABG, 32.7% for **percutaneous coronary intervention**, and 29.7% for no surgical intervention.
- **Diabetics** undergoing cardiac surgery are at increased risk of prolonged ventilation, postoperative sepsis, renal failure, and cognitive dysfunction. The perioperative management of diabetes and hyperglycemia in cardiac surgery is controversial. Insulin has been used in two strategies: tight glycemic control and as part of glucose-insulin-potassium regimens (GIK). Meta-analysis of GIK therapy indicates that trials using tight glycemic control gave the best results. This observation needs validation by other randomized trials.
- **Congestive cardiac failure** represents a complex neurohumoral syndrome that develops in response to altered cardiac

TABLE 34.6

PERIOPERATIVE RISK FACTORS FOR VALVULAR CARDIAC SURGERY

Surgical factors	Odds ratio	Patient factors	Odds ratio
High risk			
Aortic root replacement	2.78	4 Comorbidities	2
Isolated tricuspid replacement	2.26		
Emergent operation	2.11		
Multiple valve replacement	2.06		
Moderate risk			
Concurrent operation	1.58	Age ≥ 70 years 3 Comorbidities Endocarditis Coronary artery disease	1.88 1.68 1.59 1.58
Reoperation	1.61		
Valve replacement vs. repair	1.52		
Low risk			
Isolated mitral replacement	1.47	2 Comorbidities CHF Female gender Ejection fraction <0.35 Average per comorbidity	1.41 1.39 1.37 1.34 1.19
Year <1999	1.34		
Isolated pulmonic replacement	1.29		
Isolated aortic replacement	1		

Procedural risk is compared to the lowest-risk procedure—isolated aortic valve replacement.

The odds ratio for perioperative mortality during valvular surgery is compared to the lowest-risk valvular procedure (aortic valve replacement; odds ratio 1, mortality 5.6%).

CHF, congestive heart failure.

TABLE 34.7
PERIOPERATIVE RISK FACTORS FOR CABG ACCORDING TO SCORING SYSTEM

Parsonnet score	EuroSCORE	UKSCTS complex Bayes
High risk (17%–40% mortality) Cardiogenic shock Acute renal failure Acute structural defect (e.g., VSD) >80 y old	Postinfarct septal rupture Thoracic aortic surgery LV EF <30% ARF Preop IABP or inotropes Preop ventilation Active endocarditis Reoperation Age ≥75 y	Emergency surgery LV EF <30% Dialysis Creatinine >200 μmol/L (2.3 mg/dL)
Significantly elevated risk (9%–17% mortality) 75–79 y old Third reoperation Dialysis dependency Rare circumstances Recently failed intervention <24 h PA pressure ≥60 mm Hg AV pressure gradient ≥120 mm Hg	CABG plus major symptoms Emergency Systolic PAP >60 mm Hg Recent MI <90 days IVI nitrates on arrival in theater Serum creatinine >200 μmol/L (2.3 mg/dL) Neurology affecting ADL Peripheral vascular disease Age 70–74 y	Age >75 y One or more previous operations BSA <1.70 m ²
Elevated risk (3%–9% mortality) MV surgery PAP <60 mm Hg AV surgery gradient <120 mm Hg Recently failed intervention >24 h Aneurysmectomy Second reoperation Age 70–74 y LV EF <30% Hypertension BMI >35 IABP preoperative Female	LV EF 30%–50% Chronic pulmonary disease Female Age 65–69 y	Age 71–75 y Left main stem disease Diabetes Urgent surgery LV EF 30%–49% Hypertension
CABG, coronary artery bypass grafting; UKSCTS, United Kingdom Society of Cardiothoracic Surgeons; VSD, ventricular septal defect; LV EF, left ventricular ejection fraction; ARF, acute renal failure; IABP, intra-aortic balloon counter pulsation; PAP, pulmonary artery pressure; BSA, body surface area; MI, myocardial infarction; IVI, intravenous infusion; PA, pulmonary artery; AV, atrioventricular; ADL, activities of daily living; MV, mitral valve; BMI, body mass index.		

function. The stages of this condition have been classified by the ACC/AHA (Table 34.8). In the perioperative period, decompensated stage C or D heart failure represents an independent risk factor for cardiac complications.

Myocardial Preservation Interventions

- Several nonpharmacologic and pharmacologic interventions can be initiated preoperatively to improve intraoperative and postoperative outcomes.
- **Intra-aortic balloon counterpulsation (IABP)** is a nonpharmacologic intervention that can be commenced preoperatively in the appropriate group of patients (Table 34.9).
 - Good evidence exists for the benefits of IABP in **CABG patients** with ischemia or with an ejection fraction <25% undergoing nonelective operation or reoperation or who have New York Heart Association class III to IV symptoms.
 - The efficacy of IABP for **valvular surgery** is poor and is associated with a twofold increase in mortality regardless of timing of use. This probably reflects the fact that the ventricular dysfunction is either nonreversible or only partially reversible.
- IABP improves **cardiac output by approximately 20%** if set to maximal efficiency.
- **Pharmacologic therapies** include preoperative statins, β-type natriuretic peptide, calcium channel sensitizers, and antioxidant therapy.
 - **HMG CoA reductase inhibitors**, known as **statins**, have several beneficial effects. Their mechanism of action is via a lipid-dependent and a lipid-independent pathway. Statins inhibit atherogenesis, thrombosis, and inflammation and maintain endothelial integrity. Preoperative statin therapy was associated with a 1.1% absolute reduction in mortality after CABG (OR 0.25; CI 0.07–0.87), and cessation of statin therapy after surgery was associated with an increased in-hospital and late cardiac mortality.
 - **Brain natriuretic peptide.** Nesiritide is a recombinant form of brain natriuretic peptide that decreases pulmonary artery pressures and myocardial oxygen consumption and

TABLE 34.8

ACC/AHA CLASSIFICATION OF HEART FAILURE

Stage A	Patients at high risk of developing heart failure (HF) because of the presence of conditions that are strongly associated with the development of HF. Such patients have no identified structural or functional abnormalities of the pericardium, myocardium, or cardiac valves and have never shown signs or symptoms of HF.
Stage B	Patients who have developed structural heart disease that is strongly associated with the development of HF but who have never shown signs or symptoms of HF.
Stage C	Patients who have current or prior symptoms of HF associated with underlying structural heart disease.
Stage D	Patients with advanced structural heart disease and marked symptoms of HF at rest despite maximal medical therapy and who require specialized interventions.

ACC, American College of Cardiology; AHA, American Heart Association.

increases coronary blood flow and urine output. Nesiritide is used in two clinical settings: inotrope-resistant cardiac failure and postcardiac surgery patients with high pulmonary pressures and low cardiac output syndrome.

- **Calcium sensitizers.** Levosimendan is a calcium-sensitizing inodilator that improves myocardial contractility without increasing oxygen demand. It also decreases pulmonary vascular resistance in patients with heart failure and may be more effective than dobutamine in the management of severe congestive heart failure insofar as hemodynamic and mortality benefit. This drug offers enormous promise in the preoperative period in patients with severe congestive cardiac failure and poor cardiac output.
- **Antioxidants.** Reactive oxygen species, both within myocardial cells and those derived from the systemic circulation, are thought to overwhelm local endogenous antioxidant systems during bypass. They initiate cellular damage, necrosis, and apoptosis during cardiopulmonary bypass and reperfusion. Allopurinol, which inhibits xanthine oxidase,

a significant source of reactive oxygen species outside the myocardium, has been studied in 10 human CABG trials, with 8 trials showing benefit. Despite these encouraging data, allopurinol has not received widespread support. Other antioxidants used are superoxide dismutase, desferrioxamine, mannitol, vitamins C and E, and N-acetylcysteine.

There has been an improvement in the ability to identify and categorize the high-risk cardiac patient presenting for cardiac surgery. As more data are accrued, risk profiling is becoming more accurate. This will allow for cost-effective implementation of promising preoperative interventions in the appropriate patient.

PULMONARY SYSTEM

The definition of postoperative pulmonary complications include respiratory failure, atelectasis, pneumonia, pulmonary edema, and pulmonary thromboembolic disease.

- Predicting the likelihood of postoperative pulmonary complications requires preoperative pulmonary-risk stratification.

Preoperative Evaluation

- After the history and clinical examination, patients can be classified into two groups: those with **known pulmonary disease** and those with **suspected pulmonary disease**. Both groups require an assessment of their functional classification and the degree of pulmonary reversibility.
- Laboratory investigations with a good predictive value for postoperative pulmonary complications include **blood urea nitrogen >21 mg/dL**, **creatinine >1.5 mg/dL**, and **albumin <3.0 g/dL**.
- The utility and cost-effectiveness of routine preoperative chest x-ray has been extensively debated. Only patients with **known cardiopulmonary disease**, and patients **older than 50 years** undergoing procedures with **high pulmonary risk** should have a preoperative chest radiograph.
- **Spirometry** has been evaluated as a predictive tool for pulmonary disorders in noncardiothoracic surgery. There are no studies to guide spirometry evaluation in the perioperative period for **restrictive** pulmonary disorders. In **obstructive** pulmonary disorders, there are conflicting data on the utility of spirometry; however, it may identify patients at higher risk for postoperative pulmonary complications.
- In **lung resection surgery**, spirometry forms the cornerstone of the evaluation process in both Europe and North America. Other parameters evaluated are the cardiopulmonary reserve and the lung parenchymal function (Fig. 34.2). A simplified algorithm integrating these parameters assists in the preoperative workup for lung resection surgery (Fig. 34.3).
- When the information gathered from history, physical examination, and special investigations is examined, a **risk profile** can be constructed from the guidelines published by the American College of Physicians (Table 34.10).
- The relationships between individual risk factors in each risk category have not been fully elucidated; they may be either additive or synergistic. Once a risk profile is formulated, risk modification strategies should be implemented.

TABLE 34.9

INDICATIONS FOR INTRA-AORTIC BALLOON COUNTERPULSATION

- Ongoing unstable angina refractory to medical therapy
- Acute myocardial ischemia/infarction associated with percutaneous transluminal angioplasty (PTCA)
- Perioperative low cardiac output syndrome
- Cardiogenic shock after myocardial infarction
- Congestive heart failure
- Bridge to transplant
- Ischemic ventricular septal defect
- Acute mitral valve insufficiency
- Poorly controlled perioperative ventricular arrhythmias

FIGURE 34.2. The best validated test is shown in the first box. Alternative tests are shown below. DLCO, total diffusion capacity for carbon monoxide; FEV₁, forced expiratory volume at 1 second; FVC, forced vital capacity; MVV, maximal voluntary ventilation; PaO₂, arterial partial pressure of oxygen; PaCO₂, arterial partial pressure of carbon dioxide; ppo, predicted postoperative value based on the number of lung segments remaining after resection; RV/TLC, residual volume divided by total lung capacity; SpO₂, pulse oximetric oxygen saturation; VO₂, oxygen uptake/consumption.

Preoperative Management of Pulmonary System

Restrictive Pulmonary Disorders

- Characteristics of restrictive disorders include the presence of mechanical volume limitations.
- Restrictive pulmonary disorders are substantially less common than obstructive disorders. These disorders are static in nature unless bronchial hyperreactivity coexists (e.g., hypersensitivity pneumonitis). The restriction can be either pulmonary or extrapulmonary.
- Pulmonary/parenchymal causes of pulmonary restriction include pulmonary edema, adult respiratory distress syndrome, atelectasis, sarcoidosis, hypersensitivity pneumonitis, silicosis, tuberculosis, and lung resection.
- Extrapulmonary causes include pleural effusion, pneumothorax, kyphoscoliosis, and increased abdominal pressure (ascites, pregnancy, obesity).
- In the extrapulmonary group, management of the mechanical volume effects (such as drainage of pleural effusion) can improve the perioperative pulmonary status of the patient.
- Lung protective ventilation using positive end-expiratory pressures and low tidal volumes of 6 to 8 mL/kg has become the standard of care for acute respiratory distress syndrome

and other disorders of static compliance found in this group of conditions.

Obstructive Airway Disease

- Obstructive pulmonary disorders are recognized by **fixed airway obstruction**, the presence of bronchial hyperreactivity, and a predisposition to infection.
- In nonoptimized patients with chronic obstructive pulmonary disease, a component of reversible airway obstruction or **bronchial hyperreactivity** (similar to asthma) makes them prone to **acute exacerbations** of airway obstruction triggered by upper- and lower-airway infections.
- Obstructive pulmonary disorders are associated with **increased risk** of postoperative pulmonary complications, and this risk is amplified when reversible airway obstruction is present.
- The key element in the management is appropriate treatment of the reversible component of the airway disease. β_2 -Agonists have a salutary effect on airway hyperreactivity in obstructive airway disease. **Preoperative steroid** therapy, even of short duration, has been shown to decrease the incidence of wheezing after intubation. The concern for negative effects on wound healing and increased infection rates have not been borne out in the literature. Cochrane review in 2001 showed that **methylxanthines** (theophylline nor aminophylline) did

TABLE 34.10

RISK FACTORS FOR RESPIRATORY COMPLICATIONS

High risk	OR	Strength of evidence	Indeterminate risk	OR	Strength of evidence
Patient-related risk factors					
Age 60–69 y	2.09		Diabetes		C
Age 70–79 y	3.04	A	Obesity		D
ASA class ≥ 2	2.55–4.87	A	Asthma		D
CHF	2.93	A	Obstructive sleep apnea		I
Functionally dependent	1.65–2.51	A	Corticosteroid use		I
Moderate risk					
COPD	1.79	A	HIV infection		I
Weight loss	1.62	B	Arrhythmia		I
Low risk					
Impaired sensorium	1.39	B	Poor exercise capacity		I
Cigarette use	1.26	B			
Alcohol use	1.21	B			
Abnormal findings on chest exam	NA	B			
Procedure-related risk factors					
High risk			Indeterminate risk		
Aortic aneurysm repair	6.9	A			
Thoracic surgery	4.24	A	Hip surgery		D
Abdominal surgery	3.01	A	Gynecologic or urologic surgery		D
Upper abdominal surgery	2.91	A	Esophageal surgery		I
Neurosurgery	2.53	A			
Prolonged surgery	2.26	A			
Moderate risk					
Head and neck surgery	2.21	A			
Emergency surgery	2.21	A			
Vascular surgery	2.1	A			
General anesthesia	1.83	A			
Low risk					
Perioperative transfusion >4 units	1.47	B			
Special investigations					
High risk			Indeterminate risk		
Albumin level <3.5 g/dL	2.53	A	BUN level >7.5 mmol/L (21 mg/dL)	NA	B
Chest radiography	4.81	B	Spirometry		I

A, good evidence that the factor is an independent predictor; B, at least fair evidence that the factor is an independent predictor; C, at least fair evidence that the factor is *not* a predictor; D, good evidence that the factor is *not* a predictor; I, evidence is lacking, conflicting, or indeterminate.

OR, odds ratio; ASA, American Society of Anesthesiologists; CHF, congestive heart failure; HIV, human immunodeficiency virus; COPD, chronic obstructive pulmonary disease; BUN, blood urea nitrogen; NA, not available.

not offer any advantage over β_2 -agonists in the setting of acute bronchospasm.

- **Infection** increases **airway reactivity** and results in demonstrable spirometry abnormalities for **6 to 8 weeks after infection**. Elective surgery should ideally be delayed in patients with underlying bronchial hyperreactivity.
- The American Thoracic Society and the Global Initiative for Chronic Obstructive Lung Disease have issued guidelines for the assessment and management of obstructive lung disorders and their acute exacerbations. Modification for preoperative patient is presented in Figure 34.4.
- The most important intervention on a global scale is **smoking cessation** and prevention of exposure to second-hand smoke. Another intervention that can be started in the preoperative period is **nutritional support** with preferably enteral nutri-

tion with an immune-repleting formula for the malnourished undergoing elective gastroenterology and oncologic surgery. Benefits may include a decrease in the incidence of nosocomial sepsis and hospital length of stay.

RENAL SYSTEM

- The incidence of intensive care unit–associated **acute renal failure (ARF)** varies between 15% and 35%. In the United States, the incidence of **end-stage kidney disease (ESKD)** varies between 331 and 343 cases per million population. The preoperative evaluation and management of the patient with renal disease is complicated by the coexistence of multiple medical and surgical problems.

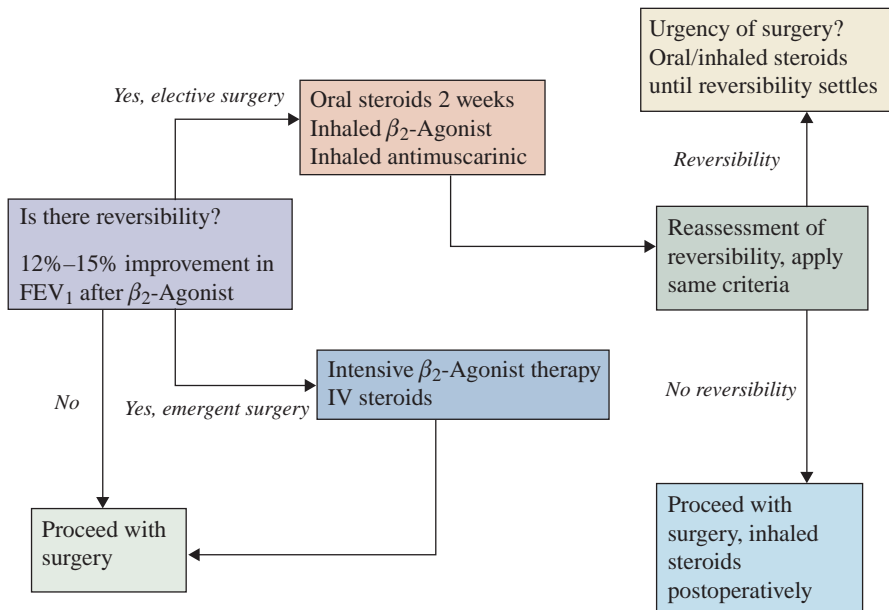

FIGURE 34.4. Preoperative optimization of obstructive airways disease. FEV₁, forced expiratory volume at 1 second; IV, intravenous.

Chronic Renal Failure

Risk Evaluation and Stratification

- Preoperative renal risk evaluation and stratification are based on (a) **comorbid** medical condition of the patient, (b) pre-existing **renal function**, and (c) the **procedure-specific** renal risk.

Comorbid Status

- Comorbid conditions that increase the risk of chronic renal insufficiency include a spectrum of **cardiovascular, endocrine, hepatic, autoimmune, and congenital disorders**. **Diabetes mellitus** is the leading cause of ESKD, with **hypertension, glomerulonephritis, and polycystic kidney disease** being the other major diagnoses.
- **CAD** is common in patients with diabetes mellitus and may be **asymptomatic** due to an associated autonomic neuropathy. A high index of suspicion for untreated CAD should be maintained for patients with diabetic nephropathy. Therefore, the preoperative workup of the diabetic patient with renal dysfunction should be done within the framework of the ACC/AHA algorithm discussed previously.
- **Hypertension** is the second leading cause of ESKD in the United States. Aggressive control of the blood pressure to approximately 125/75 mm Hg in patients with diabetic renal disease is recommended by the National Kidney Foundation
- **Polycystic kidney disease** is an inherited disorder that is characterized by multiple cysts in the kidney and the liver. It is responsible for 4% to 5% of ESKD in the United States. Important extrarenal manifestations of polycystic kidney disease include intracranial aneurysm in approximately 10% of patients, whereas 26% of patients have evidence of mitral valve prolapse.
- Once comorbid conditions and their related complications are identified, an attempt must be made to **quantify the degree of renal dysfunction**.

Pre-Existing Renal Dysfunction

- The National Kidney Foundation-Kidney Disease Outcomes Quality Initiative recently proposed a standardized classification system to assess the severity of pre-existing chronic renal disease. It is based on an estimation of the glomerular filtration rate (GFR) and the documentation of renal injury (Table 34.11).
- The GFR can be estimated using either **mathematical models** or by determining the **clearance of insulin or other filtration markers**. To estimate the GFR, either the Cockcroft–Gault equation or the formula derived from the Modification of Diet in Renal Disease Study can be used. The latter formula, although mathematically more complex, uses readily available data to provide a more accurate estimate of the GFR than the Cockcroft–Gault equation:

$$\text{GFR (mL/min/1.73 m}^2\text{)} = 170 \times [\text{P}_{\text{Cr}}]^{-0.999} \times [\text{age}]^{-0.176} \times [0.762 \text{ if patients is female}] \times [1.18 \text{ if patient is black}]$$

where SUN is serum urea nitrogen and Alb is albumin.

The presence of pre-existing renal dysfunction increases the incidence of **perioperative morbidity and mortality** in high-risk surgery. On multivariate analysis, preoperative creatinine (P_{Cr}) ≥ 2.8 mg/dL was strongly associated with postoperative ARF

TABLE 34.11

STAGES OF CHRONIC KIDNEY DISEASE

Stage	Definition
1	GFR ≥ 90 mL/min/1.73 m ² with evidence of kidney damage
2	GFR 60–89 mL/min/1.73 m ² with evidence of kidney damage
3	GFR 30–59 mL/min/1.73 m ²
4	GFR 15–29 mL/min/1.73 m ²
5	GFR ≤ 15 mL/min/1.73 m ² or dialysis dependent
GFR, glomerular filtration rate.	

(OR 10.3; 95% CI 12–411, $p < 0.0001$). Of the patients who developed ARF, the mortality rate was 49%.

Procedure-related Risk

- Procedure-related renal risk is an important determinant of perioperative renal failure. **Cardiac and major vascular procedures** are associated with a high incidence of ARF. The development of renal failure is associated with increased mortality, hospital length of stay, and cost. A 7.9% incidence of ARF and 0.7% incidence of ARF requiring renal replacement therapy have been reported with CABG patients. The mortality for patients who developed ARF was 14% compared with 1% among those who did not develop ARF. Off-pump CABG, by avoiding cardiopulmonary bypass, has less damaging effects.
- Renal insufficiency or failure exists in many patients presenting for major vascular surgery. In vascular surgery, the location of the arterial reconstruction, the duration of the aortic cross-clamp, and the emergent nature of the procedure are all strong predictors of postoperative renal complications. Reported incidence of acute postoperative renal dysfunction for thoracoabdominal reconstruction varies between 13% and 25%, whereas renal failure rates for abdominal aortic reconstruction are much lower at approximately 1.5% to 2%.

Acute Renal Failure

- ARF is a common complication of critical illness and is associated with significant morbidity and mortality. To standardize the definition of ARF, the **RIFLE classification**, which includes criteria for serum creatinine, GFR, and urine output, has been validated (Table 34.12). Multivariate logistic regression analysis demonstrates that the RIFLE classification is an independent risk factor assessment for 90-day mortality.

Classification

- ARF is divided into three categories based on its pathophysiology. They are prerenal, postrenal, and intrarenal ARF.

Prerenal Acute Renal Failure

- Prerenal ARF is reversible renal insufficiency due to renal hypoperfusion, usually associated with hypovolemia. If the renal hypoperfusion is left untreated, acute tubular necrosis (ATN) secondary to ischemia will develop. Laboratory data

include **low urine Na⁺**, **fractional excretion of Na⁺ <1%**, and bland urine sediment.

Postrenal Acute Renal Failure

- Postrenal ARF is due to **obstruction of urine flow** at any level of the urine collecting system. Postrenal ARF can be diagnosed promptly by either ultrasound or computed tomography scan, and relief of the obstruction usually results in prompt reversal of the renal insufficiency.

Intrarenal Acute Renal Failure

- Intrarenal ARF is divided into five groups based on the underlying pathology. **Acute tubular necrosis (ATN)** is injury and subsequent death of the tubular epithelium. ATN is caused by either ischemia or nephrotoxic agents. **Acute interstitial nephritis** is an inflammation of the renal interstitium and the tubules. It may occur secondary to infections or drugs, such as the penicillins or cephalosporins. **Acute glomerulonephritis**, **acute vascular syndromes**, and **intratubular obstruction** are other causes. The differential diagnosis of intrarenal ARF should be guided by history and physical exam and examination of the urine sediment. The presence of tubular epithelial cells and granular cast is suggestive of ATN, whereas the presence of red cell cast indicates glomerulonephritis. Eosinophiluria suggests the presence of interstitial nephritis; however, it is not diagnostic.
- ARF is characterized by retention of nitrogenous waste products, fluid and electrolyte abnormalities, acid-base disorders, and impairment of the hematologic and coagulation systems. The preoperative evaluation of these patients must, therefore, take into account these specific changes and the increased risk they pose during the perioperative period.

Preoperative Evaluation of Renal Failure

- The **history and physical examination** should be directed toward evaluating the severity of the **comorbid conditions** and the complications related to the acute renal dysfunction. Signs and symptoms of uncompensated **cardiac failure and pericarditis** should be elicited.
- Uremia is associated with nausea, vomiting, and recurrent episodes of hiccoughing. Severe nausea and vomiting may result in **dehydration**, and a thorough evaluation of the patient's volume status must be performed.
- **Anemia** in renal failure is multifactorial in nature. Bleeding from platelet dysfunction, malnutrition, and decreased

TABLE 34.12

THE RIFLE CLASSIFICATION SCHEME FOR ACUTE RENAL FAILURE

	GFR criteria	Urine output criteria	Mortality
Risk	Increased plasma creatinine $\times 1.5$ or GFR decrease $>25\%$	<0.5 mL/kg/h $\times 6$ h	8%
Injury	Increased plasma creatinine $\times 2$ or GFR decrease $>50\%$	<0.5 mL/kg/h $\times 12$ h	21.40%
Failure	Increased plasma creatinine $\times 3$ or acute plasma creatinine ≥ 350 $\mu\text{mol/L}$ (4 mg/dL) or acute rise ≥ 44 $\mu\text{mol/L}$ (0.5 mg/dL)	<0.3 mL/kg/h $\times 24$ h or anuria $\times 12$ h	32.50%
Loss	Persistent acute renal failure with complete loss of kidney function $\times 4$ weeks		
ESKD	End-stage kidney disease ($\times 3$ mo)		

GFR, glomerular filtration rate; ESKD, end-stage kidney disease.

erythropoietin production all contribute toward the low red cell mass.

- **Electrolyte abnormalities** are common in renal failure. Hyperkalemia, hyperphosphatemia, and hypocalcemia is the typical electrolyte profile seen in renal failure. Hypocalcemia may manifest as cramps, paraesthesia and, in severe cases, with mental status changes.

Diagnostic Testing

- **Complete blood count** helps to assess the severity of the **anemia**, **morphology of the red blood cells**, and the platelet count. There is an acquired platelet dysfunction that results in an increased risk of bleeding. To assess the degree of **platelet function**, either a bleeding time or, more accurately, a platelet function assay can be performed.
- The **basic metabolic panel** helps to determine the electrolyte profile.
- An **electrocardiogram** must be performed to determine whether ischemia, ventricular hypertrophy, or strain pattern is present. **Hyperkalemia** is characterized by tall peaked T-waves, widened QRS complex, and shortened QT interval. The electrocardiogram of patients with **pericardial effusion** may demonstrate small QRS complexes and the presence of electrical alternans (change in QRS amplitude with each heartbeat).
- A **chest radiograph** may reveal signs of pulmonary edema, cardiomegaly, or a large pericardial effusion.
- Examination of the urine and determination of the **urine indices** provides invaluable data in helping to differentiate prerenal from intrarenal ARF (Table 34.13).
- The **fractional excretion of urea** is a useful index to differentiate prerenal from intrarenal failure if diuretic therapy has been initiated:

$$FE_{UN} = \frac{(\text{urine nitrogen/blood urea nitrogen})}{(\text{urine creatinine/plasma creatinine})} \times 100$$

- Fractional excretion of urea nitrogen is primarily dependent on passive forces and is, therefore, less influenced by diuretic therapy. In contrast, diuretic therapy will falsely raise the FE_{Na+} under prerenal conditions.

Primary and Secondary Prevention

- **Primary prevention** of ARF refers to clinical strategies that reduce the occurrence of ARF in patients with or without chronic renal disease.
- **Secondary injury** is additional renal injury developing in the face of a primary insult to the renal system.

TABLE 34.13

CRITERIA TO DIFFERENTIATE PRERENAL FROM INTRARENAL FAILURE

	Prerenal	Intrarenal
Urine Na^+	<20 mEq/L	>40 mEq/L
FE_{Na+}	<1%	>2%
FE_{UN}	<35%	>50%
Urine/plasma creatinine	>40	<20
Urine/plasma osmolality	>1.3	<1.1
Urine/plasma urea	>8	<3

- The principles of management of patients with ARF are to maintain an adequate **mean arterial pressure**, maintain an appropriate **cardiac output**, ensure **euvolemia**, and **avoid nephrotoxic agents**.
- The **mean arterial pressure** required to maintain adequate renal perfusion pressure **may vary**. Patients with a long history of hypertension may require a higher mean arterial pressure to maintain perfusion.
- **Low cardiac output states** induce renal ischemia and reduce the glomerular filtration rate. It is important to restore cardiac output. This may require placement of monitors such as a **pulmonary artery catheter** or a transesophageal echocardiography probe to determine cardiac output.
- **Volume expansion** has been shown to prevent contrast-induced nephropathy and attenuate the tubular injury associated with rhabdomyolysis. High-risk patients should receive an intravenous bolus of 3 mL/kg of the study solution over an hour, before radiocontrast injection, followed by a continuous infusion of 1 mL/kg/hour during the procedure and for 6 hours after the procedure.
- In conclusion, the best evidence to date suggests that nonpharmacologic therapy strategies are more effective than drugs in reducing the risk of ARF. High-risk patients should be identified early and secondary renal injury aggressively prevented.

NEUROLOGIC SYSTEM

Ischemic Cerebrovascular Disease

- The incidence of perioperative stroke in patients undergoing nonvascular surgery under general anesthesia is <0.5%. However, the mortality associated with a perioperative stroke may be as high as 26%.

Carotid Stenosis

- The risk of a perioperative stroke increases in the presence of carotid stenosis or a history of transient ischemic attack. The presence of carotid stenosis of at least 50% is associated with a perioperative stroke rate of approximately 3.6%. Although higher than the general population stroke rate, this risk does not appear sufficient to mandate prophylactic carotid endarterectomy (CEA).
- Patients with carotid disease who present with transient ischemic attacks have a 10% risk of stroke during the subsequent year.
- The benefit of antiplatelet therapy in reducing perioperative stroke during CEA is unresolved. However, a dose range of aspirin 50 to 1,300 mg/day is commonly used.

Surgery-Specific Risk

- Noncarotid procedure associated with the highest risk of perioperative neurologic injury is **cardiac surgery**. Studies report a 3% incidence of stroke in CABG procedures, 8% in isolated valve surgery, and 11% in combined CABG-valve surgery. Advanced age and female gender are additional risk factors. The single most important factor for cerebral injury during cardiac surgery is macroembolization of atheromatous debris during aortic manipulation. Every attempt should be made to identify the high-risk patient with a large atheromatous

burden by using epiaortic echocardiography and minimizing manipulation of the aorta.

Preoperative Evaluation

- The history and physical examination of the patient with cerebrovascular disease require a thorough assessment of the cardiovascular and neurologic system.
- Patients with carotid artery stenosis are at an increased risk of CAD. Severe correctable CAD is evident in approximately 26% of patients with cerebrovascular disease, whereas only 9% of patients have normal coronary anatomy.
- Studies, though, have demonstrated the rate of medical complications in patients undergoing CEA to be low, with perioperative medical complications occurring in fewer than 10%, and only 0.4% had severe complications. Perioperative nonfatal and fatal myocardial infarction occurred in only 1% of the patients and was associated with a mortality rate of approximately 0.2%. Therefore, recommending a CABG procedure to a patient with symptomatic carotid disease and asymptomatic CAD is not justified.
- The ACC/AHA guidelines for noncardiac surgery list CEA as an **intermediate-risk procedure** where the perioperative cardiac risk is <5%.

- **Hypertension** is a prevalent and treatable risk factor for stroke. Treatment of systolic and diastolic hypertension results in a 36% and 42% stroke reduction, respectively. Knowledge of preoperative blood pressure is important in management strategy, as patients with long-standing hypertension may need a higher mean arterial pressure to ensure adequate cerebral perfusion. Poor control of blood pressure after CEA increases the risk of **cerebral hyperperfusion syndrome**. This complication occurs due to impairment of cerebral autoregulation and can result in intracerebral hemorrhage and white-matter edema. Patients with severe preoperative carotid stenosis and chronic hypertension are at greatest risk for this complication. Blood pressure should be carefully monitored and aggressively treated if symptoms of hyperperfusion syndrome develop.

CHAPTER 35 ■ ANESTHESIA: PHYSIOLOGY AND POSTANESTHESIA PROBLEMS

INTRODUCTION

- The overall **risk of death** from anesthesia is between 1 in 112,000 and 1 in 450,000.
- The characteristics of anesthetic injuries have changed over the past years, with an increase in problems related to **cardiovascular issues** and a decrease in those related to the respiratory system.

INHALATIONAL AGENTS

- The goal of inhalational anesthesia is to develop a critical partial pressure of the agent within the brain. **Brain levels** are determined by several factors presented: delivery of inhaled agents, uptake from lungs, and distribution to tissues.
- The **brain tissue partial pressure** is responsible for the depth, and some of the side effects of anesthesia, and correlates closely with the end-tidal partial pressure of the inhaled agents.

Delivery of Inhaled Agents

- The inspired concentration is important to the rate of rise of anesthetic agent concentration in the lungs; this relationship is termed the **concentration effect**.
- **The second gas effect.** When large amounts of an anesthetic agent such as nitrous oxide are rapidly taken up, the lungs do not collapse. Instead, a subatmospheric alveolar pressure is generated as a result of the rapid removal of this gas by the pulmonary blood flow. A passive inflow of additional gas (another anesthetic agent) from the anesthesia circuit replaces that which is taken up. This second gas may have a partial pressure increase which is more rapid than when it is administered alone.
- **Alveolar ventilation** (\dot{V}_A) is another important factor in delivery of inhaled agents.

Uptake of Inhaled Agents from the Lungs

- **Solubility** is the extent to which the anesthetic dissolves in blood and tissues; the more soluble the agent, the more it is

dissolved in the pulmonary blood and the longer it takes to reach the necessary partial pressure in the lungs and brain.

- A high **cardiac output** increases uptake and decreases the alveolar partial pressure of the agent. This effect is greater with more soluble inhalational anesthetics. A longer induction time is required for a patient with a high cardiac output.
- **Alveolar-to-central mixed venous anesthetic partial pressure gradient.** This factor relates the size of the anesthetic “sink” to the increase or decrease in uptake from the lungs. At the beginning of induction when the tissue anesthetic level is zero, most of the anesthetic agent in the arterial blood is removed. Thus, the venous anesthetic partial pressure is much lower than that in the arterial blood, and a large uptake of anesthetic occurs as the venous blood passes through the lungs. The alveolar partial pressure of the anesthetic agent is accordingly reduced. However, as the tissue sinks become filled, the alveolar to venous anesthetic partial pressure difference decreases.

Distribution

Tissue Solubility and Blood Flow

- The greater the solubility of an anesthetic in a tissue, the larger the capacity of that tissue for the agent. If the tissue has a large capacity but low blood flow, equilibration takes a long time; if the tissue has a small capacity and large blood flow, equilibration is rapid. The vessel-rich group is composed of the **brain, liver, heart, and kidneys**. An intermediate group includes **muscle and skin**. The vessel-poor group incorporates **skeletal elements, ligaments, and cartilage**. Fat has a poor blood supply but a great capacity. At the end of surgery, the factors that affect elimination of the agent from the body are the same as those that govern the uptake and distribution at the beginning. Factors that **lengthen the period of emergence** are hypoventilation, increased cardiac output, use of a highly soluble anesthetic agent, and an increased alveolar-to-venous anesthetic concentration gradient.

Diffusion Hypoxia

- Diffusion hypoxia may occur at the conclusion of an anesthetic if the patient is allowed to breathe room air while large quantities of nitrous oxide diffuse into the alveoli and dilute the oxygen that is present. This problem is significant only for approximately 10 minutes and can be alleviated by having the patient breathe 100% oxygen after discontinuation of the nitrous oxide.

Effects of Illness

Changes in Ventilation

- Organ system dysfunction can affect the uptake and distribution of inhaled anesthetic agents. In a hyperventilated patient, each 1 mm Hg decrease in the PaCO_2 caused by an increase in \dot{V}_A , leads to a 3% to 4% decrease in cerebral blood flow (CBF). A change in the length of time of anesthetic induction results from three factors: increased \dot{V}_A , decreased CBF, and solubility of the inhaled agents used for induction. The induction time for a moderately soluble agent such as halothane is decreased because the increased \dot{V}_A produces a more rapid rise in end-tidal halothane partial pressure that offsets the

decrease in CBF. For a relatively nonsoluble agent such as nitrous oxide, induction time is increased because the modest increase in end-tidal nitrous oxide partial pressure obtained by hyperventilation is more than offset by the decrease in CBF.

Changes in Cardiac Output

- A decrease in cardiac output yields an increase in the agent's end-tidal partial pressure, whereas a decrease in CBF decreases transfer of the agent from the lungs to the brain.

Inhalational Agents and Organ System Function

- The differential effects of various inhalation agents on organ system function must be compared at equipotent doses. The **minimum alveolar concentration (MAC)** is the amount of an inhalational agent that prevents movement in 50% of patients in response to surgical incision. In neonates, the MAC is less than in children, adolescents, and young adults. After approximately 31 years of age, the MAC value begins to decrease; theoretically, the value for a patient 100 years of age is only 25% to 50% that of a young adult.

Circulatory Effects

- **Blood pressure** is decreased with the use of all inhalational agents. This may be due to decreased **contractility**, as with halothane, or due to decreased **systemic vascular resistance**, as with isoflurane or desflurane.

Cardiac Rhythm

- Of the several methods for evaluation of the effects of inhalational agents on cardiac rhythm, a common procedure is to determine the dose of epinephrine required to produce three or more premature ventricular contractions in 50% of normal patients breathing oxygen and anesthetized at 1.25 MAC (Table 35.1).

Respiratory Effects

- All inhalational agents are respiratory depressants. Decreases in minute ventilation at 1 MAC of various agents are presented in Table 35.1.

Hepatic Effects

- Up to 20% of patients may demonstrate mild disturbances in liver function after anesthesia with halothane presenting as **abnormalities of liver function** tests. They may be due to other physiologic disturbances such as hemodynamic abnormalities during surgery or blood transfusion. This has been one of the reasons for the marked reduction in the use of halothane as a common anesthetic agent.

Renal Effects

- All potent inhalation agents result in a dose-dependent decrease in renal blood flow from 25% to 50%, glomerular filtration rate from 23% to 40%, and urine flow from 35% to 67%.

Immune Function

- Anesthesia and surgery may impair immune system function, at least *in vitro*. Relevance to clinical outcome is debated.

TABLE 35.1

RESPIRATORY AND CIRCULATORY EFFECTS OF THE INHALATIONAL AGENTS

INTRAVENOUS AGENTS

Narcotics

General Considerations

- Opiates have been used for pain for thousands of years. There are specific binding sites for opiates in the central nervous system. The opiate receptor complex with three major receptor groups have been described: μ , δ , and κ . The main drugs available for pain relief are relatively selective for the μ -receptor.
- A wide variety of narcotic drugs are available including morphine, meperidine, methadone, fentanyl, alfentanil, sufentanil and, more recently, remifentanyl.
- Problems with morphine include recall, **histamine release**, prolonged postoperative respiratory depression, hypertension, and increased blood and fluid requirements because of vasodilation.
- Synthetic drugs related to the phenylpiperidines, such as fentanyl, sufentanil, alfentanil, and remifentanyl, do **not induce histamine release**, nor do they increase blood and fluid requirements.
- **Remifentanyl** has a time to effect that is very rapid (**half-life 8–20 minutes**), and because it is metabolized by plasma esterase, is independent of liver or renal function. This makes the drug ideal for situations in which rapid discontinuation of a drug is required to enable assessment of consciousness, such as in neurosurgical procedures.
- Narcotics cannot be depended upon to provide complete anesthesia, which requires **amnesia, hypnosis, and muscle relaxation** to enable safe surgery. The addition of intravenous hypnotics and muscle relaxants, or inhaled agents, is required.

Pharmacokinetics/Pharmacodynamics

- Pharmacokinetic data for four commonly used opioids are summarized in Table 35.2.
- Similarities between the redistribution and elimination half-lives and the clearance and steady-state volume of distribution are noteworthy. The major difference is in **lipid solubility**, which correlates with **potency**.

- **Peak respiratory depressant effect** of morphine occurs at 15 to 30 minutes after injection, and 5 to 10 minutes after fentanyl. The respiratory depressant effect from morphine usually lasts longer, although that of fentanyl can be seen **after the analgesic effect has dissipated**. Remifentanyl is unique in that it has a rapid onset and offset of effect, even when delivered for a prolonged infusion.

Hemodynamic Effects

- **Hypotension** can be a significant problem with morphine in a dose of 1 to 4 mg/kg. During induction of anesthesia with morphine, systolic blood pressure may decrease to less than 70 mm Hg in 10% of patients. Possible mechanisms include vagal-induced bradycardia, vasodilation, and splanchnic blood sequestration. Some of the effects of morphine seem to result from **histamine release**.
- **Fentanyl** 30 to 100 μg/kg rarely causes hypotension even in patients with poor left ventricular function, perhaps because it does not cause histamine release. When blood pressure decreases with fentanyl, it is often secondary to a decrease in heart rate and is attenuated with a vagolytic agent.
- **Remifentanyl** has a beneficial hemodynamic profile, similar to fentanyl.

Respiratory Effects

- Significant dose-dependent respiratory depression can occur with opioids.
- Opioids block (a) **hypoxic ventilatory drive** and (b) the drive seen with increased airways resistance. The pontine and medullary centers for respiratory rhythmicity are impaired, resulting in increased respiratory pauses and delayed exhalation, producing irregular and periodic breathing.
- Morphine can trigger **bronchospasm** due to histamine release.

Neurologic Effects

- Morphine, at a dose of 1 to 3 mg/kg with 70% nitrous oxide, has no effect on **CBF**, **cerebral metabolic rate for oxygen** (CMRO₂), or **cerebral metabolic rate for glucose** (CMRG₆).
- Fentanyl, in a model of traumatic brain injury, did not lead to a reduction in CBF despite a decrease in arterial blood pressure.

TABLE 35.2

SELECTED PHARMACOKINETIC DATA FOR FOUR OPIOIDS

	Morphine	Fentanyl	Sufentanil	Remifentanyl
Lipid solubility ^a	1	580	1778	50
$t_{1/2} \pi$ (min)	0.9–2.4	1–3	0.5–2	1
$t_{1/2} \alpha$ (min)	10–20	5–20	5–15	6
$t_{1/2} \beta$ (h)	2–4	2–4	2–3	0.06
Clearance (mL/kg/min)	10–20	10–20	10–12	40–70
Vd _{ss} (L/kg)	3–5	3–5	2.5	0.2–0.3

$t_{1/2} \pi$, rapid redistribution half-life; $t_{1/2} \alpha$, slow redistribution half-life; $t_{1/2} \beta$, elimination half-life; Vd_{ss}, steady-state volume of distribution.

^aProportional to ease with which agent crosses blood–brain barrier and, hence, potency.

Gastrointestinal Effects

- Nausea and vomiting may occur secondary to stimulation of the chemoreceptor trigger zone in the area postrema of the medulla.
- There may be increased gastrointestinal secretions, decreased motility, and increased smooth muscle tone of the gastrointestinal tract and the sphincter of Oddi.

Barbiturates

General Considerations

- **Thiobarbiturates** (e.g., sodium thiopental and methohexital): The chemical structure of these barbiturates confer ultrashort onset and offset action compared with other barbiturates.
- Sodium thiopental usually comes in a 2.5% solution with a pH greater than 10, causing the drug to be irritating if accidental extravasation occurs.
- Methohexital is two to three times more potent than thiopental.

Pharmacokinetics/Pharmacodynamics

- The pharmacokinetics of thiopental, and other commonly used nonnarcotic, intravenous anesthetic agents, are summarized in Table 35.3.
- Thiopental is a highly lipophilic agent and, with a standard clinical dose of 3 to 5 mg/kg, loss of consciousness occurs within one arm–brain circulation time (i.e., 10–15 seconds). The short duration of action of this drug—**5 to 10 minutes**—

is secondary to its **redistribution** from the brain to muscle, skin and, to a lesser extent, fat. The elimination half-life of the drug is long, making thiopental into a long-acting drug when a large enough dose has been given to saturate the redistribution compartment. **Hepatic metabolism** is important for its inactivation.

- **Methohexital** is only slightly less lipid soluble than sodium thiopental. The onset and duration of loss of consciousness are approximately the same as with thiopental because of its rapid redistribution, with an elimination half-life of 3 to 5 minutes. Because it is more dependent on **hepatic blood flow** for clearance, any changes in blood flow are more significant for its final elimination.

Neurologic Effects

- The mechanisms of action of the barbiturates are multiple and dose related. It facilitates the action of inhibitory—GABA—neural transmitters and inhibition of excitatory neural transmitter action. It may be used to reduce intracranial pressure and improve cerebral hemodynamics while providing a degree of brain protection.

Cardiorespiratory Effects

- Thiopental increases coronary blood flow, heart rate, and myocardial oxygen consumption with a **decrease in the inotropic state** of the myocardium. The result is a 10% to 25% decrease in cardiac output, blood pressure, and stroke volume at clinically relevant doses.

TABLE 35.3

SELECTED PHARMACOKINETIC DATA FOR NONOPIOID INTRAVENOUS ANESTHETICS

	Thiopental	Propofol	Diazepam	Lorazepam	Midazolam	Ketamine
$t_{1/2} \alpha$ (min)	2–4	2–4	10–15	3–10	7–15	7–17
$t_{1/2} \beta$ (h)	10	1–3	20–40	10–20	2–4	2–3
Clearance (mL/kg/min)	2.6–2.8	20–40	0.2–0.5	0.7–1	4–8	18–20
Vd _{ss} (L/kg) ^a	1.4–2.8	2.8–7.1	0.85–1.4	0.7–1.3	1–1.8	2.8–3.6

$t_{1/2} \alpha$, slow redistribution half-life; $t_{1/2} \beta$, elimination half-life; Vd_{ss}, steady-state volume of distribution.

^aAssume a 70-kg person.

Modified from White PF. Propofol: pharmacokinetics and pharmacodynamics. *Semin Anesth.* 1988;7(Suppl):4.

- **Venous tone** may also decrease, resulting in decreased preload.
- At doses of 3 to 5 mg/kg, the responses to carbon dioxide elevation and hypoxia are impaired.

Immune Effects

- In patients who are given continuous barbiturate infusion, there may be an effect on immune function and they may be more prone to develop infections.

Propofol

General Considerations

- Propofol is a sedative-hypnotic agent that may be used for induction and maintenance of anesthesia. The agent is **not an analgesic** but is reported to have minimal amnestic effects.
- An alkylphenol, propofol is virtually insoluble in aqueous media and thus is provided in a 1% weight/volume (**Intralipid**) emulsion. The emulsion is composed of 1% diisopropylphenol (propofol), 10% soybean oil, 2.25% glycerol, and 1.2% purified egg phosphatide.

Pharmacokinetics/Pharmacodynamics

- The basic pharmacokinetic data of propofol are shown in Table 35.3. Propofol is extensively distributed into vessel-rich tissues and ultimately redistributed to lean muscle and fat. Accumulation occurs with repeated bolus injections or continuous infusion.
- In comparing propofol with the other agents in Table 35.3, one observes the high clearance and the short elimination half-life. This is one of the reasons that the agent is so appealing.
- A propofol dose of **2 to 2.5 mg/kg** results in loss of consciousness in less than 60 seconds. Intravenous injection of 1 to 1.5 mg/kg in the elderly or a patient who has been given narcotic or benzodiazepine premedication is often sufficient for induction.

Neurologic Effects

- The mechanisms of action of propofol are unclear. It can cause desynchronization of the awake electroencephalographic (EEG) pattern when a loading dose of 2.5 mg/kg followed by an infusion of 100 to 200 $\mu\text{g/kg/minute}$ are used.
- More than 150 $\mu\text{g/kg/minute}$ results in EEG burst suppression lasting 15 seconds or longer; the EEG returns to the awake state within 11 minutes after the drug infusion is discontinued.
- There is a dose-related **decrease in CBF and CMRO₂** and progressive EEG suppression with increasing dose of propofol, which may be useful in patients with **intracranial disease**.

Cardiovascular Effects

- A dose-dependent decrease in systolic, diastolic, and mean arterial blood pressure is observed; this effect is enhanced by narcotic premedication. Profound **cardiovascular depression** may be seen in elderly, hypovolemic patients and those with impaired ventricular function.

Respiratory Effects

- **Apnea** is seen on induction with propofol in 30% to 60% of unpremedicated patients and in virtually 100% of those

premedicated with narcotics. The respiratory response to hypoxia is significantly blunted.

Other Effects

- Up to 58% of patients with an intravenous catheter in the dorsum of the hand report **pain on injection**.
- A syndrome of severe hemodynamic compromise with bradycardia (even asystole) combined with severe metabolic acidosis called the **propofol infusion syndrome** has been described, initially in children and now in adults.
- The pathophysiology of the propofol infusion system is unclear, and various theories have been suggested: (a) **mitochondrial function** leading to extreme metabolic acidosis and rhabdomyolysis, (b2) **genetic predisposition** of mitochondria to dysfunction, or (c) problems with **lipid metabolism**, particularly in patients who have a low carbohydrate input. Risk factors include a **high dose** of the drug and its **prolonged administration**.
- **Acute lung injury** has also been reported possibly due to the effects of the lipids inciting an inflammatory response.

Benzodiazepines

General Considerations

- Commonly used benzodiazepines **diazepam, lorazepam, and midazolam** are presented in Table 35.3. Diazepam and lorazepam are insoluble in water. Midazolam, because of its imidazole ring, is water-soluble at a pH <4. Lorazepam is less lipid-soluble than diazepam, and its **slow entry into the central nervous system** may be a reason for its slower onset of action.

Pharmacokinetics/Pharmacodynamics

- **Diazepam's** sedative properties make it useful as a premedicant; peak plasma levels are seen 30 to 60 minutes after an oral dose. Intramuscular injection is painful, and absorption is erratic. With **hepatic disease**, the volume of distribution increases and metabolism decreases, resulting in an **increase in the half-life from 40 to 80 hours**. With significant renal disease, an increase in the unbound fraction of diazepam results in a twofold to threefold increase in hepatic clearance and a resultant decrease in the half-life.
- **Lorazepam** is useful in oral, intramuscular, and intravenous forms. This agent is directly metabolized in the liver to inactive, glucuronide-conjugated metabolites. The kinetics of this drug are unaltered by age or renal disease, but hepatic disease increases the half-life.
- **Midazolam** can be administered by intramuscular, intravenous, or oral routes. The drug undergoes extensive metabolism to active and inactive metabolites.

Neurologic Effects

- Benzodiazepines have multiple, dose-dependent effects on the central nervous system and potentiate **inhibitory GABA neurotransmission**. Loss of consciousness occurs 2 to 3 minutes after an intravenous induction. Antegrade amnesia is seen with all of the benzodiazepines but more so with lorazepam.

Cardiorespiratory Effects

- When used alone, negative cardiovascular effects are rare; however, cardiovascular depression has been observed when used in conjunction with other anesthetic agents.
- Decrease in the ventilatory response to carbon dioxide may occur.

Ketamine

Pharmacokinetics/Pharmacodynamics

- Ketamine is the only arylcyclohexylamine used in anesthesia. It is structurally related to phencyclidine, known in street vernacular as “angel dust.” Its pharmacokinetics are summarized in Table 35.3.
- After an intravenous dose of 2 mg/kg, consciousness is lost in little more than one arm–brain circulation time and returns 10 to 15 minutes later.
- Recovery of consciousness results from rapid drug redistribution into muscle and other tissues. However, 95% of the injected drug is metabolized by the liver, and less than 5% is recovered unchanged in the urine.

Neurologic Effects

- The exact mechanism of action of ketamine is not well understood. Specific arylcyclohexylamine receptors in the brain may be related to the μ subclass of opioid receptors.
- Ketamine increases CBF and so must be used with caution in individuals with elevated intracranial pressure (ICP).

Cardiovascular Effects

- There is an increase in systemic blood pressure and cerebrovasodilation resulting in increased intracranial pressure.
- Ketamine is often thought not to be a myocardial depressant. Nonetheless, with sympathetic blockade or in patients in prolonged shock with a significantly stressed autonomic nervous system, cardiac depression can be seen with ketamine.
- **Pulmonary vascular resistance** and right ventricular stroke work are frequently increased.

Respiratory Effects

- Although **not** commonly thought of as a respiratory depressant when used in anesthetic doses of 1 to 2 mg/kg, a moderate decrease in the PaO_2 may occur. The ventilatory response to carbon dioxide is maintained, and ketamine potentiates the bronchodilatory effects of catecholamines.
- It also increases **oral secretions** so that an anticholinergic agent may be necessary.

Other Effects

- **Postanesthetic emergence reactions**—nightmares and hallucinations—may occur in 5% to 30% of patients. A benzodiazepine and 2 mg/kg (or less) maximal doses of ketamine seem to decrease the incidence of this problem.

Etomidate

- Due to maintenance of **hemodynamic stability**, etomidate is commonly used in the induction of anesthesia or for intubation of critically ill patients.

- Etomidate causes a **dose-dependent reduction in contractility** in both normal and failing hearts, but this decrease is **minimal** and not of clinical significance.
- The major problem is adrenal suppression when used in a prolonged infusion, but adrenal failure has also been demonstrated after a single dose.

Dexmedetomidine

- Dexmedetomidine is a highly selective, short-acting **central α_2 -agonist**. It provides a dose-dependent degree of sedation, analgesia, anxiolysis, and sympatholysis. When used in postoperative patients in the intensive care unit, dexmedetomidine can provide better sedation with fewer narcotics than propofol. It may also facilitate extubation in patients who may otherwise require large amounts of benzodiazepines. The place of this agent in intensive care medicine practice is increasing.

POSTANESTHESIA PROBLEMS

- Postanesthetic complications have been found to occur in 5% to 30% of patients; the wide range results from lack of uniform criteria defining complications, different practices in individual institutions, and strictness of monitoring, and varies with the populations studied.

Hypoxemia

- Postoperative hypoxemia may result from diverse etiologies:
 - **Hypoventilation** may be caused by residual anesthetic or muscle relaxant.
 - **Upper-airway obstruction** due to a decreased level of consciousness is a common reason for hypoxemia and hypercarbia.
 - **Pulmonary edema** may result from heart failure, noncardiogenic pulmonary edema, aspiration, acute respiratory distress syndrome, infection, trauma, transfusion reaction, or neurogenic pulmonary edema from head injury.
- Postoperative hypoxemia can lead to acute complications such as **cardiac ischemia**.

Negative-pressure Pulmonary Edema

- Pulmonary edema may develop after a **strenuous inspiratory effort** against an **obstructed airway**. This type of pulmonary edema may appear immediately or up to 10 hours after the episode of airway obstruction. It is most commonly associated with **laryngospasm** during anesthetic induction or during emergence from anesthesia.
- A common explanation is that the **massive negative intrapleural pressure** generated during airway obstruction shifts the balance in the Starling forces toward a large fluid transudation from the intravascular to the interstitial space.
- Typically, the patient is a **young, vigorous adult** who sustains an episode of laryngospasm either before intubation or after tracheal decannulation.

- The radiologic picture is bilateral alveolar and interstitial **edema** (rarely unilaterally), with normal heart size but enlarged vascular pedicle.
- **Treatment is supportive.** Patients should be given oxygen to maintain an arterial saturation of at least 90%. Some patients require reintubation and mechanical ventilation with positive pressure to ensure oxygenation and to reduce work of breathing;
- Despite pulmonary edema, intravascular volume may be depleted. Diuretics should be used only if volume overload is suspected. In most cases, the edema resolves within 24 hours.

Pain and Perioperative Stress

- Early postoperative pain remains a serious concern. Up to 75% of patients receiving parenteral narcotics may have significant residual pain after the drug is administered.
- Uncontrolled pain can lead to serious physiologic consequences. **Sympathetic nervous system stimulation** leads to elevated plasma catecholamine levels, tachycardia, hypertension, increased systemic vascular resistance, and an increase in **myocardial oxygen consumption**. In the patient with underlying coronary artery disease, this may result in ischemia or infarction.
- Surgical procedures on the upper abdomen and thorax may have profound effects on the respiratory system. The ability to deep-breathe (sigh) and cough is impaired due to pain, resulting in **atelectasis** and retained secretions. Decreased oxygenation and the potential for pulmonary parenchymal **infection** may follow.

Stress Response

- **General anesthesia** should be viewed as a potential for **stress response** as there is an increase in corticotropin, corticosteroids, β -endorphins, and catecholamine levels in response to intubation, skin incision, intra-abdominal manipulation, and on emergence from anesthesia. **High-dose narcotic techniques**, commonly used in cardiac anesthesia or for patients

with ischemic heart disease, have been shown to blunt the endocrine response to stress.

- **Regional anesthesia** attenuates the stress response to surgery by avoiding the direct neural activation and transmission of noxious stimuli from the traumatized area (which general anesthesia does not do).
- **Combined anesthesia:** A common approach is to use regional anesthesia, with control of the airway by intubation, inhalational agents, and positive-pressure ventilation. The possible advantages of combined anesthesia over a purely general technique are controversial.
- **Maintenance of cardiac output and oxygen delivery** to meet the increased demands of the tissues and avoid cellular hypoxia is an important concept. Literature needs to stress the importance of **time factor** when resuscitative goals are studied. This topic is discussed in other chapters (see Chapters 7 and 8).

Delirium

- Delirium and **acute confusional states** can be very disturbing for patients and family members and impose a significant risk to patients. Incidence ranges from 0% to 73%.
- **Risk factors** include age, preoperative cognitive impairment, use of anticholinergic agents, benzodiazepines and general anesthesia.
- The reasons for postoperative delirium are many (Table 35.4).

Treatment

- Treatment depends on the etiology and removing the offending agent (see Table 35.4). **Haloperidol**, an antipsychotic with no anticholinergic properties, may be given. Haloperidol has minimum hypotensive property and is not an antidepressant. Side effects include extrapyramidal symptoms and, rarely, torsades de pointes.

Residual Neuromuscular Blockade

- Residual neuromuscular blockade usually presents in one of three ways: (a) delayed return to consciousness, which should

TABLE 35.4

ETIOLOGY OF POSTOPERATIVE MENTAL STATUS ALTERATION

Drugs	In the patient emergently anesthetized from the emergency department, street drugs such as alcohol, narcotics, and cocaine may have been present on induction; residual neuromuscular blockade must also be considered.
Postseizure	A seizure under anesthesia may be easily missed. One must consider the delayed emergence as a possible postictal event.
Glucose	Hyperglycemia or hypoglycemia can result in altered mental status.
Metabolic causes	Hypoxia, hypercarbia, hyponatremia or hypernatremia, hypercalcemia, and hypothermia (usually at or below 31°C) are several examples.
Trauma	Again, in the patient emergently anesthetized from the emergency department, head trauma must be considered.
Infection	Agitation in an infected patient is sometimes seen; this is no less so in the postoperative period.
Psychogenic causes	Rarely, a patient will feign unconsciousness for some secondary gain. This may only be diagnosed after other life-threatening and treatable causes have been ruled out.
Hemodynamic instability	Hypotension, and sometimes severe hypertension, may cause mental status changes. The former may result from hypovolemia, anaphylaxis, sepsis, or ischemia.
Pain	Pain at the operative site, a full bladder, or gastric distention can result in agitation.

TABLE 35.5

ETIOLOGY OF POSTOPERATIVE HYPERCAPNIA

- I. Central respiratory depression
 - Intravenous (narcotic) anesthetics
 - Inhaled anesthetic agents
- II. Respiratory muscle dysfunction
 - Site of incision (upper abdominal, thoracic)
 - Residual neuromuscular blockade
 - Use of drugs that enhance neuromuscular blockade (gentamicin, clindamycin, neomycin, furosemide)
 - Physiologic factors that prevent reversal of neuromuscular blockade (hypokalemia, respiratory acidosis) or enhance the blockade (hypothermia, hypermagnesemia)
- III. Physical factors
 - Obesity
 - Gastric dilation
 - Tight dressings
 - Body cast
- IV. Increased production of carbon dioxide
 - Sepsis
 - Shivering
 - Malignant hyperthermia
- V. Underlying hyperthermia
 - Chronic obstructive pulmonary disease with CO₂ retention
 - Neuromuscular—chest cage dysfunction (kyphoscoliosis)
 - Acute or chronic respiratory failure of any etiology

Modified from Feeley TW. The recovery room. In: Miller RD, ed. *Anesthesia*. 2nd ed. New York: Churchill Livingstone; 1986:1921; and Wyngaarden JB, Smith LH Jr, eds. *Cecil Textbook of Medicine*. 18th ed. Philadelphia: WB Saunders; 1988:417, 472, 474.

have been noted prior to leaving the operating room; (b) respiratory difficulty with hypercapnia (Table 35.5); and (c) muscle weakness (Table 35.6).

- Several risk factors for the development of prolonged paralysis are renal failure, concomitant drug use, length of administration, monitoring technique used, and the use of steroids in patients receiving steroid-based drugs such as pancuronium or vecuronium.

Diagnosis

- Most anesthesiologists monitor the depth of neuromuscular blockade with a **twitch-stimulating device** or a group of clinical signs. Nevertheless, some patients remain with residual neuromuscular blockade. This condition may take the form of an apparent alteration in mental status (see Table 35.4)
- The key point is to **recognize the problem**, with early intubation if necessary.

Treatment

- If residual neuromuscular blockade is present, reversal may be necessary. If prolonged blockade results from succinylcholine, which can occur in patients with pseudocholinesterase deficiency, reversal agents will not be of any benefit. The diagnosis is made by measuring pseudocholinesterase activity in plasma,
- If a **nondepolarizing blocking agent** was used, reversal may be attempted with anticholinesterases and anticholinergics (Table 35.7).

TABLE 35.6

ETIOLOGY OF PROLONGED NEUROMUSCULAR BLOCKADE

- I. Nondepolarizing neuromuscular blocking agents
 - Intensity of neuromuscular blockade
 - Renal failure (decreased metocurine and pancuronium excretion)
 - Hepatic failure (decreased pancuronium and vecuronium excretion)
 - Residual potent inhaled anesthetic agent
 - Inadequate dose of reversal agents
 - Hypothermia
 - Acid-base state
 - Hypokalemia, hypermagnesemia
 - Drugs
 - Antibiotics (gentamicin, clindamycin, and multiple other drugs with several mechanisms)
 - Local anesthetics
 - Antiarrhythmics (quinidine)
 - Furosemide
 - Dantrolene
 - Trimethaphan (possibly)
 - Underlying diseases (myasthenia gravis, myasthenic syndrome, familial periodic paralysis)
- II. Depolarizing neuromuscular blocking agents (succinylcholine)
 - Decreased effective pseudocholinesterase
 - Phase II block
 - Hypermagnesemia
 - Local anesthetics

Modified from Miller RD, Savarese JJ. Pharmacology of muscle relaxants and their antagonists. In: Miller RD, ed. *Anesthesia*. 2nd ed. New York: Churchill Livingstone; 1986:889.

Malignant Hyperthermia

- Manifestations of malignant hyperthermia (MH) may be divided into **early, late, and postcrisis** phases (Table 35.8). The differential diagnosis of MH includes sepsis, light anesthesia, thyrotoxicosis, myotonias, neuroleptic malignant syndrome, and pheochromocytoma.

TABLE 35.7

REVERSAL AGENTS USED WITH NEUROMUSCULAR BLOCKING AGENTS

Anticholinesterase	Anticholinergic
Neostigmine 35–70 µg/kg (maximum, 5 mg)	Atropine 20 µg/kg or
Edrophonium 500–1,000 µg/kg	Glycopyrrolate 10 µg/kg
Pyridostigmine 175–350 µg/kg (maximum, 20 mg)	

Modified from Miller RD, Savarese JJ. Pharmacology of muscle relaxants and their antagonists. In: Miller RD, ed. *Anesthesia*. 2nd ed. New York: Churchill Livingstone; 1986:889.

TABLE 35.8

SIGNS OF MALIGNANT HYPERTHERMIA

Early signs	Late signs	Postcrisis signs
Skeletal muscle rigidity	Hyperpyrexia—may exceed 43°C (109.4°F)	Muscle pain, edema
Tachycardia and hypertension	Cyanosis	Central nervous system damage
Elevated PetCO ₂	Serum electrolyte abnormalities	Renal failure
Acidosis	Elevated serum creatinine phosphokinase	Continued electrolyte imbalance
Dysrhythmias	Myoglobinuria	
	Coagulopathy	
	Cardiac failure and pulmonary edema	

PetCO₂, end tidal partial pressure of carbon dioxide.

Background

- MH is a pharmacogenetic clinical syndrome that usually occurs during general anesthesia. The incidence varies; fulminant cases are seen from 1 in 250,000 to 1 in 62,000 anesthetics.
- Its onset may be **delayed** for several hours

TABLE 35.9

ACUTE THERAPY FOR MALIGNANT HYPERTHERMIA

- I. **Discontinue all anesthetic agents.**
Hyperventilate with an FiO₂ of 1.0.
CO₂ is increased so hyperventilate to achieve a normal PaCO₂.
- II. **Dantrolene**
Intravenously 2 mg/kg every 5 min to a total of 10 mg/kg
Effective dosage should be repeated every 10–15 h for at least 48 h.
- III. **Sodium bicarbonate**
Initial dose (mEq) = (base excess × [body weight in kg])/4
Give half the calculated dose; repeat as determined by arterial blood gas studies.
- IV. **Control fever**
Iced fluids
Surface cooling
Cooling of body cavities with sterile iced saline
Heat exchanger with a pump oxygenator
Dantrolene
- V. **Monitor urinary output**
At least 0.5 mL/kg/h
If myoglobinuria is present, at least 1 mL/kg/h
- VI. **Further therapy**
Guided by blood studies, temperature, and urine output (Blood studies include blood gases, electrolytes, liver profile, coagulation studies [including DIC studies], serum hemoglobin and myoglobin, and urine hemoglobin and myoglobin.)

DIC, disseminated intravascular coagulation; FiO₂, fraction of inspired oxygen.

Modified from Askanazi J. Principles of nutritional support. In: Barash PG, Deutsch S, Tinker J, eds. *Refresher Courses in Anesthesiology*. Vol. 14. Philadelphia: JB Lippincott; 1986:1.

- The hallmark is rapidly **increasing temperature** caused by uncontrolled skeletal muscle metabolism that can result in rhabdomyolysis and death. Oxygen consumption can increase threefold, whereas blood lactate may increase 15- to 20-fold.
- The mechanism involves myoplasmic calcium accumulation and a failure of calcium uptake by the sarcoplasmic reticulum.
- A 24-hour per day **emergency phone number** for consultations has been set up by the Malignant Hyperthermia Association of the United States (1-209-634-4917).
- Evaluation of **susceptibility** includes a family history and measurement of baseline creatine kinase level, which is elevated in 70% of those affected.
- The definitive test is a **muscle biopsy** for contracture studies after exposure to halothane, caffeine, halothane plus caffeine, or potassium. A new approach is **genetic testing**.

Diagnosis

- Diagnosis must be considered in the presence of unexplained tachycardia, tachypnea, arrhythmias, mottling, cyanosis, hyperthermia, muscle rigidity, diaphoresis, or hemodynamic instability.
- The presence of more than one sign must initiate arterial and central venous blood gas analysis for metabolic and respiratory **acidosis** and **hyperkalemia**.
- Central **venous oxygen** and **carbon dioxide partial pressures** change more dramatically than do those of arterial blood.

Treatment

- The mortality rate of MH has decreased from 70% to less than 5% when recognized and treated appropriately because of improved therapy (Table 35.9).
- With fulminant MH, **PaCO₂ above 60 mm Hg, base excess more than –5 mEq/L, and a body temperature that is increasing by approximately 1°C every 15 minutes**, specific therapy with **dantrolene** is required.
- The mechanism of action of dantrolene is not completely clear, but it is known to affect the ryanodine receptor, which is a major calcium release channel of the skeletal muscle sarcoplasmic reticulum, thus **decreasing the intracellular calcium**. Because of dantrolene's poor water solubility, the **preparation** for intravenous use requires the full attention of at least one person. Help must be requested.

CHAPTER 36 ■ INITIAL MANAGEMENT OF THE TRAUMA PATIENT

- How does initial trauma care differ from other critical care treatment? **Time is the key**, as common traumatic injuries are rapidly lethal. Initial management of the trauma patient requires a different focus.
- **Prioritization**, aided by careful planning and a team approach, contributes to patient survival.

THE TEAM

- Treatment plan starts **before** the next trauma patient arrives.
- A multiply injured patient may require **several simultaneous interventions**.
- Having a team of **physicians, nurses, technicians, therapists, and aides** allows for parallel rather than sequential treatment.
- Adding personnel (e.g., x-ray technicians, respiratory therapists, surgical specialists) to your team can reduce treatment delays.
- Critically reviewing trauma resuscitations in your facility will reveal any needed additions or deletions of members to your team.
- Take a lesson from the National Association for Stock Car Auto Racing (NASCAR). A NASCAR team can change four tires and fill the gas tank in about a minute. To **function as a team**, you need to **practice as a team**.
- **Mock trauma drills** allow you to do it **over and over again** until you do it right. Do you have more than one chest tube set? How long does it take to get the drugs for a rapid sequence induction and intubation? Do you even have a pediatric endotracheal tube? Your team will need to establish intravenous (IV) access and administer fluid, gather baseline vital signs, and complete the primary survey in this time frame of minutes.
- Do team members understand the big picture (what needs to be done for the patient) beyond their specific assignments? Are they prepared to **shift roles** when necessary?

TRIAGE

- Called to the **scene of an accident**, paramedics initially triage the victims. They determine whom to transport and when and where to take them (following established community protocols). The number of patients and severity of their injuries are weighed against available resources.
- In a **mass casualty event**, you may need to evacuate the emergency department (ED) to make room for incoming patients. The seriously injured will be brought in slowly as patients with minor injuries flood into your waiting room. It is important that the vital role of making these initial triage decisions

be done by someone who is **experienced in trauma management**.

- Triage is **most effective at “ground zero,”** a site in the field where patients are gathered prior to transport. If roads and communications are disrupted, much of the initial trauma care may need to be provided at that site.
- Paramedics play a **critical role** even when triage is not an issue. Their observations may be the only **medical history** that is ever available.

PRIORITIZATION

- “**Airway, breathing, and circulation**” is worth repeating over and over as you struggle to revive a trauma victim. **An obstructed airway is lethal** within minutes. Securing an airway can buy enough time to address many other injuries.
- In a deteriorating patient **not responding to resuscitation**, it is more important to look for airway obstruction repeatedly (even in intubated patients).
- After ensuring **airway, breathing, and circulation**, “**D**” is a reminder to consider **disability** (i.e., to perform a **rapid neurologic assessment**). At the bare minimum, this should include an assessment of the **patient’s pupils** (size and reaction to light), **extremity motion** (looking for lateralizing signs), and **Glasgow coma scale**.
- “**E**” reminds you to **expose** the patient. Cutting off clothes may seem wasteful until you miss an unsuspected wound. Slight tracheal deviation may be the only sign of a tension pneumothorax. The odds of identifying this are vastly improved if the patient is exposed.
- Placing a **warmed blanket** allows you to quickly cover and uncover a patient. This mitigates hypothermia caused by cold IV fluid, field exposure, and ED exposure.
- In trauma, **coagulopathy is multifactorial**. Ongoing bleeding, attempted clotting, and crystalloid resuscitation lead to the direct loss, consumption, and dilution of platelets and clotting factors. With mild **hypothermia**, **platelets adhere poorly**. Below 33°C, **coagulation enzymes fail**. Once the core body temperature drops below 32°C, trauma patients have a 100% mortality. Hypothermia is a preventable cause of death mitigated by simple measures such as active warming blankets and warming the fluids and temperature of the ED trauma bay/operating room.

THE PRIMARY SURVEY

- The primary survey focuses on high-priority injuries, those that are **rapidly lethal and rapidly correctable** (Table 36.1).

TABLE 36.1

THE FOCUS OF THE PRIMARY SURVEY

Rapidly lethal and rapidly correctable injuries	Initial treatment
Airway obstruction	Obtain a secure airway
Tension pneumothorax	Needle thoracostomy
Open pneumothorax	Support ventilation
Cardiac tamponade	Decompression
Peripheral arterial injuries	Direct pressure

Airway Obstruction and Airway Management

- Failure in airway maintenance rapidly leads to death. Apart from the rare patient with severe facial trauma who requires an immediate cricothyroidotomy, trauma patients' airway should be approached in the standard fashion.
- Assume that all patients are at risk for a respiratory arrest and for a **cervical spine** injury and are likely to have a **full stomach**.
- If you have any doubt, err on the side of intubating the patient.

Airway Management and the Cervical Spine

- Any patient who rapidly decelerates (e.g., motor vehicle accident, fall) requires spinal stabilization.
- Protecting the spine is occasionally at odds with needed intervention. This conflict is best overcome by assigning one team member to maintain in-line **stabilization** (not traction) while other team members perform necessary interventions.
- **Cervical spine clearance** criteria are controversial and may require a C-spine series or computed tomography of the neck, to rule out fractures, followed by flexion/extension views or magnetic resonance imaging of the neck, to rule out ligamentous injuries. In an alert, cooperative patient who has no neck tenderness, no distracting injury, and a normal neurologic examination, the collar may be safely removed based on clinical exam.
- Clearing the C-spine is **not an immediate priority** and should be delayed until patients are stable.

Pneumothorax and Tension Pneumothorax

- **Pneumothorax** is one of the most common thoracic injuries. Air usually enters the pleural space from a lung injury. During normal inspiration, the diaphragm contracts, intrapleural pressure falls, and the lung expands via the bellows effect. If the pleural space contains trapped air, the lung cannot fully expand. Blood then circulates through nonaerated alveoli, leading to hypoxia.
- In **tension pneumothorax**, inspiration pulls air into the pleural space, but expiration compresses the lung and obstructs air egress. As pleural pressure builds, the mediastinum is **pushed to the contralateral side** (shifting the trachea), eventually kinking the superior vena cava and inferior vena cava.

- Venous pressure then rises (distending the neck veins), and **venous return falls**. As preload drops, **cardiac output drops**, and then blood pressure drops.
- Patients **die from cardiogenic shock**, not hypoxia, although hypoxia may also be present.
- **Do not wait for chest radiograph** confirmation. In rapidly deteriorating patients, chest tube insertion may take too long. Use the largest IV catheter immediately available (ideally 14- or 16-gauge). Place the catheter in the **second or third intercostal space**, in the **midclavicular line**, aiming toward the back.
- Regardless of whether the patient had a tension pneumothorax, the outcome will be a simple pneumothorax. A **chest tube** should then be placed in the fifth intercostal space in the midaxillary line.
- **Volume loading** should be done simultaneously for treating a tension pneumothorax. Increasing the venous volume (and pressure) will overcome the venous obstruction (until the mediastinum shifts further).

Open Pneumothorax and Flail Chest

- There is a large hole into the chest. As the patient tries to breathe, air moves in and out through the hole, therefore the name "**sucking chest wound**."
- Intrapleural pressure never falls, so the ipsilateral lung never expands.
- There are two treatment options: (a) **Cover the hole** and create a simple pneumothorax, which can then be treated with tube thoracostomy, or (b) intubate the patient so **positive pressure ventilation** will expand both lungs regardless of the presence of an open pneumothorax.
- **Flail chest** has similar pathophysiology. If three or more ribs are broken in two places, the "flail" segment moves in and out as the patient tries to breathe. There are three choices: (a) Place a chest tube, (b) intubate, or (c) do both.

Cardiac Tamponade

- **Beck's triad** (hypotension, jugular venous distention, and muffled heart sounds) and **pulsus paradoxus** (an exaggerated drop in systolic blood pressure of >10 mm Hg with inspiration) are the hallmarks of cardiac tamponade. These clinical signs are **less reliable in trauma**. Hypotension is nearly universal, hypovolemia may prevent jugular venous distention, and ED noise obscures heart sounds.
- The widespread adoption of focused abdominal **sonography** for trauma has made it easier to identify cardiac tamponade.
- As blood enters the rigid pericardial sack, it **prevents the heart from filling** during diastole. **Venous return is obstructed**, venous pressure rises, and cardiac output falls. The rapid infusion of IV fluid will transiently raise the blood pressure. Decompression is key, followed by definitive correction of the underlying injury.
- **Pericardiocentesis** has been used effectively for trauma. The technique is outlined in Chapter 16. However, the preferred treatment is subxiphoid pericardial window or emergency room thoracotomy. Decompression buys time but rarely addresses the underlying injury. Patients should, therefore,

TABLE 36.2

ESTIMATED FLUID AND BLOOD LOSSES BASED ON PATIENT'S INITIAL PRESENTATION

	Class I	Class II	Class III	Class IV
Blood loss (mL)	Up to 750	750–1,500	1,500–2,000	>2,000
Blood loss (% blood volume)	Up to 15%	15%–30%	30%–40%	>40%
Pulse rate	<100	>100	>120	>140
Blood pressure	Normal	Normal	Decreased	Decreased

From American College of Surgeons Committee on Trauma. *ATLS Advance Trauma Life Support for Doctors*. Chicago: American College of Surgeons; 2004:74 (Table 1).

be expeditiously taken to the operating room for median sternotomy or anterolateral thoracotomy.

Peripheral Arterial Injuries

- Significant arterial bleeding from extremity laceration is sometimes “audible.” **Direct pressure** is the treatment of choice with peripheral arterial injuries. Tourniquets cut off collateral circulation and are best reserved for those situations where you need to stop bleeding while carrying the victim to safety. Direct clamping is instantaneously effective but may be difficult in the emergency room. A clamp may crush the artery, reducing the length available for a primary anastomosis and may damage adjacent nerves and veins.

Resuscitation

- Resuscitation starts in the field and continues after arrival to ED.
- It is rare for patients to develop congestive heart failure from resuscitation in the emergency room even if they have underlying cardiac disease.
- Under-resuscitation is common. Young, athletic patients may be able to **compensate** for significant blood loss without tachycardia or hypotension. Essential **hypertension and heart block** also make it difficult to interpret vital signs in the elderly.
- As a sign of shock, tachycardia is more sensitive than hypotension; however, tachycardia may reflect pain rather than blood loss. With the foregoing caveats, **continuously monitoring the vital signs** is the best way to gauge the efficacy of ongoing resuscitation (Table 36.2).
- As a general guide, a **palpable carotid pulse** implies that the blood pressure is at least 60 mm Hg; a **femoral pulse** implies that the blood pressure is over 70 mm Hg; and a **radial pulse** implies 80 mm Hg.

Intravenous Access

- “Two large-bore IVs, placed at different sites,” is a tenet of trauma resuscitation. “Large bore” implies that the line can be used to rapidly transfuse blood.

- Commercial **warming equipment** (e.g., Level 1 or Rapid Infusion System) and simple pressure bags can greatly increase the transfusion pressure. Large IV catheters (No. 6 or No. 8 French) are readily available and can be placed easily using the Seldinger technique.
- A shorter length and larger diameter IV access are advantageous.
- If you place femoral lines in patients with pelvic trauma, you may find one of your lines infusing into the peritoneal cavity through a lacerated iliac vein. Whenever possible, **place IV lines away from the site of trauma**.

Colloid, Crystalloid, and Blood Substitutes

- Restoring volume can be achieved with colloid or crystalloid. Restoring oxygen-carrying capacity requires red cells.
- **Crystalloid** should be used first in trauma resuscitation. It must be isotonic either normal saline (0.9% NaCl) or Ringer lactate. Crystalloid equilibrates throughout the interstitial and intracellular spaces. As a consequence, 3 L of crystalloid is needed to replace 1 L of blood.
- If patient remains hypotensive after 2 L of crystalloid, O-negative or type-specific blood should be started.

Permissive Hypotension

- In models of uncontrolled hemorrhagic shock, aggressive resuscitation may increase mortality by increasing the bleeding from unsecured injured vessels. Improved outcome in younger patients with penetrating torso trauma has been reported with permissive hypotension, but this treatment should not be extrapolated to other types of patients until further studies are done.

THE SECONDARY SURVEY

This chapter has explored the initial management of the trauma patient. After ruling out injuries that are *rapidly lethal and rapidly correctable*, many **other injuries remain**. Some may be severe, contributing to death and disability. To avoid missing these injuries, the **secondary and tertiary survey** should be thorough, detailed, and compulsive.

CHAPTER 37 ■ SECONDARY AND TERTIARY TRIAGE OF THE TRAUMA PATIENT

The previous chapter covers the initial assessment and care of the injured trauma patient. The patient will make the transition to the more comprehensive capabilities of the inpatient setting. This chapter is focused on **transport, transfer of care to the intensive care unit (ICU) team, the gathering of additional information, continued resuscitation, and a more complete and thorough assessment of the patient's injuries, including commonly missed injuries.**

TRANSPORT

- Appropriate equipment, monitoring, and adequate personnel are necessary for **safe transport** (Table 37.1).

COMMUNICATION

- Communication between areas of transfer, between and among nursing staff, physicians, and even hospital administrators, is essential.
- Early **communication with the family** allows the family members to transition to an emotional state where they are capable of dealing with the issues at hand. From the family, a thorough **history** may be obtained with attention to **chronic diseases, anticoagulant use** (aspirin, warfarin, clopidogrel, etc.), and patient **allergies**. Finally, **informed consent** should be obtained for any planned invasive procedures.
- The **social worker** has the ability to obtain insight into **family dynamics** and resources. They may interact with **law enforcement** officials and get a thorough description of the circumstances surrounding the issue, even as the acute resuscitation and management phase is taking place.

INITIAL INTENSIVE CARE UNIT CARE

Reassessing the ABCs while Maintaining Vital Function

- Arrival in the ICU represents a time for **reassessment** of patient status, particularly the **ABCs (airway, breathing, circulation)**.
- The **airway** may be assessed in standard fashion: in the non-intubated patient, by patient's ability to **speak**; in intubated patients, by confirmation of endotracheal tube placement using of end-tidal carbon dioxide and chest radiograph.
- Assessment of **breathing** should consist of both auscultation of the lungs and confirmation of adequate oxygen saturation via pulse oximetry.

- Evaluation of **circulatory status** should include auscultation of the heart, confirmation of pulses, measurement of blood pressure, and verification of adequate intravenous access.
- Two large-bore **intravenous lines** should be present, although a large-bore central venous line (e.g., a No. 9 French introducer) may be preferred in the critically injured patient as it is less likely to become dislodged, allows central venous pressure measurements, and can provide a port of entry for a right heart catheter should this be desired. The authors recommend a subclavian approach due to the lesser incidence of catheter-related bloodstream. The femoral vein may also be utilized for rapid access; however, femoral venous catheters should be removed within 24 hours due to the risk of deep vein thrombosis.

PERSISTENT SHOCK

- In the trauma patient, persistent shock is **hemorrhage** until proven otherwise, and a meticulous search for hidden sources of bleeding is indicated, such as **scalp lacerations** (bleeding edges can be quickly sutured with a large monofilament suture) and **fractures**, which should be aligned and temporarily splinted to avoid further bleeding.

Management of the Patient in Persistent Hemorrhagic Shock

- Resuscitation of the bleeding patient in shock is best performed with **blood and fresh frozen plasma in a 1:1 ratio**. In patients requiring more than 10 units of blood replacement, it is helpful to have a **massive transfusion protocol** in place to guide management (Fig. 37.1).
- Patients requiring massive transfusions may benefit from **recombinant factor VIIA**, although studies demonstrating a survival benefit are lacking.

Goal-directed Therapy

- Goal-directed therapy refers to the use of resuscitation end points (**cardiac index, oxygen delivery (DO₂I), mixed venous O₂ saturation**) to guide management of the patient in shock.
- Though controversial, there is a general consensus that maintenance of tissue oxygenation is beneficial in preventing the sequelae of shock. Debate has centered on the specific end points that should be utilized, whether a pulmonary artery catheter should be used, and whether normal or supranormal oxygen delivery values should be pursued. This topic is discussed in other chapters (see Chapters 7 and 23).

TABLE 37.1**AMERICAN COLLEGE OF CRITICAL CARE MEDICINE/SOCIETY OF CRITICAL CARE MEDICINE GUIDELINES FOR INTRAHOSPITAL TRANSFER OF THE CRITICALLY ILL PATIENT**

Pretransport coordination	Continuity of care ensured by physician-to-physician and/or nurse-to-nurse communication to review patient condition and the treatment plan Confirmation by the receiving location that it is ready to receive the patient Coordination of appropriate hospital personnel (e.g., respiratory therapy) to be available on patient arrival
Accompanying personnel	Minimum of two people In unstable patients, a physician with training in airway management, advanced cardiac life support (ACLS), and critical care training or equivalent
Accompanying equipment	A blood pressure monitor (or standard blood pressure cuff), pulse oximeter, and cardiac monitor/defibrillator to accompany every patient without exception When available, a memory-capable monitor with capacity for storing and reproducing patient bedside data Airway management equipment and oxygen source to supply for projected needs and 30-minute reserve Basic resuscitation medications (epinephrine, antiarrhythmic agents) If employing a transport ventilator, must have alarms to indicate disconnection and excessively high airway pressures and must have a backup battery power supply
Monitoring during transport	At a minimum, continuous electrocardiographic monitoring, continuous pulse oximetry, and periodic measurement of blood pressure, pulse rate, and respiratory rate

Adapted from Warren J, Fromm RE Jr, Orr RA, et al. 2004. Guidelines for the inter- and intrahospital transport of critically ill patients. *Crit Care Med.* 2004;32:256.

Schedule for Massive Transfusion Protocol Shands at the University of Florida					
Shipment	Red Blood Cells	Plasma	Platelet Dose	**Cryo	***rFVIIa
*1	10 (O-Neg)	4(AB)			
2	10	4	1	10	rFVIIa
3	10	4	1		
4	10	4	1	10	rFVIIa
5	10	4	1		
6	10	4	1	10	

The shipment number refers to the allotment of blood components (Red Blood Cells, Plasma, Platelets, Cryoprecipitate, and rFVIIa) provided at each step of massive transfusion. At the conclusion of each step, the decision must be made by the team providing care whether or not to order the next shipment of blood products.

Definition of massive transfusion

Massive transfusion at Shands at the University of Florida is defined as a presumed need for the transfusion of at least 10 units of packed red blood cells (PRBC) in an adult patient or at least five (5) units of PRBC in a child within a short time frame (i.e. two (2)-hour time period).

Adult	Greater than 10 units
6-12 year old child	Greater than or equal to 5 units
4-5 year old child	Greater than or equal to 3 units
2-3 year old child	Greater than or equal to 2 units
0-1 year old child	Greater than or equal to 1 unit

*Shipment 1 is located in the Satellite Blood Bank Refrigerator, located in the Emergency Department and Operating Room.

**Cryo=Cryoprecipitate

***Recombinant Factor VIIa (rFVIIa) is not routinely shipped and must be ordered from Pharmacy. These are recommended intervals if rFVIIa is clinically warranted.

FIGURE 37.1. The massive transfusion protocol of the Acute Care Surgery Service of Shands Hospital at the University of Florida (Appendix A).

- Values obtained through **right heart catheterization** are considered the “gold standard” physiologic measurements to which noninvasive cardiovascular measurements are compared. The primary therapeutic end-point value obtained through right heart catheterization is DO_2I , which is a **function of cardiac index, hemoglobin, and oxygen saturation**.

BLUNT CARDIAC INJURY

- **Cardiac function** is **essential** in delivering oxygen to the tissues, and delayed recognition of myocardial dysfunction will lead to tissue ischemia and poor outcome.
- Blunt cardiac injury (BCI) may be classified according to descriptors of the specific abnormalities and can range from minor clinical manifestations to fulminant cardiac failure and death:
 - BCI with minor electrocardiogram (ECG) or enzyme abnormality
 - BCI with complex arrhythmia
 - BCI with coronary artery thrombosis
 - BCI with free wall rupture
 - BCI with septal rupture
 - BCI with cardiac failure
- BCI must be suspected in any case involving thoracic trauma and may coexist with rib/sternal fractures, hemopneumothorax, and pulmonary contusion.
- **Clinical exam** may show hypotension, visual sequelae of chest trauma (abrasions, bruising, seatbelt sign, or steering wheel imprint), flail chest, rib fractures, sternal fractures, findings consistent with cardiac tamponade such as abnormal heart sounds (muffling, distance, S_3 , S_4 , murmurs, bruits, or rubs), and jugular venous distention.
- **Bedside sonography** in trauma focused abdominal sonography in trauma (FAST) exam should be performed to look for fluid in the pericardium. There are no ECG findings that are pathognomonic for BCI; however, the finding of an abnormal ECG should prompt further workup. With regard to the **chest radiograph**, there are no findings that will definitively demonstrate cardiac injury, but they often prove useful by demonstrating some of the associated injuries that may accompany BCI.
- **Troponin I** testing may have a sensitivity ranging from 23% to 100% and a specificity of 85% to 97%.
- The value of **formal echocardiography** has been studied in BCI. In patients with hemodynamic instability, it is felt that transthoracic echocardiography may provide diagnostic information; however, transesophageal echocardiography also allows evaluation of the aorta.
- The patient with BCI accompanied by hypotension may benefit from use of **right heart catheterization** to maintain cardiac index and tissue perfusion.

Management

- Management consists of treating hypotension, arrhythmias, and pump failure.
- **Complex arrhythmia** occurring from 2% to 30% may consist of atrial dysrhythmia, ventricular dysrhythmia, or commotio cordis (myocardial concussion). Commotio cordis is a rare entity where a blow to the chest results in an immedi-

ate rhythm disruption without myocardial structural damage and may be the cause of **sudden death** in young people.

- **Cardiac failure** with BCI is less commonly seen. Supportive care with volume and inotropic agents is the mainstay of management in these patients. In extreme cases, use of intra-aortic balloon counterpulsation pump has been used, but the benefits and risks of heparinization in a trauma patient must be considered.
- **Myocardial wall rupture** is rare. Should this injury be suspected or the diagnosis confirmed with echocardiography, immediate operation via open thoracotomy is the sole management option.
- **Coronary artery thrombosis** with BCI is uncommon. The diagnosis is made via findings of ST-segment changes consistent with myocardial ischemia after blunt chest trauma. Management is similar to that employed when a patient presents with a myocardial infarction of another etiology. Percutaneous angioplasty, stenting, and bypass are available options. Some patients may have had a myocardial infarct first that precipitated the accident.

EXTREMITY COMPARTMENT SYNDROME

- Secondary and tertiary survey should identify fractures that may not be life-threatening but may lead to severe disability if not recognized. The extremities are divided into several fascial compartments that contain the musculature, blood vessels, and nerves that supply the respective limbs. During trauma and/or due to resuscitation, increased pressure causes impaired lymphatic, venous, and arterial flow and may lead to muscle necrosis and permanent nerve damage.

Clinical Suspicion

- Extremity compartment syndrome most commonly occurs in fractures of the **tibial shaft or distal radius**, followed by soft-tissue injuries **without fracture**. Though compartment syndrome is most commonly associated with fracture within a closed space, an open fracture does not preclude the presence of a compartment syndrome. Patients taking anticoagulant medications are at increased risk.

Diagnosis and Monitoring

- The presence of the “six P’s” (**pain, pulselessness, pallor, pressure, paresthesias, and paralysis**) are the keys to diagnosis, although originally described for acute arterial occlusion rather than compartment syndrome.
- **Pain during passive range-of-motion** exercises is often the first sign of a developing problem. **Pulselessness** is a late finding once compartmental pressures have become great enough to overcome arterial pressure. **Paresthesias** are potentially ominous signs, as they may represent muscle or nerve ischemia;
- As the clinical diagnosis can sometimes be difficult and/or unclear, **monitoring devices** have been developed to evaluate intracompartmental pressures. Patients demonstrating a ΔP value of 20 mm Hg between measured compartment pressure and diastolic blood pressure should undergo fasciotomy.

Management

- **Fasciotomy** in the extremity is accomplished through either a single incision on the anterolateral calf or incisions on the medial and lateral calf, with subsequent division of the fascial compartments.
- After fasciotomy, a popular method of dressing the patient is with **vacuum-assisted closure** although wet-to-dry dressings with saline will provide adequate coverage. In cases where the patient has developed muscle necrosis, debridement will be necessary at an interval operation between fasciotomy and closure. Closure may be accomplished primarily, if tension allows, or by secondary intention. Skin grafting is the final option and should be considered any time that tension precludes closure by the first two techniques.

ABDOMINAL COMPARTMENT SYNDROME

- Abdominal compartment syndrome (ACS) occurs from increased intra-abdominal pressure either from a primary cause (bleeding) or from resuscitation. There is hypoperfusion secondary to a **low cardiac output** (from impaired venous return) and **high peak inspiratory pressure** with **hypercarbia**, and there is **oliguria**. The surgical technique performed for damage control is a continuum that includes primary resuscitation, damage control celiotomy, secondary resuscitation, and delayed reconstruction. If ACS is recognized late or goes unrecognized, it can lead to multiple organ failure and death.

Clinical Suspicion, Diagnosis, and Monitoring

- A normal intra-abdominal pressure is approximately 5 mm Hg but may be higher with obesity. **Bladder pressure** may be measured by injecting 50 to 100 mL of sterile saline into the aspiration port of the Foley drainage tube. The catheter is then clamped distal to the aspiration port, and a 16-gauge needle is used to connect a pressure transducer to the aspiration port of the catheter. The pressure transducer should be zero-referenced to the level of the **midaxillary line** or the symphysis pubis.
- For continuous, indirect intra-abdominal pressure measurement, a balloon-tipped catheter in the stomach or a continuous bladder irrigation method is recommended (Fig. 37.2). A pressure of 25 mm Hg or higher is associated with organ dysfunction and considered clinical intra-abdominal hypertension.
- The inaugural World Conference on Abdominal Compartment Syndrome held in Australia in December 2004 produced consensus definitions as follows:
 - **Intra-abdominal hypertension** is defined by either one or both of the following: (a) an intra-abdominal pressure ≥ 12 mm Hg, recorded by a minimum of three standardized measurements conducted 4 to 6 hours apart; (b) an **abdominal perfusion pressure** (abdominal perfusion pressure = mean arterial pressure–intra-abdominal pressure) ≤ 60 mm Hg, recorded by a minimum of two standardized measurements conducted 1 to 6 hours apart.

TABLE 37.2

GRADING OF INTRA-ABDOMINAL HYPERTENSION

Grade	Intra-abdominal pressure (mm Hg)
I	12–15
II	16–20
III	21–25
IV	>25

Adapted from World Society of Abdominal Compartment Syndrome. <http://www.wsacs.org/>.

- Intra-abdominal hypertension is graded as described in Table 37.2.
- ACS was defined as the presence of an intra-abdominal pressure ≥ 20 mm Hg, with or without an **abdominal perfusion pressure** < 50 mm Hg, recorded by a minimum of three standardized measurements conducted 1 to 6 hours apart and single or multiple **organ system failure** that was not previously present.

Management

- Aggressive, nonsurgical, critical care support is of utmost importance and should include continuous cardiorespiratory monitoring and aggressive intravascular fluid replacement. **Excessive fluid resuscitation**, however, is **detrimental**. **Hyper-tonic** lactated or saline resuscitation may reduce the risk of secondary ACS due to lower fluid volume requirements during the acute resuscitation phase.
- Nonsurgical management of ACS is listed in Table 37.3.
- **Decompressive laparotomy** is the gold standard for treatment of ACS. Mesh can be used for temporary abdominal closure. Skin closure itself may be associated with increased intra-abdominal pressure, so care must be taken when selecting this option.

TABLE 37.3

COMPONENTS OF NONSURGICAL MANAGEMENT OF THE ABDOMINAL COMPARTMENT SYNDROME

Gastric decompression
Rectal enemas
Colonic prokinetic agents (neostigmine)
Continuous venovenous hemofiltration with aggressive ultrafiltration
Paralysis
Botulinum toxin into the internal anal sphincter
Paracentesis
Gastrointestinal prokinetic agents (cisapride, metoclopramide, domperidone, erythromycin)
Furosemide with or without use of human albumin 20%
Sedation
Body positioning

Adapted from Sugrue M. Abdominal compartment syndrome. *Curr Opin Crit Care*. 2005;11:333.

FIGURE 37.2. Intra-abdominal pressure monitoring device. The device is placed into the urinary drainage circuit. By changing the valve from “drain” to “measure,” intermittent measurements may be taken. This device allows measurement of intra-abdominal pressure without breaking or interrupting the urinary drainage circuit.

- Permanent abdominal closure is usually planned for a time after the acute phase of resuscitation when edema has subsided.

Potential Complications if Abdominal Compartment Syndrome is not Diagnosed in a Timely Manner

- Multiple organ dysfunction results from inadequate oxygen delivery to the tissues with low cardiac output and ventilatory failure. Prolonged bowel ischemia is associated with intestinal necrosis. The mortality rate is high if not promptly recognized and treated.

PELVIC FRACTURES

- Pelvic fractures often are indicative of a **high-energy** impact as the pelvic ring is an extremely stable bony structure; thus, pelvic fractures rarely occur in isolation.
- Mortality rate is about 10% in all patients and up to 80% with hemodynamic instability.
- Patients involved in motorcycle crashes, pedestrian injuries, falling from heights >15 feet, and in automobile accidents are high risk.
- Pelvic pain, pain on hip rotation, pain on pelvic compression, the presence of blood at the urethral meatus, and finding a perineal and/or scrotal hematoma have all been associated with pelvic fractures and warrant further investigation.

- Pelvic fractures represent another “hidden” source of hemorrhage, as patients may bleed >20 units into the retroperitoneal space; thus, a patient with an appropriate mechanism of injury and unexplained hypotension should have the diagnosis of pelvic fracture considered.

Diagnosis

- Plain film radiographs done in the ED usually identifies pelvic fractures but computerized tomography is superior to plain films and offers the advantage of identifying active hemorrhage at the site of pelvic fracture, in the form of a contrast “blush” on arterial phase imaging. The presence of a

blush should prompt mobilization of the interventional radiology team.

Management

- Beyond the usual components of the trauma resuscitation, management of the patient with severe pelvic fracture is aimed at **control of hemorrhage** and fixation of fractures.
- One of the first and fastest ways to decrease bleeding after pelvic fracture is through **external compression** of the pelvis. Circumferential wrapping of the pelvis with a bed sheet and clamping the sheet anteriorly is one technique. “Pelvic binders” are also commercially available.

- An **external fixator** may be applied reasonably rapidly, particularly in the case of a posterior ring disruption where a C-clamp may be used; fixations involving anterior disruptions may require the operating room.
- **Preperitoneal and retroperitoneal packing** have recently been receiving attention. This procedure can be performed rapidly and decreases the need for emergent angioembolization. Decreased transfusion requirements and a reduction in mortality have been observed. This method is helpful when angioembolization is not immediately available for hemodynamically unstable patients.
- In cases where computed tomography (CT) demonstrates a potential arterial source of bleeding (a blush), **angioembolization** should be performed. These techniques involves obtaining arterial access, selective cannulation of the iliac

vessels, and instillation of contrast dye to localize the bleeding source under fluoroscopic visualization. Upon identification of an actively bleeding site (noted by extravasation of contrast), embolization is performed through the injection of Gelfoam or coils. Angioembolization is extremely successful in the control of hemorrhage.

Delayed Diagnosis

- The evaluation of the critically injured patient does not always allow for immediate identification of all the injuries. Limitations in the examination of the patient due to mental status changes, and injuries that do not manifest on initial studies, lead to delays in diagnosis and possibly mortality.

COMMONLY MISSED INJURIES

- **4% to 6% of musculoskeletal injuries** are missed in multisystem trauma patients and rank number one in the missed-injury list. Risk factors include significant multisystem trauma, physiologic instability, altered sensorium, quickly applied splints for a less serious injury, poor-quality initial radiographs; and inadequate significance being applied to minor signs and symptoms.
- Injuries involving **retroperitoneal structures** have a strong potential for presenting in delayed fashion. Although CT scan has allowed for early detection of retroperitoneal hematomas, **pancreatic and duodenal** injuries can remain undetected in the initial survey.
- **Pancreatic injuries** occur in <5% of blunt abdominal trauma; however, they carry with them a substantial morbidity and mortality. In the alert patient, exam findings are typically nonspecific, with vague abdominal pain, epigastric discomfort, nausea, vomiting, and fever. Laboratory testing provides equally imprecise findings as an **elevated amylase** may hint at the diagnosis, but is not specific. CT findings are often subtle and may be delayed after injury.
- **Duodenal injuries** occur in <5% of blunt abdominal trauma and are equally challenging to diagnose, with similar features as pancreatic injury. Physical exam demonstrates ambiguous abdominal pain. Patients have nausea and vomiting, with development of progressively increasing tachycardia and fever. Laboratory findings are nonspecific, with elevated amylase levels suggestive of, but not diagnostic for, duodenal injury. Repeat CT scan may detect retroperitoneal air and extravasated oral contrast.
- Jejunum and ileal injuries may go undetected because the findings may be subtle. Small-bowel injuries affect 0.9% of blunt

trauma victims but have a high morbidity (29%) and mortality (19%).

- Physical examination is nonspecific with abdominal pain, nausea, vomiting, and later, signs and symptoms of peritonitis if perforation occurs. CT scan may show **unexplained free abdominal fluid with no solid-organ injury, bowel wall thickening** or, in the case of a perforation, free air or extravasated gastrointestinal contrast material. **Diagnostic peritoneal lavage (DPL)** may be helpful in this group of patients. It is recommended that patients with positive microscopic, white cell count, or biochemical criteria on DPL undergo exploratory laparotomy. The technique of DPL is described in Chapter 16.

THE ROLE OF THE TERTIARY SURVEY INSTRUMENT

- A **formal trauma tertiary survey** allows for the detection of missed injuries, should be done **in the first 24 hours after injury, and may detect 56% of all missed injuries and 90% of all clinically significant missed injuries.**
- Examples of our Acute Care Surgery Service's tertiary survey form are seen in Figures 37.3 and 37.4.
- We take advantage of the tertiary survey instrument to review and record the patient's mechanism of injury, medical history, physical examination findings, laboratory trends, final radiologist reads on imaging findings, the interventions that have been performed up to that point in time, and the patient's immediate plan of care.
- When many issues are being handled in the ICU, this **systematic approach to secondary and tertiary survey** assists in detecting missed injuries.

CHAPTER 38 ■ SURGICAL AND POSTSURGICAL BLEEDING

GENERAL OVERVIEW AND IMMEDIATE CONCERNS

- In patients experiencing life-threatening hemorrhage, a defined approach for prompt recognition of the underlying cause is used.
- First, attention is directed toward **stabilizing the patient**. This includes securing an adequate airway, ventilation, vascular access, and restoring intravascular volume.
- There should be immediate dialogue with individuals involved in the intraoperative management of the patient.

Bleeding related to **technical factors** that can be associated with the conduct of any surgical procedure (“**surgical bleeding**”) must be considered.

- A generalized slow oozing of blood from raw surfaces (often termed “**nonsurgical bleeding**”) is often a manifestation of a systemic disorder of hemostasis.
- The evolving coagulopathy may proceed swiftly in critically ill patients. Qualitative abnormalities of **platelet** function, depletion of both platelets and plasmatic **coagulation factors**, and **hypothermia** contribute to the coagulopathic state.
- Early recognition of the clinical symptoms and signs attributable to **hypovolemia**, (restlessness, anxiety, shortness

of breath, pallor, tachycardia, and oliguria) is compulsory. **Hypotension is a late sign** of significant hypovolemia.

- It is important to differentiate the **inherited (primary)** coagulation disorders, which are associated with a history of bleeding diatheses, from the more commonly **acquired (secondary)** coagulation disorders, which are the consequence of pathologic conditions and numerous medications.
- In parallel with the ongoing resuscitation of the bleeding patient, attention must be directed toward expeditiously **determining the need for surgical re-exploration.**

CAUSES OF POSTOPERATIVE BLEEDING

- Postoperative bleeding, often termed **local hemostatic failure** or **surgical bleeding**, is a known potential complication of any surgical procedure.
- The vast majority of patients affected typically present within the **immediate perioperative period**. Subtle signs may be evident in the postanesthesia care unit and generally become apparent within the first 8 hours after surgery.
- A high index of suspicion is necessary given that the **signs are nonspecific** in the postoperative period. Tachycardia may be from pain and anxiety, mental status changes from narcotic administration, or oliguria could be from anticipated third-space fluid sequestration after major surgery. **Hypotension is a late sign!**
- On occasion, **localized symptoms** may be elicited. Kehr sign is referred pain to the right shoulder due to blood under the right hemidiaphragm.
- **Serial hemoglobin** levels may assist in determining the degree of bleeding, but isolated, single values can be difficult to interpret due to either hemoconcentration or hemodilution.
- Certain surgical procedures are not associated with exsanguinating hemorrhage but can be life threatening. An expanding neck hematoma results in airway obstruction from both mechanical compression and from mural edema caused by lymphatic obstruction. The cause is frequently venous bleeding compounded by hypertension and liberal preoperative use of antiplatelet medications. Acutely reopening the incision and evacuating the hematoma is often lifesaving, although endotracheal intubation or rarely cricothyroidotomy may be required as a temporizing measure until the airway edema resolves.
- Caution must be exercised in interpreting **drain output** as drains can malfunction or tubings can obstruct with clot.
- There is no single criterion available to direct re-exploration for control of postoperative bleeding, and this decision is based on considering a number of variables. **The timing of the active bleed relative to the operative procedure, its duration, its rate, the potential for additional complications, the patient's age as a surrogate for physiologic reserve, and other comorbid diseases** must be considered.
- The most **conservative treatment** is to **return to the operating room** with **early control** of surgical bleeding. It is desirable to **correct any coagulopathy** prior to returning to the operating room. However, situations characterized by exsanguinating hemorrhage from failure of local surgical hemostasis may not allow for correction of the coagulopathy because of rapid ongoing consumption of coagulation factors and platelets.

- There are certain circumstances where operative re-exploration is obligatory, despite the fact that the bleeding may be self-limiting. A vascular anastomosis with a contained leak must be repaired to avert the consequences of false aneurysm formation and later rupture.
- There are some instances where bleeding is optimally addressed **without surgical intervention**. Some bleeding is amenable to arteriography with embolization or endoscopic control.

EVALUATION OF BLEEDING: CLINICAL HISTORY AND THE UTILITY OF DIAGNOSTIC TESTING

History

- A detailed **history and physical examination** are the most important preliminary steps in elucidating the cause of surgical bleeding and should be done simultaneously with resuscitative efforts. Collateral history from family members and previous medical records is helpful.
- A **history** of easy bruisability, excessive gingival bleeding after brushing of teeth, bleeding diathesis with dental extractions, hypermenorrhagia, frequent spontaneous epistaxis, melanic stools or spontaneous hematuria, petechiae or purpura, hemarthroses, and a family history of bleeding disorders may indicate a congenital or familial coagulation disorder, such as hemophilia A or B or von Willebrand disease.
- The **family pedigree** may provide important clues as to the presumptive disease process based on the pattern of inheritance, whether autosomal or sex-linked, dominant or recessive. Suspicion for a congenital disorder of coagulation is further raised by a **history of blood transfusions** required for common ambulatory procedures such as dental extractions, circumcisions, tonsillectomies, or biopsies. Due to differences in gene penetrance, not all individuals afflicted with inherited coagulation disorders are diagnosed at an early age, and coagulopathy may become unmasked when confronted by a major surgical procedure or trauma.
- A history of **liver disease or heavy ethanol consumption** should alert the clinician to the possibility of acquired plas-matic factor deficiencies, in addition to thrombocytopenia resulting from secondary hypersplenism with platelet sequestration.
- A thorough **medication history** is essential for many medications that interfere with hemostasis (aspirin, nonsteroidal anti-inflammatory agents, warfarin, ticlopidine, clopidogrel, or semisynthetic penicillins). Popular **supplements** that may aggravate bleeding are ginkgo, garlic, ginger, ginseng, feverfew, and vitamin E.
- **Nutritional assessment** is paramount, and careful evaluation for the presence of a **vitamin K deficiency** is obligatory, as this may occur in patients on parenteral nutrition or with cancer cachexia.
- Other variables that may affect the integrity of the coagulation system include previous irradiation, renal failure, and sepsis, which affect the coagulation cascade at multiple points.

Physical Exam

- Physical findings may assist in distinguishing localized surgical bleeding from systemic bleeding resulting from a coagulopathy.
- Presence of petechiae, purpura, and mucosal bleeding is often indicative of thrombocytopenia, a qualitative functional disorder of platelets or increased vascular fragility. Ecchymoses or spontaneous, nontraumatic hemarthrosis is consistent with plasmatic coagulation factor abnormalities or deficiencies such as hemophilia. Both platelet and plasmatic coagulation disorders are associated with hematomas.
- **Hepatic** insufficiency or failure can be presumptively identified by recognizing jaundice, ascites, angiomas, palmar erythema, asterixis, congestive splenomegaly, and testicular atrophy.
- **Splenomegaly** itself may also be associated with hematologic dyscrasias and malignancies associated with hemostatic abnormalities (lymphomas and leukemias).
- **Connective-tissue or collagen vascular disorders** that result in increased vascular fragility may manifest with petechiae, joint abnormalities, and a history of delayed wound healing. These conditions focus attention on the increased risk for a perioperative bleeding complication, which underscores the need for vigilance both intraoperatively and postoperatively.
- The **possibility of sepsis** as an underlying cause for the development of a coagulopathy must always be entertained in the postoperative, critically ill patient.

Coagulation Tests

- The establishment of a definitive diagnosis of a coagulation disorder rests on a **limited battery of laboratory tests**, usually **quantitative platelet count**, **prothrombin time (PT)**, **activated partial thromboplastin time (PTT)**, **fibrinogen level**, **thrombin time (TT)**, and **template bleeding time**.
- The PTT provides a global measure of the activity of factors XII, XI, IX, and VIII in addition to the common pathway factors shared by the extrinsic system (factors X, V, II, and I) and, therefore, identifies many of the inherited disorders of bleeding, typically a deficiency of factor VIII (hemophilia A), IX (hemophilia B), or von Willebrand factor, vWF (von Willebrand disease). It is worth noting that factor XII deficiency is not associated with any significant bleeding tendency despite abnormal prolongation of the PTT. Enzymatically active vWF is a necessary cofactor for optimum functioning of the factor VIII procoagulant protein.
- The PT exclusively evaluates factor VII, which is one of the vitamin K-dependent factors (in addition to factors II, IX, and X). Therefore, the PT is prolonged in individuals on warfarin therapy.
- Factor levels reflect a dynamic equilibrium, and **fibrinogen** is an acute-phase protein that increases in response to stress. The TT is a **qualitative measure of fibrinogen levels** and will be prolonged if the fibrinogen level is <100 mg/dL, by the presence of dysfibrinogenemia associated with liver disease, and also by circulating inhibitors. Its most useful role clinically is in the **detection of circulating heparin** not detectable by changes in the PTT.

DISORDERS OF PLASMATIC COAGULATION FACTORS: OVERVIEW

- Hemostasis involves a **complex interplay** between elements of the **vascular endothelium**, **plasmatic coagulation factors**, **platelets**, and **the fibrinolytic system**.
- Primary isolated disorders of the fibrinolytic system as a cause of major bleeding are rare in the critically ill patient and are covered elsewhere.
- Disorders of the clotting system can be broadly classified as **congenital or acquired**.
- **Acquired coagulopathies** are **relatively common** in the postoperative intensive care unit patient, and these disorders can be operationally separated into those involving **platelets**, the **plasmatic coagulation factors**, or both.

Platelet

- Surgical and postsurgical bleeding may therefore result from either **quantitative (thrombocytopenia)** or **qualitative (abnormal function)** platelet disorders.

Quantitative Platelet Disorders

- Defined as a platelet count $<140 <10^9/L$ may be attributed to (a) a **decrease in production** of platelets (aplastic anemia, hypoplastic bone marrow, chemotherapy, space-occupying lesions of the bone marrow as seen with malignancy), (b) **ineffective production** (vitamin B₁₂ or folic acid deficiency states), (3) **platelet sequestration** (primary or secondary hypersplenism), or (d) **increased destruction or consumption** (hemorrhage, microangiopathic processes such as thrombotic thrombocytopenic purpura, disseminated intravascular coagulation [DIC], hemolytic-uremic syndrome, immune destruction due to antiplatelet antibodies such as in posttransfusion purpura or idiopathic thrombocytopenic purpura), or dilution of circulating platelet volume (massive blood transfusion).
- Platelet counts of $50 <10^9/L$ or higher are generally considered adequate for surgical hemostasis in the absence of an associated qualitative functional defect. Counts **below 20** $<10^9/L$ are associated with increased risk for **spontaneous hemorrhages**.

Qualitative Platelet Disorders

- Qualitative bleeding disorders are not measured by the standard battery of coagulation tests. The template bleeding time is not commonly used. This test has been attended by poor reproducibility.
- Defects may be **inherited** (Bernard-Soulier syndrome, abnormal release mechanism, Glanzmann thrombasthenia, storage pool disease, or von Willebrand disease) or **acquired** (uremia, drugs, myeloproliferative disorders).
- Numerous drugs are associated with inhibition of platelet function. It is generally recommended that antiplatelet medications, such as aspirin, ticlopidine, and clopidogrel, are discontinued approximately **7 to 10 days** prior to surgery. For **nonsteroidal anti-inflammatory agents**, some investigators advocate 2 days of abstinence.

- Discontinuing the antiplatelet drug combined with use of **desmopressin** and **platelet transfusions** has been beneficial in treating bleeding encountered in these situations.
- **Hypothermia** is another common cause of acquired qualitative platelet defect.
- There is a qualitative platelet function defect related to the **degree of uremia**. Use of desmopressin and cryoprecipitate may be helpful temporizing measures until dialysis is initiated. Conjugated estrogens have also been used with some success, but the effects are not immediate.
- Petechiae, purpura, and mucosal oozing, characteristic of thrombocytopenic states, may also be observed in qualitative platelet disorders and in conditions associated with increased vascular fragility.

Coagulation Factors

- Disorders involving plasmatic coagulation factors are generally caused by either (a) a **decrease in production** of clotting factors or (b) an **increase in consumption** of circulating coagulation factors.

Decreased Production

- Decreased production of circulating plasmatic coagulation factors occurs secondary to **liver failure** (with the exception of factor VIII); **vitamin K deficiency** (seen with oral antibiotic usage, which depresses gut flora in the setting of nutritional deficiency); **malabsorption** syndromes (seen in celiac sprue, chronic diarrheal conditions, or **obstructive jaundice**); and use of **warfarin**.
- In these situations, therapy is acutely centered on replacement of coagulation factors, most commonly with use of **fresh frozen plasma (FFP)**. **Vitamin K** is administered parenterally in patients with deficient states or to reverse the effects of warfarin, although the effects are not generally seen for 24 to 36 hours after administration.

Impaired Function

- The effect of **hypothermia** on antagonizing normal functioning of the hemostatic mechanism globally has been described under qualitative platelet abnormalities, but all enzymatic processes function optimally in a narrow temperature range. Reliance solely on the values of the PT, PTT, or TT is misleading since these assays are performed by both manual and automated **laboratory methods at 37°C**.
- **External warming measures** include blankets generating heated air, warming of all fluid infusions, heated humidifier in ventilated patients, and warming the environment.
- Normal physiologic processes (fibrinolytic system) exist to control for unremitting clot formation. Impaired function of the coagulation cascade may be the result of various disorders that are characterized by **circulating anticoagulants**, abnormal protein products, or accumulation of proteinaceous breakdown products that affect the normal function of coagulation proteins.
- Collagen vascular diseases, such as systemic lupus erythematosus, is an example. In these patients an antibody is produced (**lupus anticoagulant**) that affects the coagulation cascade at the juncture of the intrinsic and extrinsic systems,

resulting in **prolongation of both the PT and PTT *in vitro***. Paradoxically, these patients tend to be **hypercoagulable**, and if clinically significant bleeding is noted, it is attributable to associated thrombocytopenia and increased vascular fragility.

- When there are elevated titers of either the **lupus anticoagulant** or **anticardiolipin antibodies**, or both, these patients may present with manifestation of the antiphospholipid antibody syndrome with generalized microvascular thrombosis, thrombocytopenia, gangrene of the extremities, multiorgan failure, and death. Plasmapheresis, anticoagulation, and immunosuppressive therapy serve as the foundation of treatment.
- Other commonly acquired inhibitors or circulating anticoagulants include **factor VIII inhibitors** and **factor IX inhibitors**, related primarily to prior frequency of transfusion with plasma-derived blood concentrates and alloimmunization. Exogenously administered **heparin**, the prototype for anticoagulation therapy, binds to circulating **antithrombin III** and catalyzes its ability to neutralize the action of a number of coagulation factors. The end result is interference with the normal coagulation cascade.
- Disorders characterized by the production of abnormal globulins, often referred to collectively as the **paraproteinemias** (associated with multiple myeloma and Waldenstrom macroglobulinemia), also result in interference with coagulation proteins and inhibition of fibrin polymerization. In these conditions the PT, PTT, and TT are prolonged. **Fibrinogen/fibrin degradation products** also inhibit fibrin polymerization, as does uremia, with prolongation of the PT, PTT, and TT. Treatment of the coagulopathy associated with all of these conditions consists of replacement of deficient coagulation factors when bleeding is dominant and definitive treatment directed at the underlying disease process.

Increased Destruction or Consumption

- The most common cause of increased destruction of plasmatic coagulation factors has been variously termed **DIC**, **defibrination syndrome**, or **consumptive coagulopathy**. This syndrome is characterized by a hemorrhagic diathesis with unrestrained clotting and fibrinolysis in the vascular microcirculation, initiated by activation of the intrinsic or the extrinsic system, or both.
- The end point is normalization of the PT, PTT, TT, and platelet count.
- The underlying pathophysiology has been best elucidated with Gram-negative infections, with **endotoxin** (cell wall lipopolysaccharide) triggering the intrinsic system by activation of factor XII directly and by factor XII exposure to subendothelial collagen. **Traumatic injuries** (particularly involving brain, bone, or liver), thermal injuries, and severe crush injuries, as well as surgical procedures may produce a consumptive coagulopathy. Secondary infection and hemorrhagic shock further serve to aggravate the coagulopathy, especially if acidosis, hypothermia, or tissue ischemia and necrosis develops.
- **Obstetric complications** can result in some of the most profound and challenging instances of DIC from amniotic fluid embolism, abruptio placentae, retained dead fetus, and eclampsia. There is massive systemic release of tissue thromboplastin that generates a fulminant course characterized by bilateral renal cortical necrosis to frank cardiopulmonary collapse, shock, multiorgan failure, and death.

- The **laboratory diagnosis** of DIC is readily established with routinely available tests. The **PT, PTT, and TT are all prolonged**, and the **platelet count is decreased**. Depending on the severity of the disease process, **fibrinogen** may not be detectable. Fibrinogen/fibrin **degradation products** are elevated, and the peripheral blood smear often reveals the presence of schistocytes. Factors I (fibrinogen), V, VIII, and XIII tend to be markedly depressed. In milder forms, fibrinogen levels may not be significantly decreased.
- Optimum management of DIC requires aggressive treatment of the **underlying disease process** and supportive therapy with coagulation factor and platelet replacement. FFP and platelet concentrates are the two most common blood products used as a temporizing measure.
- Stored or banked whole blood is a reasonable source of most clotting factors if the units are <24 hours old. The biologic half-life of factors V, VII, VIII, and IX are on the order of 24 hours or less; hence whole blood stored for longer than 24 hours may not provide adequate amounts of these coagulation factors.

TREATMENT

- An important concept is **not to fall behind** in factor replacement. Due to the lag time in receiving laboratory values, in clinical conditions where the patient is actively bleeding, initiation of FFP and platelets should be started early with red cell transfusion.
- In patients with known warfarin use and a small bleed in an uncompromising area (skull), FFP should be used *before* patients develop increasing intracranial hemorrhage.
- FFP is the most commonly used blood component for plas-matic coagulation abnormalities since it provides **all necessary coagulation factors** in concentrations that approach those found in normal plasma.
- **Cryoprecipitate**, a component made from thawing FFP in the cold under specialized conditions, is rich in **factors XIII, VIII, I, vWF, and fibronectin**. It has been used in factor VIII-deficient states (**hemophilia A**) if virally inactivated plasma-derived or recombinant factor VIII concentrates are not readily available; in **von Willebrand** disease recalcitrant to desmo-

pressin and if virally inactivated plasma derived factor VIII concentrate rich in vWF is not readily available; in **hypofibrinogenemic or dysfibrinogenemic conditions**; in hemorrhage associated with massive blood transfusions; in **DIC**; in **factor XIII deficiency** (FFP is also used); in bleeding **uremic** patients with qualitative platelet function defects unresponsive to desmopressin therapy; or as a **topically** applied surgical sealant (“fibrin glue”).

- For specific coagulation disorders, such as hemophilia A, hemophilia B (deficiencies of factor VIII and IX, respectively), and von Willebrand disease, virally inactivated plasma-derived factor concentrates are commercially available, as are recombinant products, and these are the blood components of choice if available for use.
- For deficiencies of the **vitamin K-dependent factors (II, VII, IX, X)**, **prothrombin complex** concentrates are also commercially available, as is recombinant factor VII for isolated factor VII deficiency states.
- Platelet concentrates are used for both **quantitative (thrombocytopenias)** and **qualitative platelet disorders** associated with significant bleeding.
- Patients transfused with any blood component, whether FFP, cryoprecipitate, plasma-derived factor concentrates, or platelet concentrates, incur similar risks of complications attributed to all types of blood component therapy such as febrile and allergic reactions, transmission of blood-borne pathogens (human immunodeficiency virus, hepatitis B and C), immunosuppression, transfusion-related pulmonary injury, and hemolytic transfusion reactions if a substantial volume of ABO-incompatible units is transfused. Therefore, judicious use of blood component therapy must always be adhered to.

SUMMARY

Postoperative bleeding requires immediate recognition of early shock, resuscitation, and differentiation between surgical and nonsurgical bleed. Knowledge of coagulation and appropriate replacement of blood and blood products is essential. Careful history and evaluation of the patient helps to identify primary or secondary coagulation disorders.

CHAPTER 39 ■ ABDOMINAL TRAUMA: NONOPERATIVE MANAGEMENT AND POSTOPERATIVE CONSIDERATIONS

INTRODUCTION

- The intensivist should be familiar with the implications of specific injuries including guidelines for nonoperative management, postoperative care, and expected postinjury complications and their sequelae.
- It should not be assumed that the emergency department evaluation was comprehensive and accurate. A repeated history and physical examination performed in light of imaging studies and pertinent intraoperative findings, called the **tertiary survey** (see Chapter 37), should be performed.
- Further information is obtained from family members, and the physician has time for a more meticulous physical examination. Key elements include the patient's **medical history**, specifically issues such as **cardiopulmonary disease** and **medications**.
- Some patients will **require imaging** upon arrival to the intensive care unit (ICU); patients with intracranial or thoracic injury may go emergently to the **operating room (OR)** prior to computed tomography (CT) scanning of the abdomen. These patients, once hemodynamically stable in the ICU, should undergo CT scanning to delineate any associated intra-abdominal injuries. Even in patients who undergo exploratory laparotomy, CT of the abdomen may be necessary to diagnose spine fractures and to evaluate the retroperitoneum.
- Routine postadmission studies include **repeat chest film and laboratory studies**. A chest film is important to determine central line catheter, tube thoracostomy, and endotracheal tube positions, as any of these could become dislodged with transport. The chest radiograph may also show **interval change** in a patient's hemothorax, pneumothorax, or pulmonary contusion. Based upon physical exam findings in the tertiary survey, further imaging of extremities may also be required.
- Once the patient has been fully evaluated by the treating ICU physicians and associated imaging and laboratory results obtained, there is concurrent cardiopulmonary resuscitation, and there is treatment of known injuries, ongoing evaluation for missed injuries, and monitoring for the sequelae of recognized injuries.

POSTINJURY RESUSCITATION

- ICU management undergoes distinct phases because there are differing goals and priorities.
- The period of acute resuscitation, typically lasting for the first 12 to 24 hours, combines several principles: **optimizing tis-**

sue perfusion, ensuring normothermia, and restoring coagulation.

- There are a multitude of management algorithms aimed at accomplishing these goals—the majority involves **goal-directed resuscitation** (1) with initial volume loading to attain adequate preload, followed by judicious use of inotropic agents or vasopressors.
- Although the optimal hemoglobin (Hb) level remains debated, during shock resuscitation a **Hb >10 g/dL** optimizes oxygen delivery. A more judicious transfusion trigger of Hb <7 g/dL in the euvolemic patient after the first 24 hours of resuscitation limits adverse inflammatory effects and improves mortality, but the **optimum hemoglobin** level may vary depending on the patient's **cardiac function**.
- A challenging aspect of early care is balancing cardiac preload vs. promoting an **abdominal compartment syndrome** or tissue edema with fluids. During this initial treatment period, a low urine output is usually suggestive of a low preload and not an indication for diuretics.
- Invasive monitoring with **pulmonary artery catheters (PACs)** may be a critical adjunct in the multiply injured patient. PACs allow minute-to-minute monitoring and additional information on volume status, cardiac function, peripheral vascular tone, and response to intervention. **Cardiac indices (CIs)** and **oxygen delivery (DO₂)** become important variables in the ongoing ICU management. Resuscitation to values of DO₂I >500 mL/minute/m² and CI >3.8 L/minute/m² are the goals (1).
- PACs allow rapid titration of vasoactive agents. Although norepinephrine is the agent of choice for patients with low systemic vascular resistance unable to maintain a mean arterial pressure >60 mm Hg (1), patients may have an element of myocardial dysfunction requiring inotropic support. In patients with ongoing need for pressors, one should evaluate for **adrenal insufficiency**.
- Adequate **resuscitation is mandatory**, especially when future return to the OR is necessary. Specific goals of resuscitation whether patient needs further surgery or not include **core temperature >35°C**, **base deficit less negative than 6**, and **normal coagulation indices**.
- Although correction of base deficit and lactate values is desirable, how quickly this should be accomplished requires careful consideration. Adverse sequelae of aggressive crystalloid resuscitation include increased intracranial pressure, worsening pulmonary edema, and intra-abdominal visceral and retroperitoneal edema resulting in secondary abdominal compartment syndrome.
- Exogenous **bicarbonate**, occasionally given to improve cardiovascular function and response to vasoactive agents if the

TABLE 39.1

GENERAL GUIDELINES FOR OPERATIVE OR RADIOLOGIC INTERVENTION DURING NONOPERATIVE MANAGEMENT OF SOLID ORGAN INJURIES

LIVER: Hemodynamically unstable with 4 units of packed red blood cells (PRBCs) in 6 h or 6 units PRBCs in 24 h
SPLEEN: Hemodynamically unstable with need for initial transfusion related to splenic injury rather than associated trauma

serum pH is <7.2, obfuscates the acid-base balance, and lactate may be a more reliable indicator of adequate perfusion.

NONOPERATIVE MANAGEMENT OF TRAUMA

Blunt Liver and Spleen Injuries

- The liver and spleen are the most commonly injured solid organs after trauma, occurring in approximately 10% to 15% of all trauma admissions. Although the liver is more often injured, splenic injuries tend to be more precarious clinically.
- Nonoperative management of solid organ injuries is pursued in **hemodynamically stable** patients who do not have overt peritonitis or other indications for laparotomy. CT findings of high-grade injuries, a large amount of hemoperitoneum, contrast extravasation, and pseudoaneurysms are not absolute contraindications for nonoperative management; however, these patients are at **high risk for failure** and are more likely to need **angioembolization**. There is no age cutoff for nonoperative management.
- A multidisciplinary approach including angiography with selective **angioembolization** and **endoscopic retrograde cholangiopancreatography (ERCP)** with stenting has resulted in decreased nonoperative failure rates and improved survival in liver and splenic injuries.
- If a patient is going to fail nonoperative management, the **time to failure** is different for liver versus spleen injuries. Typically liver injuries rebleed within the first hours of admission, whereas splenic laceration may have delayed rupture or bleeding weeks after the original injury.
- **General guidelines for operative intervention or angioembolization** are noted in Table 39.1.
- Repeat imaging in patients with complex hepatic injuries can be performed with bedside ultrasound. Patients with evidence of right upper quadrant fluid collections or clinical deterioration (increasing abdominal pain, worsening liver function tests, unexplained fever) should undergo CT scanning.

Pancreatic Injuries

- With the recent evolution of nonoperative management for solid organ injuries, a nonresectional management schema has been developed for select pancreatic injuries. Observation of **pancreatic contusions**, particularly those in the head of the

pancreas that may involve ductal disruption, includes **serial exams** and monitoring of serum amylase.

- Patients with pancreatic injuries involving the major ducts, **originally a strict indication for operative intervention**, may now be managed with **ERCP and stenting** in select patients; durability of this approach is currently under investigation.

Duodenal Hematomas

- After blunt trauma, duodenal wall hematomas may **obstruct** the lumen. Clinical exam findings include epigastric pain associated with either emesis or high nasogastric tube (NGT) output; CT scan imaging with oral contrast failing to pass into the proximal jejunum is diagnostic.
- Nonoperative management includes continuous NGT decompression and nutritional support with total parenteral nutrition. A marked drop in NGT output heralds resolution of the hematoma, which typically occurs within **2 weeks**; repeat imaging to document these clinical findings is optional.
- If the patient does not improve clinically or radiographically within **4 weeks**, operative evaluation is warranted.
- If **perforation** is suspected by clinical deterioration or imaging with retroperitoneal free air or contrast extravasation, immediate surgery is needed.

Penetrating Wounds

- Patients with abdominal gunshot wounds violating the peritoneum undergo **emergent laparotomy** due to an approximate 90% visceral injury rate.
- Select patients with isolated low-energy gunshot wounds to the **right upper quadrant** are observed; CT scan imaging must delineate the **track of the bullet**, which should be confined to the parenchyma of the liver, and the patient must be hemodynamically **stable** with a benign clinical examination. In some cases, **laparoscopy** will be done to assess the penetrating liver injury and ensure the viscera are not violated.
- Patients with abdominal stab wounds to the back or flank with negative CT imaging or an isolated kidney injury are also managed nonoperatively.
- Regardless of the trauma surgeon's decision for operative versus nonoperative management, it is essential that these patients undergo **repeated abdominal examination**.
- Observation for a **missed small- or large-bowel injury** is critical; clinical findings in such patients include a rising white blood cell count, fever, tachycardia, and increasing abdominal pain or frank peritonitis.
- In patients with isolated liver injuries, complications are similar to those for patients with blunt injuries, namely bleeding and bile leaks or biliary sepsis.

COMPLICATIONS OF NONOPERATIVE INJURY MANAGEMENT

Liver

- **Bile leak or biloma** occurs in up to 20% of patients. Clinical presentation includes abdominal distention, intolerance of enteral feeds, and elevated liver functions tests. CT scanning

effectively diagnoses the underlying problem, and the vast majority are treated with **percutaneous drainage and ERCP with sphincterotomy**.

- Occasionally, laparoscopy or laparotomy with drainage of biliary ascites is indicated if ileus and fever persist.
- Hemobilia** (connection between a blood vessel and the biliary tree) manifests with **right upper quadrant pain, jaundice, and upper gastrointestinal bleeding**. Angiography and embolization may be needed to control the brisk gastrointestinal bleeding.
- Delayed rupture** of a subcapsular hematoma with hemorrhage is infrequent.
- Patients undergoing angioembolization for liver trauma must be carefully monitored for **hepatic necrosis** and may occasionally require delayed formal hepatic resection.

Spleen

- The most common problem is **delayed bleeding**. Patients undergoing splenic embolization can fail with rebleeding and 13% of patients requiring splenectomy. Successful angioembolization patients typically have **significant pain** associated with their “splenic infarct,” and up to 20% develop splenic abscesses.

ONGOING EVALUATION FOR INJURIES (HOW TO AVOID A MISSED INJURY)

- With the paradigm shift from operative to nonoperative management of trauma, the clinician must have a heightened sense of awareness to avoid missing an occult injury. CT scan imaging is not 100% accurate; repeat CT scan imaging, diagnostic peritoneal lavage (DPL), ultrasound, and even laparotomy may be necessary for definitive evaluation.
- Missed bowel injuries** are the most commonly pursued injury, not due to their frequency (<5% of blunt trauma) but rather their associated **morbidity** caused by even short delays in diagnoses.
- DPL should be considered if a patient’s initial CT scan of the abdomen shows **free fluid without evidence of a solid organ injury** to explain such fluid; if there is increasing intra-abdominal fluid on bedside ultrasound even with a solid-organ injury but a stable hematocrit; and/or in patients with unexplained clinical deterioration.
- DPL at the bedside is done, with specific laboratory values indicating need for laparotomy (Table 39.2). Attention should be paid to elevations in white blood cells (WBCs), bilirubin, alkaline phosphatase, and amylase when pursuing a diagnosis of bowel injury. Red blood cell count is not the issue, as DPL is not being done to rule out bleeding.
- Missing a **rectal injury** may be life threatening in patients with pelvic fractures. If a **rectal exam** has been omitted in the trauma bay, the intensivist should ensure that this exam is done. Flexible sigmoidoscopy is easy to perform at the bedside; endoscopic evaluation should rule out **blood within the canal, clear intestinal perforation, or ischemic mucosa**.
- Pancreatic contusions**, with or without associated ductal disruption, are difficult to diagnose in patients with blunt

TABLE 39.2

A POSITIVE DIAGNOSTIC PERITONEAL LAVAGE AFTER BLUNT TRAUMA DEFINED BY SPECIFIC LABORATORY VALUES

Laboratory study	Positive value
White blood cell	>500 cells/ μ L
Red blood cell	>100,000 cells/ μ L
Amylase	>19 IU/L
Alkaline phosphatase	>2 IU/L
Bilirubin	>0.1 mg/dL

abdominal trauma. The initial CT scan may show nonspecific stranding of the pancreas. Associated fluid around the pancreas should prompt further invasive studies such as ERCP or magnetic resonance cholangiopancreatography to rule out a biliary or pancreatic duct injury. Serial determinations of amylase/lipase may be considered and prompt a repeat CT scan, a duodenal C-loop study, a DPL, or an ERCP depending upon the suspected lesion.

POSTOPERATIVE MANAGEMENT OF SPECIFIC INJURIES

- Communication between the operating surgeon and the intensivist is critical and should include **intraoperative findings and procedures, any tenuous operative repairs, anticipated problems or complications, the need for repeat operative exploration, and location of drains**. The **intraoperative estimated blood loss** and associated blood product transfusion requirements are essential data to anticipate events in the postoperative period.
- Remember that **injuries can be missed** even with prior operative intervention.

Liver and Spleen Injuries

- Life-threatening bleeding from the liver is most often controlled with perihepatic liver packing or sometimes with additional Foley catheter tamponade of deep lacerations. Immediate concerns in the postoperative period are **rebleeding** and **parenchymal ischemia**.
- Signs of **rebleeding** are a falling hematocrit, blood clots accumulating under a temporary abdominal closure device, and bloody output from the Jackson–Pratt drains. Patients with recurrent hemorrhage may be treated with angioembolization or may necessitate repeat operative packing depending on the rate of bleeding.
- Hepatic ischemia** is usually due to either a prolonged intraoperative Pringle maneuver (with anticipated resolution of ischemia) or hepatic artery ligation (which may result in liver necrosis). Patients are typically returned to the OR for pack removal 24 to 48 hours after initial injury.
- Other complications are intra-abdominal **abscess, biloma, and hemobilia**, and “liver fever” for the first 5 postinjury days.
- Operative intervention for splenic injuries includes splenectomy and splenorrhaphy. **Postoperative hemorrhage** may be

due to the splenic hilar vessel tie loosening, a missed short gastric artery, or recurrent bleeding from the spleen if splenic repair was used.

- An immediate postsplenectomy increase in platelets and WBCs is normal; however, beyond postoperative day 5, a WBC count >15,000 should prompt a thorough search for underlying infection.
- Other complications are unrecognized iatrogenic injury to the **pancreatic tail** during rapid splenectomy resulting in pancreatic ascites or fistula.
- Left upper quadrant abscess after splenectomy may occur, but presumptive drainage does not prevent this complication.
- Routine care also includes **immunizations** for encapsulated organisms (*Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Meningococcus*) usually just prior to discharge, optimally at 2 to 3 weeks postsplenectomy.

Gastrointestinal Injuries

- Operative intervention for either penetrating or blunt gastrointestinal injuries entails primary repair, resection with primary anastomosis, or resection with a stoma diversion. If an **ileostomy or colostomy** was required, one should inspect it daily to ensure it is pink without evidence of necrosis. Postoperative complications include anastomotic leak, prolonged ileus, and bowel obstruction.
- A devastating complication is an **anastomotic leak** with intra-abdominal contamination or sepsis and presents with increasing abdominal pain, fevers, and respiratory. CT scan is diagnostic, and repeat operation is often required.
- Important questions for the intensivist after operative intervention for pancreatic injuries include how much of the pancreas was resected (potential for diabetes), is there a pancreatocoenteric anastomosis (potential for leak), was the pancreatic stump closed with either staples and/or fibrin glue, was the spleen preserved, and where were drains placed?
- Postoperative complications include **pancreatic fistula, pseudocyst, abscess, pancreatocoenteric leak, and pancreatitis**. The most common of these is a pancreatic fistula seen in 7% to 20% of patients with isolated pancreatic trauma and up to 35% of patients with combined pancreatic and duodenal injuries. CT scan imaging should be performed to evaluate for an intra-abdominal fluid collection. Drainage by interventional radiology is performed for fistula diagnosis and control. Pancreatic fistulae after trauma are managed in a fashion identical to those occurring after elective pancreatic resection.

Abdominal Vascular Injuries

- Vascular injuries can produce rapid exsanguination and threaten extremities or may be a clinically silent time bomb due to temporary retroperitoneal tamponade. Few result in a delayed diagnosis, particularly with CT scanning, and hence the focus of the intensivist is in postoperative management.
- Main causes of patient morbidity and mortality are associated **soft-tissue and nerve injuries** once the vascular repair has been accomplished. Therefore, optimizing the patient's hemodynamic status, maintaining euthermia, and correcting coagulopathy are critical points of resuscitation.

- Prosthetic graft infections are rare complications, but preventing bacteremia is imperative.
- There are specific injuries that require additional care: (a) **Abdominal aortic injuries** are repaired using either a polytetrafluoroethylene patch or interposition grafting; the patient's systolic blood pressure should not exceed 120 mm Hg for at least the first 72 hours postoperatively; (b) patients requiring **ligation of an inferior vena cava injury** often develop marked bilateral lower extremity edema; to limit the associated morbidity, the patient's legs should be wrapped with ACE bandages from the toes to the hips and elevated at a 45- to 60-degree angle; (c) **superior mesenteric vein injuries**, either **ligation or thrombosis** after venorrhaphy results in marked **bowel edema**; fluid resuscitation should be aggressive and abdominal pressure monitoring routine in these patients; and (d) in complex hepatic trauma, the **right or left hepatic artery or the portal vein may be selectively ligated**; persistent elevation in liver transaminases indicates secondary liver **necrosis** and may necessitate delayed resection. Of note, if the right hepatic artery is ligated intraoperatively, **cholecystectomy** must be performed to prevent gangrenous gallbladder.

Abdominal Wounds

- Wounds sustained from trauma or from surgery should be **examined daily** for progression of healing and signs of infection. Complex soft-tissue wound care includes wet-to-dry dressing changes twice daily, or application of the wound vacuum-assisted closure.
- One should carefully watch for **infection**, development of necrotizing fasciitis, subcutaneous abscess, or associated undrained hematoma.

Damage Control Surgery

- Damage control surgery (DCS) is an abbreviated operation the goals of which are to control hemorrhage, limit contamination from enteric sources, and enable rapid transport to the ICU for correction of adverse physiology. There are standard indications for performing the DCS abbreviated laparotomy in patients with unresolved metabolic failure (Table 39.3).
- Intraoperative techniques of DCS include perihepatic packing, balloon tamponade of deep liver lacerations, segmental

TABLE 39.3

INTRAOPERATIVE INDICATIONS TO PERFORM DAMAGE CONTROL SURGERY

Factor	Level
Body temperature	Temperature <35°C
Acid-base status	
Arterial pH	pH <7.2
Base deficit (BD)	BD < -15 mmol/L in patient <55 y BD < -8 mmol/L in patient >55 y
Serum lactate	Lactate >5 mmol/L
Coagulopathy	PT or PTT >50% of normal
PT, prothrombin time; PTT, partial thromboplastin time.	

stapled bowel resection left in discontinuity, ligation of abdominal venous injuries, shunting of abdominal arterial injuries, and pancreatic drainage.

- After DCS, the surgeon will “close” the abdomen with a **temporary closure** device using either a plastic intravenous bag or wound vacuum-assisted closure dressing. The temporary abdominal closure allows egress of abdominal contents and contains the edematous bowel while providing excellent decompression.
- Upon transfer to the ICU, aggressive resuscitation of the patient is performed to reverse metabolic failure. This includes vigorous **rewarming** through heating the room, infusion of fluids and blood products through a warming device, and use of a active warming blankets. Continuous **arteriovenous rewarming** may be warranted for refractive temperatures $<34^{\circ}\text{C}$. **Restoration of a normal cardiovascular state** is attained by infusion of fluids and blood products and judicious use of vasopressor agents. Finally, the patient’s **coagulopathy** must be reversed with appropriate blood products including fresh-frozen plasma, cryoprecipitate, and platelets. Occasionally, recombinant activated factor VII (rFVIIa; NovoSeven, NovoNordisk, Denmark) is needed.
- Ideally, **physiologic correction** should occur within **12 to 24 hours** of admission to the ICU, with planned return to the OR for definitive repair.
- There are several specific management points of the patient with an open abdomen that deserve mention. Despite a widely

open abdomen, patients can develop **abdominal compartment syndrome**; Patients with an open abdomen lose between 500 and 2,500 mL/day of abdominal effluent.

Abdominal Compartment Syndrome

- Diagnosis and management are also presented in Chapter 37.
- Organ failure can occur over a wide range of recorded bladder pressures; there is **not a single measurement** of bladder pressure that prompts therapeutic intervention, except >35 cm H_2O . Rather, emergent decompression is warranted in the patient with intra-abdominal hypertension with **end-organ dysfunction**.
- **Mortality** is directly affected by abdominal decompression, with 64% mortality in patients undergoing presumptive decompression, 70% mortality in patients with a delay in decompression, and 89% mortality in those without decompression.

CHAPTER 40 ■ NEUROLOGIC INJURY: PREVENTION AND INITIAL CARE

HEAD INJURY

Nearly 1.4 million people sustain a **traumatic brain injury** (TBI) per year in the United States, 235,000 are hospitalized, and approximately 50,000 die. In children younger than 14 years, TBI results in 2,685 deaths per year, with 37,000 hospitalizations and 435,000 emergency department visits. TBI death rate for males is 3.3 times higher than for females and highest in persons at age 75 years or older.

Subdural Hematoma

- Subdural hematomas (SDHs) are more common than epidural hematomas and were seen in 25% of patients with severe head injury. SDH typically results from tearing of the bridging veins between the brain and the draining venous sinuses. The mechanism usually involves high-velocity acceleration and deceleration forces.

- Imaging shows a **crescent-shaped hyperdensity** that follows the contours of the brain.
- Acute SDH carries a **poor prognosis** and is one of the most lethal of all head injuries. Fifty to 60% of patients with SDH die, and only 19% to 38% will achieve functional recovery despite surgical treatment.
- Early evacuation within the first 4 hours of injury decreased mortality from 90% to 30% in a single study of 82 consecutive comatose patients. This suggested that preventable secondary injury was the cause of the high mortality, despite multiple studies, these findings have not been replicated.

Epidural Hematomas

- An epidural hematoma requires a great impact force and is often associated with a skull fracture that disrupts the **middle meningeal artery** in the supratentorial space or causes injury to the venous sinuses in the posterior fossa.

- Classically, patients present awake and alert, known as the lucid interval, and quickly lapse into unconsciousness.
- Imaging shows a **lenticular-shaped hyperdensity**.
- With rapid evacuation, epidural hematoma has a relatively **good prognosis**, and the mortality rate is 5% to 10%. Factors determining mortality and functional outcome include age, best motor response on the Glasgow coma score (GCS), hematoma volume, and degree of midline shift.

Cerebral Contusions

- Cerebral contusions result from direct impact of the brain on the skull. These are known as **coup injuries**. Alternatively, acceleration/deceleration injury of the brain against the contralateral side of the direct impact causes **contrecoup injuries**. The most common areas of contusion are the frontal, temporal lobes, and occipital regions. These lesions are **hyperintense areas** within the parenchyma on computed tomography (CT) scan.
- Clinical deterioration or elevation in intracranial pressure (ICP) requires urgent repeat cerebral imaging.

Intraparenchymal Hemorrhage

- Intraparenchymal hemorrhage (IPH) is **hyperintense** on CT scan. It is a focal process and less diffuse than a contusion, as it is caused by direct vascular injury or by stretching of the vessels with brain shift and distortion.
- Hemorrhage in the **upper brainstem (midbrain and pons)**, known as Duret hemorrhages, can occur with rapidly evolving **transtentorial herniation** and may be due to stretching of the perforating arterioles or from venous thrombosis and infarction. Spontaneous causes of IPH are hypertensive hemorrhagic stroke or hemorrhaging due to arteriovenous malformation, aneurysm, amyloid angiopathy, or tumor. In the setting of hemorrhage in the basal ganglia, cerebellum, or thalamus, the clinician should consider the differential of spontaneous IPH as a possible **cause** of the traumatic event, **rather than the result**.

Subarachnoid Hemorrhage

- Subarachnoid hemorrhage (SAH) occurs in 21% to 53% of patients with severe TBI and worsens outcome. In contrast to aneurysmal SAH, traumatic SAH (tSAH) is less likely concentrated in the basal cisterns and is usually found over the hemispheric convexities. The presence of tSAH in the basal cisterns is predictive value of unfavorable outcome of up to 70%.

Intraventricular Hemorrhage

- Intraventricular hemorrhage in isolation is not commonly seen in closed-head injury. However, like traumatic SAH, it has been associated with **worsened outcome**. **Obstructive hydrocephalus** may result and may require cerebrospinal fluid (CSF) diversion by external ventricular drainage.

Diffuse Axonal Injury

- Diffuse axonal injury occurs in approximately half of patients with severe closed-head injury. Sudden acceleration-deceleration impact causes rotational forces and **shear injury to axons**. The axon may not be entirely transected, but axoplasmic transport is disrupted, causing swelling and disconnection and Wallerian degeneration. Outcome is worsened with severe diffuse axonal injury.

PHYSIOLOGIC PRINCIPLES

- The **Monro–Kellie hypothesis** describes the skull as a semi-closed compartment containing brain and interstitial fluid (80%), CSF (10%), and blood (10%). Compensatory mechanisms to decrease cerebral blood or CSF volume (decreased synthesis) become active where ICP and volume increase.
- **Cerebral perfusion pressure (CPP)** is determined by the difference of the mean arterial pressure (MAP) and ICP. CPP supplants MAP goals. Normal ICP is <10 mm Hg.
- Brain Trauma Foundation guidelines recommend **CPP >60 mm Hg and ICP between 20 and 26 mm Hg**. Prior to placement of an intracranial monitor, recommendations are to maintain a MAP of 90 mm Hg or greater.

Evaluation

- On arrival at the intensive care unit (ICU), the initial focus is on **respiratory and hemodynamic stability**. In addition examination of the head for scalp lacerations, which can be a major source of bleeding and orbital, facial, and depressed skull fractures, basilar skull fractures with raccoon eyes, and middle fossa or temporal bone fractures with postauricular ecchymosis known as the Battle sign seen. **Cervical spine precautions** are maintained.
- Repeated neurologic monitoring includes the vital signs with special attention to extremes in blood pressure. **Hypotension** may result in secondary injury, whereas **hypertension**, not always associated with bradycardia, can be a sign of impending cerebral herniation. If ICP rises, cerebral autoregulation elevates MAP to maintain an adequate CPP.
- A rapid neurologic assessment includes **level of consciousness** and ability to speak or understand language by assessing the ability to follow simple commands. Vision is assessed by asking the patient to count fingers placed in the right or left visual field with one eye covered or to mimic finger movements.
- In patients with a lower level of consciousness, **vision** is assessed by blinking to a visual threat. Pupillary response to light (cranial nerves [CN] II, III), corneal reflex (CN V, VII), and gag and cough (CN IX, X) responses assess **cranial nerve** and brainstem function.
- **Oculocephalic maneuvers** (CN III, VI, VIII) should not be performed in patients who have a risk of **cervical spine fracture**. **Ice water caloric response** (CN III, VI, VIII) can be performed if the tympanic membranes are intact. The head of the bed should be up at 30 degrees, and 60 to 90 mL of ice water instilled into the otic canal. A normal response is a slow lateral deviation to the side stimulated with ice water and nystagmus with the fast phase to the opposite ear. Absence may be caused by medications or **brainstem injury**.

TABLE 40.1**GLASGOW COMA SCALE**

Score	Eye opening	Best verbal	Best motor
1	No response	No response	No response
2	To pain	Incomprehensible	Extensor
3	To speech	Inappropriate	Flexor
4	Spontaneous	Disoriented	Withdraws to pain
5	—	Oriented	Localizes pain
6	—	—	Obeys command

From Teasdale G, Jennett B. Assessment of coma and impaired consciousness: a practical scale. *Lancet*. 1974;2:81–84.

- **Motor response** is assessed by verbal commands to move the limbs. In patients with lower levels of consciousness, motor responses are elicited by painful stimuli delivered to the sternum or fingernail bed. During **painful stimulation**, the examiner should also reassess facial movement for asymmetry. If flexion is noted, pain is applied to the supraorbital ridge or by trapezius squeeze to test for localization.
- In the lower extremities, it is important to recognize a **triple flexion response**, which is described by the flexion of the ankle, knee, and hip. Triple flexion is a **spinal reflex to painful stimulation** of the legs or feet. It is stereotyped in appearance independent of the location of pain delivery on the lower extremity. It does not reflect brainstem or upper–spinal cord function. Patients who are brain dead or with higher cord complete lesions can triple-flex lower extremities.
- The GCS has been divided into three categories: (a) a **GCS of 8 or less** is defined as severe head injury, (b) a **GCS of 9 to 12** represents moderate head injury, and (c) a **GCS of 13 to 15** is mild or minor (Table 40.1).
- The **best GCS** after adequate fluid resuscitation and stabilization has previously been shown to be predictive of outcome. A **change between the field and arrival GCS** can be predictive of outcome.
- **Laboratory evaluation** of patients with head injury include complete blood count with platelet counts, partial thromboplastin time, prothrombin time, electrolytes with blood urea nitrogen, creatinine, glucose, and liver function tests, toxicology screen. Arterial blood gas and lactic acid levels help assess volume status and whether ventilation is adequate.

Imaging

- **Noncontrast head CT** is the fastest, most widely available noninvasive imaging technique to determine this. All patients with altered mental status and/or focal neurologic findings should have an initial CT scan performed.
- Progressive intracranial hemorrhage consistent with an evolving contusion is seen in 14% to 38%. Although worsening CT findings do not necessarily require treatment, 54% of patients may require neurosurgical intervention, including ICP monitoring or craniotomy subsequent to the findings on a repeat scan.
- In stable patients without clinical neurologic deterioration, the utility of repeat imaging is debated. Risk factors for progression include associated tSAH, SDH, older age, and prolonged partial thromboplastin. A large initial contusional or intraparenchymal hemorrhage size and effacement of

cisterns are strongly predictive of failure of nonoperative management.

SECONDARY BRAIN INJURY PREVENTION: TREATMENT AND MANAGEMENT

- After immediate impact and anatomic damage, **secondary damage** at the cellular level from inflammation, edema, free radicals, and excitatory neurotransmitters can worsen outcome.
- Contributing factors include **hypoxemia**, **hypotension**, **seizures**, **fever**, and **intracranial hypertension**. Immediate postinjury care focuses on the prevention of these problems.

Hypoxemia and Respiratory Management

- Hypoxia, defined as a $\text{PaO}_2 < 60$ mm Hg or O_2 saturation less than 90%, can independently **increase mortality from 27% to 50%** and increase poor outcome from 28% to 71%. Early intubation can prevent aspiration, and minimizing hypoxic and hypercapnic events is recommended. A **GCS of 8 or less** is the usual threshold for endotracheal intubation.
- Hyperventilation with resultant **hypocapnia** causes **cerebral vasoconstriction** and a reduction in cerebral blood flow (CBF). Prolonged hypocapnia appears to slow neurologic recovery, and hyperventilation of PaCO_2 less than 35 mm Hg should be avoided.
- PaCO_2 as low as 30 mm Hg may be necessary for brief periods for immediate treatment of intracranial hypertension.
- **Pulmonary infections** were seen in 41% of patients registered in the Traumatic Coma Data Bank. Bedside management includes adequate pulmonary toilet and strategies such as elevation of the head of the bed to decrease the risk for ventilator-associated pneumonia.

Neurogenic Pulmonary Edema

- Neurogenic pulmonary edema (NPE) results from central sympathetic stimulation. TBI causes a **sympathetic discharge**, which **increases systemic and pulmonary vascular pressures**. The resultant increase in pulmonary capillary pressure increases the hydrostatic pressure and causes pulmonary capillary injury; this in turn causes leakage of fluid and protein and pulmonary hemorrhages.
- Clinical signs include dyspnea, tachypnea, tachycardia, and chest pain if the patient is awake. Chest radiography shows a bilateral alveolar filling process.
- There are two distinct forms of NPE. The classic form appears **early**, within minutes to a few hours after acute brain injury. A **delayed form** of NPE slowly progresses over 12 to 72 hours after injury. Treatment is supportive and often requires supplemental oxygen and positive pressure ventilation.

Hypotension

- Hypotension, defined as systolic blood pressure **<90 mm Hg**, independently worsens mortality. Adequate fluid resuscitation with euolemia is essential. Once an ICP monitor is

placed, the optimal blood pressure is determined by a CPP ≥ 60 mm Hg.

Contraction Band Necrosis

- After head trauma, subarachnoid hemorrhage, seizures, or stroke, patients may have **cardiogenic shock** with global hypokinesia associated with transient cardiac arrhythmias and repolarization changes.
- **Arrhythmias** may include supraventricular tachycardias, sinus bradycardia, atrioventricular block, atrioventricular dissociation, nodal rhythms, and paroxysmal ventricular tachycardia.
- **Myofibrillar degeneration** (also known as **contraction band necrosis** or coagulative myocytolysis) is seen. It is postulated that centrally mediated sympathetic or exogenous catecholamine stimulation of the myocardium results in cellular calcium overload and results in the formation of the contraction bands predominantly located in the subendocardium affecting the conducting system, which results in the associated arrhythmias.

Posttraumatic Vasospasm

- After TBI, **focal cerebral ischemia** as a result of **posttraumatic vasospasm** can occur in 24% to 36% of patients and may manifest as lateralizing neurologic deficits such as hemiparesis and aphasia between 2 to 37 days after injury.
- If vasospasm is suspected, cerebral angiography can confirm the diagnosis. The effectiveness of treatment of posttraumatic vasospasm with modalities used after aneurysmal SAH (e.g., hypervolemic, hypertensive therapy, or nimodipine) has not been assessed.

Fever

- **Hyperthermia accelerates neuronal injury** by increasing basal energy requirements (neuronal discharges), excitatory neurotransmitters, free radical production, calcium-dependent protein phosphorylation, ICAM-1 and inflammatory responses, DNA fragmentation, and apoptosis, causing blood-brain barrier changes as seen by extravasation of protein tracers.
- Therapeutic hypothermia lowers ICP by **reducing the cerebral metabolic rate 7% for each degree Celsius decrease**. This treatment can be lifesaving and result in reasonable neurologic recovery.
- **Pentobarbital coma** and/or **neuromuscular blockade** may be necessary to achieve cooling without shivering. New techniques for intravascular and topical cooling are available.
- Complications of hypothermia include **arrhythmias, hypotension, bradycardia, thrombocytopenia, and pneumonia**.

Hyperglycemia

- Hyperglycemia causes **brain-tissue acidosis**, and early hyperglycemia has been associated with worsened neurologic outcome after TBI. Although tighter glucose control with TBI is theoretically reasonable, based on current evidence, it is

not clear that aggressive treatment of hyperglycemia in the neurologic and neurosurgical population improves outcome.

Coagulopathy

- Brain is rich in tissue thromboplastin and may cause a **disseminated intravascular coagulopathy**. Associated coagulopathy and thrombocytopenia increases mortality in TBI.
- Although there are no guidelines for correction of coagulopathy or thrombocytopenia, usual practice is to transfuse **platelets** for values $< 100,000/\text{mL}$ and fresh-frozen plasma for an **elevated thromboplastin time or a prothrombin time international ratio of 1.5 or more**. Other alternatives such as activated factor VII or prothrombin complex concentrate may be effective emergently.

INTRACRANIAL PRESSURE MONITORING AND MANAGEMENT

- Normal ICP is < 10 mm Hg. ICPs > 20 mm Hg to 25 mm Hg should be treated.
- Maneuvers for management of ICP begin with those with fewer potential side effects and progress to more invasive treatments with higher complication risk (Fig. 40.1).
 - **Elevation of the head of bed to > 30 to 45 degrees** not only decreases the risk of ventilator-associated pneumonia but can also facilitate cerebral venous drainage and lower ICP. In orthostatic, hypovolemic patients, however, head of bed elevation can lower MAP. Adequate fluid resuscitation is necessary.
 - Adequate **pain therapy** with opioids and adequate **sedation** with sedative-hypnotics decrease ICP. Constant infusion may be hemodynamically better tolerated than bolus administration.
 - $\text{PaCO}_2 < 35$ mm Hg should be avoided except in the situation of impending herniation or refractory intracranial hypertension.
- **Osmotic therapy** is a mainstay in ICP management. Mannitol or hypertonic saline are both effective. However, repetitive dosing by the preceding agents may worsen the volume of injured brain. Doses of **0.25 g/kg to 1 g/kg of mannitol** are effective. An osmolar gap of > 10 from baseline may be a better indicator for maximizing mannitol administration. **Hypertonic saline** may be more effective and have a longer duration of action on lowering ICP than mannitol. Doses include **250 mL of 3% or 7.5% saline or 30 mL of 23.42% saline**.
- **Neuromuscular blockade** lowers ICP by decreasing muscle tone, especially during shivering. Shivering increases the metabolic rate and generates carbon dioxide. After administering neuromuscular blockade, an arterial blood gas should be obtained to ensure that the PaCO_2 has not dropped below 35 mm Hg. Neuromuscular blockade also cools the patient. The patient is unable to effectively clear secretions, and empiric pulmonary toilet with frequent suctioning is often necessary.
- **Barbiturate-induced coma** lowers the cerebral metabolic rate. This results in lowered cerebral blood volume and ICP. Thiopental or pentobarbital infusions can be used. Thiopental in long-term infusion, because of its lipophilicity, may take over a week to clear after the infusion is stopped. For

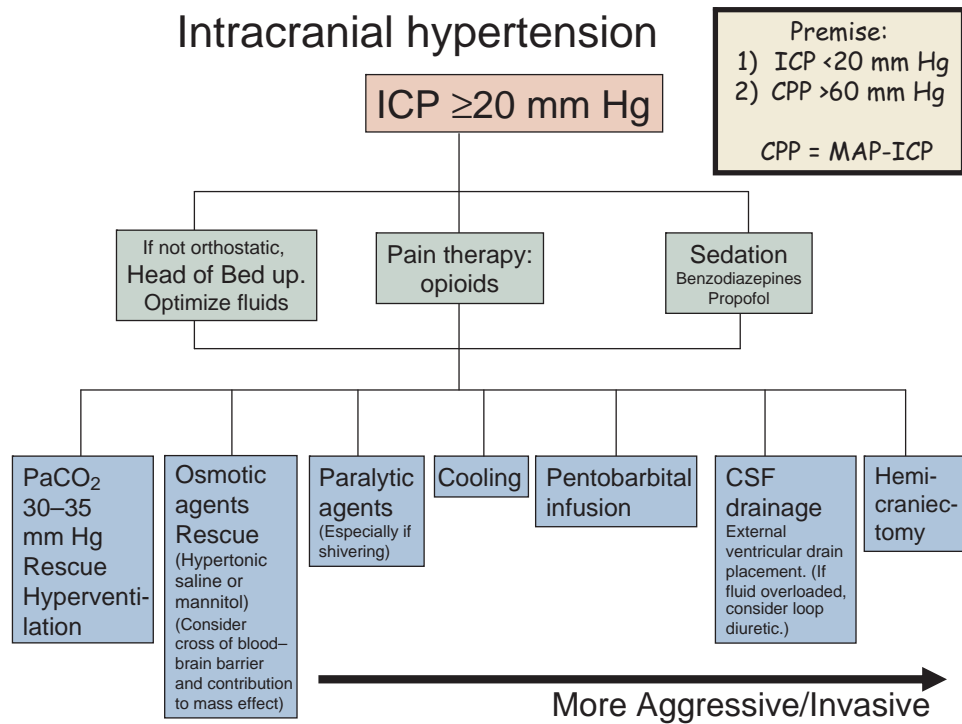

FIGURE 40.1. Algorithm for management of intracranial hypertension. CPP, cerebral perfusion pressure; CSF, cerebrospinal fluid; ICP, intracranial pressure.

pentobarbital, 20 mg/kg is given as a slow loading dose followed by a maintenance infusion of 1 mg/kg per hour. The loading dose may significantly lower mean arterial pressure. Often fluids and vasopressor administration may be necessary. Electroencephalography is critical to titrating the dose during barbiturate coma.

- Side effects include hypotension from peripheral vasodilation, decreased cardiac inotropy, and ileus. Cough reflex is diminished, and decreased bronchociliary activity and slowed leukocyte chemotaxis increase the risk for pneumonia. A quiescent hypothalamus that no longer modulates body temperature and hypothermia occurs.
- Loop diuretics have been used to help manage ICP by decreasing CSF production in the choroids plexus. Loop diuretics will decrease volume status and should not be used in hypovolemic patients.
- For refractory intracranial hypertension, placement of an external ventricular drainage allows for CSF drainage. Hemisectomy may be lifesaving and a viable option depending on the patient.

Brain Tissue Oxygenation

- Hypoxic brain injury causes secondary damage. Jugular bulb oximetry (SjvO₂) is a global measure of the balance between oxygen delivery to the brain and oxygen consumption. Local brain tissue partial pressure oxygen (PBtO₂) is measured by a polarographic Clark-type microcatheter.
- An increase in cerebral oxygen delivery is reflected by increases in SjvO₂ and PBtO₂. Oxygen delivery to the brain is manipulated by increases in blood pressure, cardiac output,

and red blood cell transfusion. Optimal SjvO₂ is generally accepted as 50% oxygen saturation. The optimal PBtO₂ has not been established but should be maintained > 15 mm Hg to 25 mm Hg.

OTHER INTENSIVE CARE UNIT CONSIDERATIONS

Antibiotic Prophylaxis

- Fractures of the skull base and severe facial trauma can result in a CSF leak. Studies conflict as to whether prophylactic antibiotics decrease the risk of infection, and there are no guidelines or recommendations. Constant surveillance for meningitis is essential.
- After penetrating head trauma, a CSF leak is the primary predictor of intracranial infection. Current recommendations are to treat with empiric broad-spectrum antibiotics after penetrating brain injury.
- For clean neurosurgical procedures, such as external ventricular drain placement or craniotomy, guidelines have been established by the Surgical Infection Prevention and Surgical Care Improvement Projects that recommend cefazolin within 1 hour prior to surgical incision.

Posttraumatic Seizures

- Early posttraumatic seizures occur within 7 days of injury. Three percent to 6 percent of patients with closed-head injury

suffer early posttraumatic seizures compared to 8% to 10% with penetrating brain injury.

- **Antiseizure medications** (e.g., phenytoin and carbamazepine) are recommended for the **first week** after closed and penetrating brain injury.
- There is no evidence that continuing prophylactic antiseizure medications beyond a week prevents late seizures.

Thromboprophylaxis

- After major head injury, the risk for deep vein thrombosis (DVT) is as **high as 54%**.
- Patients undergoing major neurosurgical procedures receive thromboprophylaxis in the form of **intermittent pneumatic compression** devices with or without **graduated compression stockings** (grade 1A). Acceptable alternatives include subcutaneous unfractionated **heparin** (grade 2B) or postoperative low-molecular-weight heparin (LMWH, grade 2A). In high-risk neurosurgery patients, the combination of mechanical and pharmacologic prophylaxis is recommended (grade 2B).
- In patients who are not neurosurgical candidates, a grade 1A recommendation is that trauma patients receive LMWH as soon as it is considered safe to do so. Inferior vena cava filters are not considered acceptable primary prophylaxis in trauma patients (grade 1C).

Nutrition

- After severe TBI, patients have a hypermetabolic, catabolic state, with rapid weight loss associated with a negative nitrogen balance and protein wasting.
- **Early parenteral or enteral nutrition** can speed neurologic recovery and decrease disability and mortality. Early enteral nutrition with glutamine and probiotics may decrease the infection rate and length of ICU stay. Arginine and glutamine modulate gut permeability. There is some debate whether glutamine should be used in brain injury patients due to the potential increase in cerebral glutamate with neuroexcitatory properties and cell damage.
- Current guidelines in severe TBI are to replace 140% of resting metabolism in nonparalyzed patients and 100% of resting metabolism expenditure in paralyzed patients within 7 days.

Stress Gastritis

- Stress gastritis was seen in 91% of 44 comatose mechanically ventilated patients within 24 hours of head injury. **Sucralfate, H₂-antagonists, proton pump inhibitors, or antacids** in patients with mechanical ventilation may be effective; none are recommended over another with regard to risk of ventilator-associated pneumonia.

Prognosis

- Survivors of TBI variably suffer from long-term cognitive, motor, sensory, and emotional deficits. These manifest as

weakness, incoordination, emotional lability, impulsivity, and difficulty with vision, concentration, memory, judgment, and mood.

- **Independent predictors of outcome** include older age at time of injury, the postresuscitation GCS, injury severity score, pupillary response on admission, and CT scan findings of diffuse edema, subarachnoid hemorrhage, subdural hematoma, partial obliteration of the basal cisterns, or midline shift.

Spinal Cord Injury

- The annual incidence of acute spinal cord injury (SCI) in North America is between 27 and 47 cases per million, cases per million; in the United States about 11,000 cases per year.

Management

- Primary SCI results from cord compression. Secondary injury results from systemic and local vascular insults, which may be a result of hypotension, electrolytes changes, edema, and excitotoxicity.

Immobilization

- Spine immobilization can be uncomfortable, carries potential morbidity of pressure sores and risk of aspiration, and may limit respiratory function; however, it is the usual treatment for all patients with a mechanism of injury that may cause spinal injury.
- Various methods for complete spine immobilization can be used, but a rigid cervical collar with supportive blocks on a rigid backboard is effective.

Radiologic Evaluation

- No cervical radiologic evaluation is recommended in **awake, alert, nonintoxicated** trauma patients who have **no neck pain or tenderness** and no distracting injury. The CT scan is better than magnetic resonance imaging (MRI) for evaluating bones; however, flexion/extension radiographs in an awake patient or MRI **within 48 hours** of injury can best detect ligamentous injury.
- Newer-generation CT scanners are sensitive, and some centers no longer perform plain radiographs. However, current American Association of Neurological Surgeons standards are for an anteroposterior, lateral, and odontoid cervical spine series supplemented with CT scan in the initial evaluation. In an awake patient with neck pain, options to clear the cervical spine include normal flexion/extension films or a normal MRI within 48 hours of injury. In obtunded patients with normal cervical spine films, options to clear the spine include (a) dynamic flexion/extension studies under fluoroscopy, (b) normal MRI obtained within 48 hours of injury, or (c) the discretion of the treating physician.

Hemodynamic Support

- Systemic hypotension, which contributes to secondary SCI, can result from trauma-related hypovolemia and from neurogenic shock. **Neurogenic shock** is defined as the loss of sympathetic innervation that causes loss of peripheral vasoconstriction and cardiac compensatory mechanisms of tachycardia

and increased stroke volume and cardiac output. Augmentation of **mean arterial pressures to 85 to 90 mm Hg** for 5 to 7 days after injury improves outcome.

- Treatment typically includes **volume** resuscitation with crystalloid or red blood cell transfusion if the patient is anemic. **Vasoactive medications** such as norepinephrine, dopamine, and phenylephrine are used as needed. Volume-resistant hypotension is fivefold more common among patients with complete SCI above the thoracic sympathetic innervation.
- In the subset of patients requiring vasopressors and inotropes, central venous catheters and invasive monitoring with arterial catheters should be used.

Surgical Intervention

- The timing of surgical decompression, reduction of bony structures, and fusion in the treatment of acute SCI remains in debate. There is little agreement on optimal timing. Early surgery may be associated with shorter hospitalizations and reduced pulmonary complications.

Pharmacologic Intervention

- After acute SCI, a cascade of biochemical processes is activated that produces excitatory amino acids, calcium fluxes, free radicals, acidosis, protein phosphorylation, phospholipases, and apoptosis, which can further injure surrounding tissue. Pharmacologic agents targeted to interrupt this cascade may provide neuroprotection by preventing secondary injury.
- **Methylprednisolone at 30 mg/kg bolus followed by 5.4 mg/kg/hour infusion for 23 hours** given within 8 hours of injury reported significant improvement in motor function and pin and light touch at 6 months compared to those treated after 8 hours and those treated with naloxone or placebo. There are criticisms of this study, and other trials have not shown benefit of early steroid usage.
- Increased complications from steroid usage such as a higher rate of respiratory complications including pneumonia, gastrointestinal hemorrhage, sepsis, and longer hospital stays have been reported.

Pulmonary Support

- The most common cause of death in patients with SCI is due to **pneumonia, pulmonary emboli, and septicemia**. Patients with high-level cervical injuries (C3–5) may fatigue over the first few hours to days. Early measurements indicating the need for elective endotracheal intubation include the use of **vital capacity (<20 mL/kg)** and **negative inspiratory force (less negative than –20 cm H₂O)**. Hypoxia and hypercapnia are late signs of respiratory failure, and intubation should not await these findings.

Associated Vascular Injury

- Blunt cervical spinal trauma can result in **vertebral artery injury** and cause posterior circulation ischemia. Incidence varies from 0.05% to 1% and may depend on screening methods. Mortality ranges from 23% to 28%.
- Patients at risk include those with **cervical fractures with subluxation** or with a **fracture through the transverse foramen**, especially those with displaced or complex midface or

mandibular fracture, a basilar skull fracture involving the carotid canal or sphenoid sinus, near-hanging resulting in cerebral hypoxia, and cervical vertebral body fracture or distraction injury.

- Suspicion should be high if the patient develops a **lateralizing neurologic deficit with normal initial CT scan**, or evidence of a recent ischemic stroke on cerebral imaging. Although CT angiography with a 16-channel detector shows high sensitivity for screening, the gold standard is four-vessel cerebral angiography. Aspirin or heparin therapy should be initiated if no contraindications are present.

Thromboprophylaxis

- **Prophylactic anticoagulation** for all patients with acute SCI is a grade 1A recommendation from the American College of Chest Physicians. The recommended anticoagulation is LMWH once primary hemostasis is achieved or a combination of intermittent pneumatic compression and either low-dose unfractionated heparin or LMWH. If anticoagulation is contraindicated, it is recommended that intermittent pneumatic compression with or without graduated compression stockings be used (grade 1C).
- The period of highest risk for deep vein thrombosis is in the first few months after injury. For this reason, duration of treatment is recommended for **at least 6 to 12 weeks**. Warfarin is recommended for the rehabilitative phase of SCI. Vena caval filters are not recommended as primary prophylaxis. There are no prospective randomized studies of the safety of anticoagulation after spinal surgery.

Nutritional Support and Metabolic Changes

- As described earlier, traumatic injury is associated with a hypermetabolic, catabolic state with nitrogen loss.
- In SCI victims, indirect calorimetry will be more accurate than the Harris–Benedict equation to determine metabolic needs.

Autonomic Dysreflexia

- Autonomic dysreflexia is a life-threatening hypertensive emergency that typically occurs in patients with motor-complete SCI **above the T6 neurologic level**, typically seen in the **rehabilitative phase** of SCI described as early as 4 days after injury.
- **Noxious stimuli** including fecal impaction, bladder distention, or pain to the lower extremities increases **sympathetic outflow below the injury level**. Resultant vasoconstriction of the splanchnic bed forces blood into the system circulation and increases blood pressure. Reflex parasympathetic outflow rostral to the injury allows flushing of the skin above the level of the lesion and bradycardia.
- Recognition of this entity and detection and removal of the inciting noxious stimulus is primary. Blood pressure treatment traditionally included ganglionic blockers, although intravenous antihypertensives such as nicardipine or nitroprusside can be effective.

Prognosis

- Incomplete injury has a better prognosis than those that are complete. MRI shows that complete SCI was associated with more substantial maximum canal compromise, spinal cord compression, length of lesion, hemorrhage, and cord edema and poorer prognosis.

- Two clinical entities described in SCI are pertinent to prognosis: (a) **Spinal shock** is a transient loss of spinal cord sensorimotor function, patients present with **flaccid paralysis** and loss of all spinal cord reflexes including the bulbocavernosus, cremasteric, and deep-tendon reflexes, and **priapism** can be seen due to local **unopposed parasympathetic outflow**; if there

is no anatomic injury, function returns within hours to days; (b) **central cord syndrome**, in which the motor deficit in the **upper extremities** is disproportionately **worse** than that in the lower extremities, occurs with bowel and bladder dysfunction and variable sensory loss below the level of injury. The natural history of central cord syndrome is good neurologic recovery.

CHAPTER 41 ■ ORTHOPEDIC TRAUMA

- Bony and soft-tissue injuries often complicate trauma. Patients treated suboptimally are at risk for myriad complications such as fat embolism syndrome, pulmonary embolus, soft-tissue infection, and multiple organ failure. There is little prospective randomized data to guide treatment decisions in patients with bony injuries.
- **Fracture stabilization** is an operative procedure of significance. Some patients may be too critically ill or injured at the time of initial presentation to tolerate definitive fracture fixation. The critical care staff must be well versed in the management principles that govern musculoskeletal injuries, as they will often have important roles to play in decision making.
- Orthopedic surgeons and/or anesthesiologists may not have sufficient information on total patient physiology to make these decisions without input from the critical care staff.
- **Fractures missed** at the time of initial presentation can cause significant morbidity or mortality (see Chapter 37). Careful ongoing assessment of an intubated obtunded patient is critical. A delayed diagnosis can produce substantial disability that is lifelong. Even worse, unrecognized ischemia and/or compartment syndrome can place a limb at jeopardy, requiring amputation later. Unrecognized ischemia can also produce life-threatening electrolyte abnormalities such as hyperkalemia and/or be the source of multiple organ failure.

TREATMENT OPTIONS FOR FRACTURES

- Fractures that are not associated with life-threatening bleeding are **not** the highest priority. However, all long-bone fractures should be **splinted** as part of the initial management. Every time the patient is moved, unsplinted fractures are displaced, producing **blood loss** and **pain** and **risking secondary nerve or vascular injury**.
- Rigid fracture fixation is generally obtained via **open reduction/internal fixation (ORIF)** or closed **intramedullary (IM) nail** fixation.
- **ORIF** involves directly exposing the fracture fragments. Overlying muscles must often be divided for exposure, fracture

manually reduced, and rigid fixation is achieved with plates and screws or rods. This also allows for debridement of nonviable and/or contused muscle and irrigation of the fracture hematoma.

- **Closed IM nailing** involves making a small incision proximally or distally in the extremity, then the fracture fragments are reduced under fluoroscopic visualization. A nail is then driven up the medullary canal over the guide wire.
- Either of these can produce **systemic inflammatory response syndrome (SIRS)** and/or **acute lung injury**.
- **External fixation** involves placing an external frame that spans the fracture, limiting fracture movement. It can be rapid and noninvasive and result in substantially less blood loss than ORIF or IM nailing and is reserved for unstable patients.
- **Open fractures** require an initial debridement and irrigation of the fracture fragments as a minimum. This is done to reduce the rate of early soft tissue infection and late osteomyelitis.

OPTIMAL TIMING OF FRACTURE FIXATION

- The definition of **early fracture fixation** usually implies within **24 hours of injury**. Paradoxically, the advantages are most pronounced in patients with multiple system injury who are at risk for any operative procedure. Judgment is needed to weigh **risks and benefits** to early fracture fixation.
- Nonoperative management requires that the patient remain supine in bed. In some patients, inability to elevate head of bed may aggravate intracranial pressure. There is higher risk of atelectasis, pneumonia, aspiration, pain, bleeding, SIRS, and thromboembolic complications.
- **Fracture hematoma** may be a **metabolically active organ**, capable of producing **SIRS** and **multiple organ failure**. Early fracture fixation allowed for irrigation of the fracture hematoma.
- Caution should be exercised in patients with **traumatic brain injury**, and conflicting results have been reported, with some studies demonstrating worse neurologic outcome whereas others have not.

- Several factors should be considered: (a) the risk of anesthesia and the magnitude of the operative procedure; (b) does the patient have a reasonable nonoperative option—could a lesser procedure be adequate? (c) finally, is the patient in optimal condition? Can cardiac performance be improved with volume and/or inotropes? Will 1 to 2 days allow ventilatory requirements to be reduced? Would a delay improve renal function? Only when all of these questions are answered can an intelligent decision about the **optimal time and fracture fixation** be made.

Damage Control Orthopedics

- Traditional teaching was to repair all injuries at the time of initial surgical procedure. Unfortunately, this often required prolonged operative care, and patients would develop a **lethal triad of acidosis, coagulopathy, and hypothermia** and die in the intensive care unit of acute organ failure within 24 hours.
 - Many trauma centers began using a staged approach where **only lifesaving procedures are performed at the time of the initial procedure**. The patient was then admitted to the intensive care unit and resuscitated. Between 1 and 3 days later, the patient was taken back to the operating room to care for all the other injuries. This resulted in improved outcome.
 - The same principles can be applied to bony injuries and is called **damage control orthopedics (DCO)**. There are clear advantages to early fracture fixation. Yet, some patients may not be best served by such technique. A technique that would achieve many of the advantages of fracture fixation without the disadvantages of definitive surgery would be advantageous for some patients.
 - For that subset of patients whose physiologic condition precludes primary definitive operative stabilization of fractures (early total care), **external fixation** can be a useful technique for temporary stabilization of long-bone fractures.
 - Such external fixation is advantageous because it can be applied rapidly, with minimal blood loss and with sufficient restoration of stability to prevent ongoing soft-tissue injury and to prevent ongoing release of inflammatory mediators. Effective limitation of secondary effects of shock has been demonstrated with this type of initial DCO approach.
 - DCO may be effective in patients with **polytrauma and lung or brain injury**. For the majority of patients with femoral shaft fractures, including most polytrauma patients, primary reamed femoral nailing **within 24 hours of injury** remains the gold standard of treatment.
 - Defining the “at-risk” patients who are unable to tolerate early reamed nailing is difficult, but if adequate resuscitation and normalization of serum lactate are achieved, damage control should rarely be necessary.
 - In borderline patients who are physiologically unstable because of severe chest or head injury or inadequate resuscitation, temporizing external fixation and damage control orthopedics may be advantageous.
- pressure compromises blood flow and subsequently results in tissue damage if left untreated.
- The clinical diagnosis of compartment syndrome can be elusive. In the alert patient, pain is typically the first symptom. **Sensory deficits** may occur late and are typically in the distribution of the sensory nerve traversing the affected compartment. **Motor weakness** is a late and ominous sign. **Loss of palpable pulses** is very late and rare.
 - In the patient who is not awake and alert, the diagnosis of compartment syndrome requires extreme vigilance and a high degree of clinical suspicion. The diagnosis in these patients requires frequent physical examination and tissue pressure measurements.
 - Many techniques have been described, but the simplest and most widely used is the **STIC Device** (Stryker Corporation, Kalamazoo, MI). The handheld STIC catheter utilizes a disposable syringe and needle and, after zeroing the monitor, insertion of the needle through the fascia of the compartments.
 - There is some debate concerning the measured pressure at which the diagnosis of compartment syndrome should be made and fasciotomy performed. Many advocate the use of absolute values of **>30 to 35 mm Hg**. Others have stressed the importance of the difference between **diastolic pressure and measured compartment pressure** with a $\Delta p < 30$ mm Hg.
 - In the patient who is **at risk** of compartment syndrome, tight casts, splints, and dressings should be avoided. The optimal position is to place the affected extremity at the level of the heart to optimize both arterial and venous flow.
 - **Surgical decompression** is the treatment.
 - In the patient at high risk for the development of compartment syndrome, **prophylactic fasciotomy** may be appropriate. If the patient will be unexamined, unable to complain of symptoms, and unavailable for serial measurements of compartment pressures, prolonged hypotension, arterial vascular repairs, or concomitant venous injury, fasciotomy should not be delayed because venous insufficiency may exaggerate edema and increase the risk of the development of compartment syndrome.
 - Once fasciotomies are performed, **sterile dressings or a closed vacuum suction** device should be applied and the wounds re-examined in about 48 hours. Muscle with borderline or questionable viability should be left and re-examined in 24 to 48 hours.
 - **Complications** of untreated compartment syndrome include **muscle necrosis, irreparable nerve damage, and limb loss**. When treatment is delayed more than 12 hours, amputation rates may be more than 20%.
 - **Myonecrosis** can result in the release of large amounts of myoglobin particularly during the reperfusion phase after fasciotomy. **Myoglobin** can precipitate **renal failure** via three mechanisms: decreased renal perfusion, renal tubular obstruction due to cast formation, and direct toxic effects of myoglobin on the kidney. Treatment is aggressive hydration and maintenance of high-volume urine output. Some have advocated the use of mannitol and urine alkalinization.

COMPARTMENT SYNDROME

- Compartment syndrome occurs when there is increased tissue pressure within a confined osseofascial space. This increased

FAT EMBOLISM SYNDROME

- Fat embolism syndrome (FES) is most commonly associated with long bone fractures. Although fat embolism may occur

in up to 90% of trauma patients, **FES occurs in only 2% to 5%** of patients with long-bone fractures characterized by both pulmonary and systemic fat embolism and includes a spectrum from subclinical to mild to fulminant presentations.

- Clinical FES typically involves multiple organ systems; however, involvement of the **pulmonary, neurologic, hematologic, and dermatologic systems** is the most common.
- Fat embolization can occur at the time of fracture and long-bone fixation. Elevated pressures during reaming of the intramedullary canal appear to be temporally associated with embolization to the pulmonary circulation when studied with echocardiography. Once fat is liberated into the circulation and embolizes, the pulmonary microvasculature becomes occluded. Smaller globules may traverse the pulmonary microvasculature and reach the systemic circulation, leading to the common neurologic manifestation of FES. Although the **pulmonary, cerebral, retinal, and skin microcirculations** are typical clinical manifestations of FES, fat embolization can affect any **microcirculatory bed**.
- **Acute lung injury and adult respiratory distress syndrome** may result from fat emboli occluding pulmonary capillaries, and biochemical alterations directly damage the pulmonary capillary endothelium.
- Biochemical fat embolization is associated with the **release of free fatty acids**. **free fatty acids** in the lung are locally hydrolyzed in pulmonary circulation by lipoprotein lipase, which releases toxic substances that injure the capillary endothelium and may initiate disseminated intravascular coagulation and platelet aggregation, further compounding **systemic inflammation**.
- Fat emboli that pass through the pulmonary vasculature result in systemic embolization, most commonly in the **brain and kidneys**. **Cerebral FES** is rare, yet potentially lethal. Neurologic symptoms vary from confusion to encephalopathy with coma and seizures. In severe cases, **intracranial pressure (ICP) monitoring** may be helpful. A clinical diagnosis may be diffi-

cult as cerebral FES may be masked by other clinical scenarios. **Diffuse encephalopathy, petechial hemorrhages, localized cerebral edema, and white-matter changes** may be seen with magnetic resonance imaging, whereas computed tomography scan may be normal.

- **Treatment is supportive.**
- The outcome in patients with FES who receive supportive care is generally favorable, with mortality rates of **<10%**. Pulmonary, neurologic, and retinal abnormalities generally resolve completely.

PELVIC FRACTURES

- Pelvic fractures occur from high-impact trauma and are associated with mortality rates ranging from 10% to 50%. The principles of pelvic fracture management after the initial assessment of “airway, breathing, and circulation” include **detection of associated injuries** (especially intraperitoneal bleeding source), **stabilization of pelvic fracture** in patients who demonstrate signs of hemorrhage (external compression devices), **early embolization** of pelvic arterial bleed, and **avoiding coagulopathy** and hypothermia by vigilant monitoring and treatment.
- **Older patients (≥ 60 years)** have a higher likelihood of **arterial bleeding** with more transfusion requirement. After control of life-threatening issues such as bleeding, careful assessment of other injuries that may cause significant morbidity such as rectal and vaginal tears and bladder and urethral injuries need to be assessed.
- **Missed open pelvic fractures** will lead to sepsis. Pelvic exam in females and rectal exam should be done in all patients.
- Adequate hydration, monitoring for abdominal compartment syndrome, and vigilant secondary and tertiary survey are necessary. Some patients require **more than one embolization** to control hemorrhage.

CHAPTER 42 ■ FACIAL TRAUMA

GENERAL ISSUES

- Comprehensive management and treatment of facial trauma involves airway control, control of bleeding, reduction of swelling, prevention of infection, repair of soft-tissue lacerations, and repair of fractures to restore function and esthetic form to the face.
- Essential component of initial care begins with the ABCs (airway, breathing, circulation) and cervical spine assessment.
- As with any other trauma patient, the facial trauma patient should be evaluated in a systematic and comprehensive fashion in cooperation with the trauma team.

- Abdominal, thoracic, cervical spine, and neurosurgical emergencies take priority over maxillofacial injury.

AIRWAY

- Early airway control and neurologic assessment of a potential head injury are critical because the eyes and oropharynx are the “shock organs” of the face, and development of facial edema will obscure the pupils and obstruct the upper airway. Immediate treatment of maxillofacial trauma patients is indicated in the following situations: (a) airway

compromise, (b) severe hemorrhage, (c) large open wounds, (d) superior orbital fissure and orbital apex syndrome, (e) mandibular condylar impaction into the cranial fossa, and (f) if urgent surgical procedures need to be performed by other services.

- Definitive treatment of facial fractures can be delayed as much as 2 weeks after injury as long as the fractures do not violate the cranial space.
- Spinal injuries are increased fourfold if there is a clinically significant head injury (Glasgow coma scale score <9).
- The following subsets of patients require immediate securing of airway to prevent respiratory failure: patients with (a) Glasgow coma score <9, (b) sustained seizure activity, (c) unstable midface trauma, (d) direct injuries to the airway, (e) aspiration risk or unable to maintain an airway, and (f) oxygenation problems.
- The airway should be cleared of debris, foreign bodies (teeth), blood, and secretions. The classic “chin lift” or “jaw thrust” maneuvers are commonly employed for assessment of airway patency and to remove obstruction of the tongue base. However, jaw thrust and chin lift may cause distraction of at least 5 mm in a cadaver with C5–6 instability.
- Manual in-line axial stabilization must, therefore, be maintained throughout. Bag-and-mask ventilation also produces significant degrees of cervical spine movement at zones of instability. The “sniffing the morning air” position for standard endotracheal intubation should similarly be avoided as it flexes the lower cervical spine and extends the occiput on the atlas. Atlanto-occipital extension is necessary to visualize the vocal cords. Patients with unstable C1 or C2 injuries are at risk.
- The hard C-collar may interfere with intubation efforts. The front part of the collar can be removed to facilitate intubation as long as manual stabilization remains in effect.
- The safest method of securing an endotracheal tube remains debatable. Orotracheal intubation is the fastest and surest method although the Advanced Trauma Life Support recommends a nasotracheal tube in the spontaneously breathing patient and orotracheal intubation in the apneic patient. With caution, patients may be safely intubated orally with a modified rapid sequence induction technique with preoxygenation and cricoid pressure.
- Nasotracheal intubation is (relatively) contraindicated in patients with potential skull base fractures or unstable midface injuries that typically involve the naso-orbito-ethmoid complex. Any paranasal manipulation (including insertion of a nasogastric tube) may produce or recreate local hemorrhage, making airway manipulations difficult or impossible. Inadvertent placement and contamination/violation of the cranial space are also possible.
- The need for a surgical airway should be recognized and obtained without delay. A percutaneous needle cricothyroidotomy with high-flow oxygen is indicated in emergency situations when standard tracheotomy is not feasible or advisable. The potential for carbon dioxide retention with this technique must be remembered and the levels in arterial samples monitored.
- Cricothyroidotomy is contraindicated in laryngeal or tracheal trauma, cervical infection, and young children but is necessary if unable to intubate. A standard tracheotomy is essential in unstable patients who require prolonged maxillomandibular fixation for fracture stabilization and management.

HEMORRHAGE

- Because the face and neck have a rich vascular supply, injuries in these areas can lead to substantial blood loss. Major hemorrhage can result from large scalp wounds, nasal or midface fractures, and penetrating wounds.
- Hence, external hemorrhage can usually be controlled by direct pressure to the wound and/or bleeding areas. Pressure can also be applied proximal to major arteries if direct pressure to the wound is not effective.
- Scalp wounds can be rapidly approximated with 2.0 non-absorbable sutures (nylon, Prolene) or staples if available. Sutures should be placed away from the wound edge to ensure hemostasis as the galea tends to retract.
- Nasal fractures and midface fractures can result in tearing of the ethmoidal arteries. Most of these can be controlled with direct pressure or packing. Nonintubated patients with nasal packing in place should have the head of the bed elevated 30 degrees and be observed and monitored for respiratory distress. Continued bleeding may not be apparent on the nasal side of the packing. Nasal packing easily slips posteriorly with swallowing or out with movement or sneezing. The posterior oropharynx should be checked regularly.
- Fractures of the posterior maxillary wall, as in LeFort I and II fractures, may be associated with profuse bleeding from the internal maxillary artery. Bleeding from this artery can be very difficult to control by gauze packing.
- Hypoxemia and hypercarbia can cause respiratory and cardiac complications. Airway obstruction and asphyxiation can occur if the nasal packing slips back into the airway, particularly during sleep. Complications may occur if a pack compresses the eustachian tube. Rarely, infections can develop in the nose, sinus, or middle ear after nasal packing and lead to toxic shock syndrome.
- When tight nasal/oral packing fails in unstable patients, supraselective arteriography and embolization are the treatment of choice in institutions where this modality is available. Ligation of the external carotid artery is a last resort in the unstable multitrauma patient who cannot be transported. However, due to collateral circulation of the face, ligation is seldom truly effective. Best control of hemorrhage is obtained by exploratory surgery and fixation of fractures. In patients with isolated LeFort fractures, open reduction/internal fixation is the first line of treatment.

WOUND MANAGEMENT

- There are some basic rules that apply in treating soft-tissue injuries. Soft-tissue injuries are only properly evaluated after the wound is cleaned of dirt, foreign bodies, debris, and dry blood.
- Facial nerve function should be assessed in all patients with facial lacerations, and nerve function should be documented *prior* to anesthetic use. Ideally, repair of the facial nerve should occur as soon as possible but no later than 72 hours unless the wound is heavily contaminated.
- In patients with deep lacerations of the cheek, the wound should also be explored for injury to the parotid duct (Stensen duct). One may see saliva in the wound if the duct is lacerated. The parotid duct is repaired over a stent to prevent stenosis.

- Optimum timing of facial laceration repair is a topic of debate. After tetanus prophylaxis, soft-tissue repair can be performed within 12 to 24 hours provided the wounds are irrigated, cleaned, and kept moist.

Cranial Nerve Exam

- Olfaction (cranial nerve one [CN I]) is typically not examined in the acute trauma bay setting but reserved for later trauma surveys (tertiary survey). Damage to CN I should be considered with the naso-orbito-ethmoid complex and frontal sinus fractures if disruption of the cribriform plate is present.
- Pupillary responses (CN II, III) may be difficult to examine in patients with extensive orbital trauma, as the eyelid swells rapidly. Next, examine with a flashlight. Note the direct constriction of the illuminated pupil and the consensual constriction of the opposite pupil. In an afferent pupillary defect, there is decreased direct response in the affected eye. This can be demonstrated by moving the flashlight back and forth between the eyes, with a lag of 2 to 3 seconds. The afferent defect becomes evident when the flashlight is moved from the normal to the affected eye because the affected eye will dilate in response to light. Brief pupillary oscillations of the stimulated pupil (hippus) are normal and should be distinguished from pathologic response. Finally, test the pupillary response to accommodation, by moving an object (e.g., finger) from far to near. The pupils should constrict. The direct response of the ipsilateral pupil is absent in lesions to the ipsilateral optic nerve, the pretectal area, the ipsilateral sympathetic nerves traveling with CN III, or the pupillary constrictor muscle of the iris. The consensual response is impaired (contralateral pupil illuminated) in lesions of the contralateral optic nerve, the pretectal area, the sympathetic nerves, or the pupillary constrictor of the iris. Accommodation is affected for the same reasons and in pathways from optic nerve to the visual cortex. Accommodation is spared in injury to the pretectal area.
- Extraocular movements (CN III, IV, VI) are readily checked by asking patients to look in all directions without moving their head and asking them if they experience any diplopia in any direction. Test “smooth pursuit” by slowly moving an object or finger up and down and sideways. Test convergence by asking the patient to fixate on an object that is moved toward a point between the eyes. During these tests, look closely for nystagmus and dysconjugate gaze.
- Facial sensation and muscles of mastication (CN V) are tested using a soft object or finger in the forehead, cheek, and lower jaw line to capture all three branches of the nerve. Test the masseter muscles during jaw clench. In facial fractures, the most commonly affected nerve is the Vb branch, which may indicate maxillary, orbital, or zygomaticomaxillary complex fractures.
- Muscles of facial expression and taste (CN VII) are tested by looking for asymmetries in spontaneous facial expressions such as blinking, smiling, and squinting. Taste testing is usually not performed. Facial weakness can be caused by lesions of upper motor neuron in the contralateral cortex or in descending nerve pathways (ipsilateral). Upper motor neurons to the upper face cross over to both facial nuclei so in intracranial injury or stroke, motor functions of the upper face remain intact. Lower motor neuron lesions typically cause weakness to the entire ipsilateral face.
- Hearing and vestibular sense (CN VIII) are seldom checked in the acute setting. Vestibular sense is typically not tested except in patients with vertigo.
- Palate elevation and gag reflex (CN IX, X) are tested by an intraoral exam and observing palatal motion when the patient says “aaah.” Observe the gagging motion when the posterior pharynx is touched. The gag reflex is usually checked in patients with suspected brainstem pathology.
- Sternocleidomastoid and trapezius muscles (CN XI) are examined by asking the patient to shrug the shoulders and turn the head from side to side. Of note is that bilateral upper motor neuron projections control the sternocleidomastoid, analog to the bilateral CN VII projections controlling the upper face.
- Tongue (CN XII) will deviate toward the weak side. Lesions of the motor cortex cause contralateral tongue weakness as opposed to lower motor lesions or lesions of the tongue muscles.

Fractures

Nasal Fracture

- Due to its prominence, the nose is the most commonly fractured bone in the facial skeleton. Nasal fracture diagnosis is often a clinical, and not a radiologic, diagnosis as evidenced by mobility, swelling, flattened or deviated nose, epistaxis, septal deviation/hematoma, and mouth breathing. Septal hematoma must be ruled out in every patient. A septal hematoma forms between the septal cartilage and perichondrium from which it gets its blood supply. It appears as edema and ecchymosis of the septum with narrowing of the nasal airway on speculum exam. Septal hematoma is treated with incision and drainage. Failure to treat can lead to a septal abscess, intracranial complications, or delayed saddle nose deformity due to cartilage loss.
- Leakage of cerebrospinal fluid (CSF) indicates a fracture through the cribriform plate of the ethmoid bone. This potentially carries a risk of meningitis. There is controversy on the use of prophylactic antibiotics. Epistaxis is treated by packing the nose as discussed earlier. If this is not successful, an epistaxis catheter can be inserted to control bleeding from branches of the anterior ethmoidal artery. Treatment of most noncomminuted nasal fractures is closed reduction. Manipulation is required to restore an obstructed nasal airway and for restoration of facial cosmesis. The ideal timing for manipulative treatment varies. If reduction is not performed within the first few hours after injury, treatment is delayed 3 to 5 days for swelling to resolve. After a prolonged period (7–14 days), manipulation becomes increasingly difficult as the nasal bones will be difficult to move into place without osteotomies and a formal rhinoplasty may be required.

Naso-ethmoid-orbital Fracture

- Naso-ethmoid-orbital fractures are evidenced by (a) flat nasal bridge with splaying of nasal complex and crepitus, (b) saddle-shaped deformity of nose (“punched-in” look), (c) telecanthus (increased distance between the medial canthi), (d) circumorbital edema and ecchymosis (“raccoon eyes”), (e) subconjunctival hemorrhage, (f) epistaxis, (g) CSF rhinorrhea, or (h) supraorbital/supratrochlear nerve paresthesia.

- With true nasoethmoidal fractures, a CSF leak should be assumed even if not clinically evident.
- Closed manipulation of naso-orbito-ethmoid injuries notoriously gives a poor result, with a high incidence of persistent or recurrent deformity postoperatively.

Orbital Blowout Fracture

- The term *orbital blowout fracture* is reserved for a fracture of the bones of the orbit. This may involve the orbital floor, walls, or roof. The majority of cases involve the orbital floor and medial wall, as these areas comprise the thinnest bone of the orbit.
- Often, the thin bone of the floor displaces downward into the maxillary antrum, remaining attached to the orbital periosteum as one fragment (“trap door”). The periorbital fat herniates through the defect, thereby interfering with the inferior rectus and inferior oblique muscles, which are contained within the same fascia sheath. This prevents upward movement and outward rotation of the eye, and the patient experiences diplopia on upward gaze. This clinical finding should be distinguished from true “entrapment,” which indicates impingement of the ocular muscles. Those patients will present with pain, tenderness around the eye, swelling, and subjective diplopia in all outer fields of gaze.
- Ophthalmologic evaluation is advised if significant eye trauma is detected. If the patient is unresponsive, an afferent pupillary defect may uncover occult visual loss. If indicated clinically, tonometry may be used to assess intraocular pressure.
- Complications of unrecognized orbital floor fracture are as follows:
 - Posttraumatic persistent enophthalmos
 - Hypoglobus (inferior displacement of the orbit)
 - Persistent diplopia
 - Lower eyelid retraction (ectropion) and scleral show
 - Persistent edema of the lower eyelid

Zygoma Fractures

- Prominent zygoma is the second most commonly fractured facial bone.
- Clinical features of zygomaticomaxillary complex fractures are as follows:
 - Swelling and bruising over the cheek or flattening
 - Step-off deformity at the orbital rim
 - Periorbital ecchymosis
 - Subconjunctival hemorrhage
 - Para-/anesthesia of the infraorbital nerve
 - Trismus and restricted lateral excursion
 - Para-/anesthesia of Z-facial/temporal nerves
- Because the zygoma articulates superficially with the maxilla, frontal, and temporal bones, zygomatic fractures in the past have been referred to as tripod or trimalar fractures. However, the fourth articulation with the sphenoid really makes it a quadripod fracture.
- Owing to traction on the infraorbital nerve, patients often complain of upper lip/tooth numbness. Trismus may be

present as the masseter muscle pulls the malar fragment down, which impinges on the mandible.

- For the zygoma, timing of repair is 5 to 7 days after injury to allow tissue edema and swelling to subside. After 10 days, masseter contracture may complicate closed reduction of the zygoma.

Midfacial Skeleton: LeFort Fractures

- LeFort fractures tend to result from anterior forces. The fracture possibilities and combinations thereof are numerous; hence, classification schemes fail to describe them all.
- The LeFort I fracture essentially separates the lower maxilla, including the alveolar ridge and teeth, from the rest of the midface.
- The LeFort II fracture is a pyramidal fracture that includes the entire piriform aperture in the distracted midface. The fracture line includes the frontonasal suture, passes through the inferomedial orbit, and runs between the zygoma and maxilla for a larger area of dissociation.
- The LeFort III fracture is a suprazygomatic fracture through the lateral orbit. The fracture line extends from the dorsum of the nose and the cribriform plate along the medial and lateral wall of the orbit to the ZF suture line. This is also known as craniofacial dissociation, as the bones of the midface are essentially completely disarticulated from the cranium.
 - All complete LeFort fractures will create mobility of the maxilla, especially the upper alveolus (tooth-bearing portion of the maxilla). Hence, all will lead to subjective (and objective) malocclusion in varying degrees of severity.
- Comminuted fractures and fractures with malocclusion are treated with maxillomandibular fixation and/or by open reduction/internal fixation. Truly rigid fixation of the midface, unlike the mandible, is unattainable owing to the thin bones and correspondingly thin plates.

Unfortunately, many trauma patients are obtunded or intoxicated and unable to provide any subjective information. Physical examination alone is inconclusive in the majority of cases. On physical examination, the examiner should note presence and location of lacerations, ecchymoses, and gross asymmetry. Palpation is done to assess instability, crepitus, tenderness, bony stepoffs, and canthal tendon disruption. The trigeminal nerve should be tested. Ophthalmologic examination deserves special mention. Many authors believe that it is impractical to expect ophthalmologic consultation on every patient with facial injury. Most physicians are able to test visual acuity (subjective and objective), pupillary function, ocular motility, anterior chamber exam (to look for hyphema), and funduscopic exam. Ophthalmologic consultation should then be obtained as indicated. Last, but not least: Although cosmesis is not an immediate concern, it is of great concern to patients, especially once the acute trauma experience has worn off. Long-term goals and appearance outcomes should, therefore, be discussed with every patient on an individual basis to avoid misunderstandings and misconceptions.

CHAPTER 43 ■ BURN INJURY: THERMAL AND ELECTRICAL

BURN PHYSIOLOGY AND THE EFFECTS ON ORGAN SYSTEMS

- Burn injury has a systemic effect on the patient, and each organ system responds to this injury in a predictable manner proportional to the extent of burn.

Cardiovascular System

- Resultant fluid losses and increased capillary permeability lead to hypovolemia.
- The loss of fluid leads to decreased cardiac preload and decreased cardiac output.
- Early and late inflammatory mediators influence myocardial contraction and relaxation in the first 24 to 48 hours after burn injury.
- Multiple formulas exist for fluid management (see later). Myocardial depression can be supported pharmacologically with the use of inotropic agents.

Pulmonary System

- The pulmonary response is characterized by transient pulmonary hypertension, decreased lung compliance, and hypoxia, mediated by multiple factors including inflammation, acid-base imbalance, airway injury, and chest wall restriction.
- Chest burns with edema formation result in decreased chest wall compliance, restricted ventilation, and increased airway pressures; burn wound escharotomy of the chest wall may be indicated.
- Burn wound infection may lead to lung dysfunction secondary to inflammatory mediator release.
- Complications associated with intubation after burn injuries include ventilator-associated pneumonia and tracheal stenosis. Extubation at the earliest opportunity afforded by the patient's physiology—and his or her operative schedule—is important in reducing this complication.
- Smoke inhalation injury affects between 10% and 30% of burn patients and is associated with increased mortality over that predicted by age and extent of burn alone. High-frequency percussive ventilation has been used to treat patients with severe inhalation injury with promising results.

Renal System

- Renal failure has been reported in up to 20% of burn injury patients, with a clinical picture related to the size and severity

of burn injury. The time course of renal failure falls into early or late categories.

- Early acute renal failure appears to be directly associated with clinical events such as delayed resuscitation, underresuscitation, hypotension, and rhabdomyolysis. Rhabdomyolysis is often associated with electrical injury.
- Late episodes of acute renal failure are more commonly associated with sepsis, toxic drugs, and pre-existing medical conditions.
- Treatment includes adequate fluid resuscitation initiated as early as possible, monitoring urine output as a measure of renal perfusion. Sepsis from lines, wound, pneumonia, or urinary tract should be controlled by replacing the lines, excising the burn wound, and providing adequate antibiotic therapy for pneumonia and urinary tract infection.
- When needed, renal replacement therapy should be instituted.

Gastrointestinal Tract and Liver

- Ileus presents in patients with burns exceeding 20% total body surface area (TBSA).
- Using the gastrointestinal tract with some—even minimal—level of feeding is advocated early after injury and is usually well tolerated. Tube feeding should be instituted for patients with large burns where the patient is unable to tolerate sufficient intake.
- Gastroduodenal stress ulceration has markedly decreased with the use of antacids, H₂-antagonists, and proton pump inhibiting medications.
- Poor perfusion of the gut during resuscitation may lead to segmental ischemia in the watershed areas of the intestine leading to perforation. The use of vasoactive medications during burn resuscitation or during prolonged septic events may increase this risk.
- Normal gut flora have been identified as an infection source, and maintaining gut integrity with nutritional support in the form of glutamine supplementation has been studied. Selective gut decontamination has been shown to reduce bacterial translocation from the gut. Clinical success with this approach is not well documented.
- Intra-abdominal hypertension, as defined by a bladder pressure of 30 mm Hg or greater is the precursor to the abdominal compartment syndrome. Respiratory compromise with increasing peak airway pressures, renal compromise with decreased renal perfusion and urine output, and increased mortality have been observed. Burn patients with >30% burn injury are at risk for this complication. We recommend monitoring bladder pressures. Reduced fluid administration, sedation, and chemical paralysis of the patient are the initial treatments. Escharotomies and peritoneal drainage

make up the next most invasive line of management and, ultimately, abdominal decompression through a laparotomy may be needed to relieve the symptoms.

Central Nervous System

- Autoregulation of cerebral blood flow is effective to a point and then begins to fail as resuscitation proceeds, suggesting that the cerebrovascular system has a limited reserve to tolerate the effects of burn injury.

Endocrine System

- The elevations in stress-related hormones are noted in a time- and burn size-dependent manner after injury.
- The hypothalamus responds by secreting antidiuretic hormone that acts on the collecting ducts of the kidney to facilitate the reabsorption of water into the blood.
- The anterior pituitary releases adrenal corticotrophic hormone, which stimulates the release of the mineralocorticoid aldosterone and glucocorticoid cortisol.
- The adrenal medulla releases the tyrosine-derived neurotransmitters adrenaline and noradrenaline.
- Several medications are available that can modify the endocrine response to burn injury and include use of oxandrolone and beta-blockade to modify the metabolic response.

Hematopoietic System

- The red blood cell (RBC) mass in the burn patient declines in a burn size- and severity-dependent fashion.
- Initial heat injuries to the RBCs and sequestration of blood in the burn eschar are early factors in the loss of RBCs. Damage to RBCs secondary to the inflammatory response to the burn wound is a later development.

Immune System

- The risk of infection and its complications are directly related to the size of the burn injury and additional factors such as inhalation injury and pre-existing medical conditions. Burned skin loses its barrier function against the environment, and normal skin flora and environmental pathogens are able to gain access to the system.
- Damaged skin is the most obvious portal for bacterial entry. Burn-related hypotension and peripheral vasoconstriction may permit intestinal hypoperfusion and translocation of normal gastrointestinal flora into the systemic circulation. Other portals of entry are intubations of the respiratory, vascular, and genitourinary systems.

Musculoskeletal System

- Bone loss is due to (a) an increase in glucocorticoids that inhibit bone formation and osteoblast differentiation; (b) hypercalciuria secondary to hypoparathyroidism; and (c) vitamin-D deficiency.
- Muscle loss is secondary to an intense catabolic state initiated by the inflammatory response. Intravenous pamidronate

administration may help preserve bone mass in children with >40% surface area burns.

FLUID RESUSCITATION

- Aided by the use of the rule of nines and Lund-Browder charts, a patient's TBSA of burn and weight measurements are used to determine his or her initial fluid requirement. One half of the fluid requirements calculated are given in the first 8 hours after the burn injury, with the remaining amount administered over the subsequent 16 hours (Table 43.1).
- Adequate resuscitation is measured by end organ perfusion. A surrogate measure of the success of fluid administration is the measurement of urine output to a rate of 0.5 to 1.0 mL/kg using the ideal weight. The combination of blood pressure, heart rate, oxygenation, and central venous pressure are used in tandem to determine the adequacy of treatment.
- Postburn tissue edema will decrease the accuracy of cuff blood pressure measurements, and the vasoconstriction caused by catecholamine release will adversely affect the accuracy of indwelling arterial lines.
- Urinary rates of one-third the predicted value or less of the patient's body weight over 2 consecutive hours should prompt an increase in intravenous fluid administration.
- Patients running one-third or more over their expected urine output may benefit from decreased fluid administration.
- A graded increase or decrease of the intravenous fluid rate of 20% per hour is a measured and conservative response to these situations.
- Those patients who do not respond as expected to calculated fluid administration or who require more than 6 mL/kg per percent of TBSA burn should be considered for more invasive monitoring. A decision can be made to either support the cardiac output or reduce the peripheral vascular resistance, or both.
- Insensible water losses become more significant with larger TBSA burns and peak on the third day after burn. An estimation of insensible water losses may be calculated as follows:

$$\text{Insensible water loss (in mL/h)} = (125 + \% \text{TBSA burned}) \times \text{TBSA (in m}^2\text{)}$$

The total body surface area involved may be estimated using the formula of DuBois and DuBois as follows:

$$\text{BSA} = (\text{W}^{0.425} \times \text{H}^{0.725}) \times 0.007184$$

where W is the weight in kilograms and H is the height in centimeters. Initially, the replacement fluid should free water and then be altered based on electrolyte measurements.

TABLE 43.1

COMMON RESUSCITATION FORMULAS

	Common burn formulas		
	Evans formula	Brooke formula	Parkland formula
Colloid	1.0 mL/kg/%	0.5 mL/kg/%	None
Crystalloid	1.0 mL/kg/%	1.5 mL/kg/%	4.0 mL/kg/%
Free water	2,000 mL	2,000 mL	None

ELECTRICAL INJURY

- Electrical injuries can be divided into those due to low voltage (<1,000 volts), and those due to high voltage ($\geq 1,000$ volts).
- Electrical energy interacts with human anatomy following the basic principles of physics. Current flowing through tissue is related to the voltage drop across the resistance of that tissue. Heat produced by this current can be represented mathematically as follows:

$$J(\text{heat in Joules}) = I^2 \times R \times T$$

where I is current, R, resistance, and T, time in seconds. Differing tissues would create varying degrees of heat and subsequent damage; interestingly, clinical findings do not wholly support this concept. The highest resistance is found in the bone, fat, and tendons, whereas the lowest resistance has been identified in the muscles, blood, and nerves; skin has an intermediate resistance.

- Contact wounds on the hands and feet are common. Each of the contact areas might have a low cross-section, releasing more heat in that area; as the current crosses the “bottleneck” areas of the ankles and wrists with more tissue damage generated at these sites. At its most extreme, heat released by high-voltage injuries produces coagulation necrosis of the tissues and varying other effects on the organs as the electricity passes through.
- Arc injuries are less common but just as destructive. Electricity can travel 2 to 3 cm/10,000 volts and may travel 10 feet or more to its target. Temperatures at the contact points range from 2,000°C to 4,000°C, with spikes of up to 20,000°C; this intense temperature leads to severe and deep tissue damage.
- With high-voltage injuries, cardiac standstill and ventricular fibrillation are the most lethal cardiac injuries. Other electrocardiography includes atrial fibrillation, focal ectopic arrhythmias, supraventricular tachycardia, right bundle branch block, and nonspecific ST-T segment changes. These clinical findings are thought to be associated with direct myocardial muscle damage, coronary vasospasm, and coronary endarteritis.
- Renal injury is usually due to rhabdomyolysis. Large quantities of muscle protein, hemoglobin, and other tissue proteins released from the tissues coagulated by high voltage and current are filtered into the renal tubules, causing acute renal failure with oliguria or polyuria. Up to 15% of patients injured in high-voltage accidents will suffer from this type of renal injury.
- Central nervous system injury ranges from instant death to more subtle findings. Altered levels of consciousness with varying degrees of recovery have been reported, whereas progressive neurologic deterioration has been noted in both the central and the peripheral nervous systems. With high-voltage injuries, progressive deterioration of the microvascular nutrient vessels to the nerves has been identified and is thought to lead to ischemia, necrosis, and fibrosis of the injured nerve; progressive loss of function can be seen as a late developing problem.
- (b) asphyxiant gases and hypoxic environments, and (c) carbonaceous particle deposition.
- The diagnosis of inhalation injury is based on several site-specific and clinical findings surrounding each burn patient. Closed-space injuries or explosions, noxious fumes noted at the scene, and facial burns are some findings associated with inhalation injury, with the elderly being more susceptible.
- Signs and symptoms of a true airway burn injury include hoarseness; stridor and/or wheezing; carbonaceous sputum; singed nasal hair, eyebrows, or facial hair; and edema or inflammatory changes in the upper airway. The resultant upper-airway edema formation can threaten the airway and the patient’s breathing.
- Asphyxiant gases and hypoxic environments lead to the second area of pathology associated with inhalation injury. In fires involving structures, the ambient oxygen level markedly decreases leading to carbon monoxide—generation—a byproduct of incomplete combustion. Carbon monoxide binds tightly to hemoglobin, reducing the amount of oxygen delivered to end organs, causing hypoxic injury. Cyanide generation is associated with burning plastics; this molecule is highly lethal. Treatment of carbon monoxide intoxication includes a high concentration of oxygen and, sometimes, hyperbaric oxygen. Cyanide poisoning treatment includes delivery of oxygen and a three-part regimen to bind the cyanide compound in the blood.
- The flame-generated toxins that are bound to the carbon particles will induce a chemical tracheal bronchitis. The clinical sequelae include bronchorrhea, bronchospasm, distal airway obstruction, and atelectasis and pneumonia. Epithelial injury leads to sloughing of the mucosa and blockage of the airways with this cellular debris. Air trapping in this situation leads to atelectasis and the development of barotrauma and pneumonia.
- Endotracheal intubation to protect the airway should be performed early. Patients suffering from carbon monoxide exposure and showing clinical signs of intoxication should be treated with 100% oxygen to displace the molecule from hemoglobin. In severe neurologic symptoms, hyperbaric oxygen therapy should be administered if readily available.
- Cyanide toxicity presents clinically with lethargy, nausea, headache, weakness, and coma. Cyanide combines with cytochrome oxidase, thereby blocking oxygen use and inhibiting high-energy phosphate compound production. Cyanide toxicity begins at 0.1 $\mu\text{g/mL}$ of serum and quickly leads to death at concentrations of 1 $\mu\text{g/mL}$. Laboratory studies show a decreased arterial-venous oxygen difference with severe metabolic acidosis; this acidosis is unresponsive to fluids and oxygen administration. S-T segment elevations may be seen mimicking a myocardial infarction.
- Treatment of cyanide toxicity includes the administration of 100% oxygen and a three-part medication regimen: (a) administration of amyl nitrate pearls, by inhalation for 15 to 30 seconds every minute, (b) 10 mL 3% sodium nitrate solution (300 mg) intravenously over 3 minutes, repeated at one-half the dosage in 2 hours if symptoms persist or recurrent signs of toxicity are present, (c) sodium thiosulfate 50 mL of a 25% solution (12.5 gm) intravenously over 10 minutes, repeated at one-half the dosage in 2-hour intervals if persistent or recurrent signs of toxicity are present.

INHALATION INJURY

- The pathophysiology associated with smoke inhalation injury falls into three categories: (a) upper-airway injury,

INFECTION CONTROL

- The new challenge in burn injury is the concurrent development of infection in a compromised host.
- The advent of topical antibiotic/anti-infective agents addressed this new area of pathology. Subsequent movement toward early wound excision and skin grafting led to improvements in the rates of wound sepsis and its complications. Although the burn wound has become less of a risk for infection, other portals of entry have persisted in plaguing the burn patient. With our current methods of intubating the respiratory, vascular, and genitourinary systems, we expose the burn patient to other portals of entry for pathogens.

NUTRITION

- Basic principles are (a) an assessment of the patient's initial nutritional status, (b) monitoring of his or her nutritional status throughout the hospital course, and (c) adjustments based on the monitoring measures.
- Nutritional assessment should begin with measurement of the patient's weight, estimation of the patient's calorie and protein needs, measurement of the patient's serum albumin, pre-albumin, and C-reactive protein levels. Pre-existing illnesses should prompt the practitioner to make adjustments in the rate of feeding, use of additional medications, and the need for additional nutrient support.
- Glutamine supplementation has been shown to improve morbidity and mortality when administered to critically ill patients. Glutamine affects the immune system, the antioxidant status, glucose metabolism, and heat shock protein response.

WOUND MANAGEMENT

- The patient should be covered with a clean sheet and blanket to conserve body heat and minimize burn wound contamination during transport to the hospital.
- The application of ice or cold water soaks, when initiated within 10 minutes after burning, may reduce tissue heat content and lessen the depth of thermal injury. Care must be taken to avoid causing hypothermia and limiting this form of therapy to 10% or less burn of the body surface area.
- Daily wound care involves cleansing, debridement, and dressing of the burn wound. On the day of injury, the burn wound is best cleansed by means of hydrotherapy. Hydrotherapy is accomplished by means of showering, immersion, or use of a spray table.
- Immersion hydrotherapy often is used for patients in a less acute stage who have a moderate or smaller injury. Soaking promotes removal of therapeutic creams and exudate, debridement of loose eschar, and active participation by the patient in range-of-motion exercises. Immersion hydrotherapy should be avoided in patients with an extensive thermal injury as this process may spread contamination. The consensus is that a hydrotherapy session of 30 minutes or less is optimal for patients with acute burns.

- Mechanical debridement is accomplished through application and removal of gauze dressings, hydrotherapy, irrigation, and use of scissors and tweezers. Wet-to-dry or wet-to-moist dressings are sometimes used to debride exudative wounds.
- Mafenide acetate (Sulfamylon), silver sulfadiazine (Silvadene), and silver nitrate are the three most commonly used topical antimicrobial agents for burn wound care.
- Mafenide acetate burn cream is an 11.1% suspension in a water-soluble base. This compound diffuses freely into the eschar and is the preferred agent in heavily contaminated burn wounds or in situations where burn wound care has been delayed by several days. This agent is highly effective against Gram-negative organisms, including most *Pseudomonas* species. Hypersensitivity reactions occur in 7% of patients and pain or discomfort lasting 20 to 30 minutes.
- Mafenide inhibits carbonic anhydrase, resulting in a diuresis of bicarbonate with development of metabolic acidosis. Inhibition of this enzyme rarely persists for >7 to 10 days, and the severity of the acidosis may be minimized by alternating applications of mafenide with silver sulfadiazine cream every 12 hours.
- Silver sulfadiazine burn cream is a 1% suspension in a water-miscible base. Unlike mafenide, silver sulfadiazine has limited solubility in water and limited ability to penetrate into the eschar. This agent is painless on application, and serum electrolytes and acid-base balance are not.
- Silver sulfadiazine occasionally induces neutropenia by a mechanism thought to involve direct bone marrow suppression; white blood cell counts usually return to normal after discontinuation. With continual use, resistance to the sulfonamide component of silver sulfadiazine is common, particularly in certain strains of *Pseudomonas* and many *Enterobacter* species.
- A 0.5% silver nitrate solution has a broad spectrum of antibacterial activity imparted by the silver ion. This agent does not penetrate the eschar, as the silver ions rapidly precipitate on contact with any protein or cationic material. The dressings are changed twice daily and moistened every 2 hours with the silver nitrate solution to prevent evaporation from increasing the silver nitrate concentration to cytotoxic levels within the dressings. Transeschar leaching of sodium, potassium, chloride, and calcium should be anticipated and replaced. Hypersensitivity to silver nitrate has not been described.
- Mafenide acetate, silver sulfadiazine, and 0.5% silver nitrate are effective in the prevention of invasive burn wound infection. Because of their lack of eschar penetration, silver nitrate soaks and silver sulfadiazine burn cream are most effective when applied soon after burn injury.
- Acticoat is a new burn wound dressing. It consists of a urethane film onto which nanocrystalline elemental silver is deposited. When moistened, application of this dressing to the wound results in a sustained release of elemental silver, which is bactericidal and fungicidal. The mechanism of action is probably much like that of silver nitrate dressings; however, Acticoat does not cause transeschar leaching of electrolytes. The silver does not penetrate the eschar, limiting its use on heavily contaminated wounds. The use of Acticoat is currently limited to partial-thickness burns.
- Aquacel Ag hydrofiber is another dressing containing elemental silver, though at a much lower concentration. When compared to silver sulfadiazine on partial-thickness burns,

this dressing was associated with an increased rate of re-epithelization and was slightly more cost-effective.

PAIN MANAGEMENT AND ANXIOLYSIS

- An appropriate rationale is to titrate the drug dose to the desired effect rather than to rely on a particular textbook dose for all patients. Owing to the development of drug tolerance, opioid analgesic dose may exceed those recommended in standard dosing guidelines.
- Anxiety, in itself, can exacerbate acute pain. This has led to the common practice in many burn centers of using anxiolytic drugs in combination with opioid analgesics.

TEAM APPROACH

- This multidisciplinary care spans the early resuscitative phases of care through the long-term rehabilitation and reconstructive phases. Team members include burn surgeons, plastic and reconstructive surgeons, critical care specialists, anesthesiologists, critical care burn nurses, physical therapists, occupational therapists, clinical nutritional specialists, psychologists, social workers, and pastoral care support personnel.
- This concept of team care, originating in the 1950s when the first burn centers opened, has persisted to this day and is a model of coordinated, interdisciplinary, outcome-driven patient care.

CHAPTER 44 ■ TEMPERATURE-RELATED INJURIES

- The balance between heat generation and dissipation is the key to maintaining optimal body temperature. Under normal circumstances, body temperature is 37°C under the tongue, 38°C in the rectum, 32°C at the skin, and 38.5°C in the central liver. Significant deviation from normal body temperature is a critical condition that requires prompt diagnosis, treatment, and normalization of the temperature alteration.

HYPOTHERMIA

- Hypothermia is defined as a core temperature below 35°C (95°F): Mild hypothermia is that between 35°C and 32°C, moderate hypothermia between 32°C and 28°C, and severe hypothermia below 28°C.
 - Table 44.1 outlines the classification of severity and clinical manifestations.
 - Hypothermia is considered to be an underrecognized condition, especially in the aged with inadequate home heating and inappropriate clothing for actual ambient temperatures.
 - Several confounding factors can further impair temperature control (Table 44.2).
- Accidental hypothermia is defined as a spontaneous decrease in core temperature, often caused by a cold environment.
 - Mortality rates for accidental hypothermia have been reported to range between 10% and 80%.

Clinical Syndromes

Cardiovascular

- A sympathetic response increases myocardial oxygen consumption and causes tachycardia and peripheral vasoconstriction—that is, diminished pulses, pallor, acro-

cyanosis, and cold extremities—in patients with mild hypothermia (core temperature of 32°C–35°C).

- Blood pressure and heart rate are initially increased and followed by bradycardia, which further deteriorates at 32°C, and consequently, cardiac output, myocardial contractility, and arterial pressure fall.
- Electrocardiographic (ECG) findings include the Osborne J-wave after the QRS complex as hypothermia becomes severe (Fig. 44.1) The Osborne J-wave is an important diagnostic feature, (also seen in central nervous system lesions and sepsis), but it is frequently absent.
- Atrial and ventricular fibrillation are common, and electrical defibrillation during hypothermia is often ineffective.
- Hypothermic myocardium is irritable, making placement of pulmonary artery or other central catheters dangerous.

Respiratory System

- Respiratory rate falls. The patient becomes apneic or has an agonal respiratory pattern when the body temperature is <28°C.

Central Nervous System

- The electroencephalogram becomes flat at 19°C to 29°C (12). Cerebrovascular autoregulation remains intact until the core temperature falls to below 25°C, but mentation starts to drop at 30°C. Dysarthria and hyperreflexia occur below 35°C, and hyporeflexia occurs below 32°C.

Coagulation

- Hypothermia produces coagulopathy via three major mechanisms: (a) the enzymatic coagulation cascade is impaired, (b) platelet dysfunction occurs, and (c) enhanced plasma fibrinolytic activity is seen.

TABLE 44.1

CLASSIFICATION OF HYPOTHERMIA

Core temperature	Consciousness	Shivering	Heart rate	ECG	Respiration
Mild (35°C–33°C)	Normal	+	Normal	Normal	Normal
Moderate (33°C–30°C)	Depressed (stupor)	–	Slight decrease	Prolongation	Depressed
Severe (30°C–25°C)	Confusion	–	Decreased	Osborne J-wave	Apneic/agonal
25°C–20°C	Coma	Muscle rigidity	Decreased	Atrial fibrillation	Apneic
Below 20°C	Coma	Muscle rigidity	Asystole	Ventricular fibrillation	Apneic

ECG, electrocardiogram.

- Because coagulation tests, such as prothrombin time or partial thrombin time, are performed at 37°C in the laboratory, a major disparity between clinical coagulopathy and the reported values is frequently observed.
- A disseminated intravascular coagulation (DIC) type of syndrome is also reported.

Renal System

- Exposure to cold induces a diuresis irrespective of the state of hydration. Centralization of the blood volume—due to the initial peripheral vasoconstriction—stimulates the diuresis.
- Hypothermia depresses renal blood flow by 50% at 27°C to 30°C, and the renal cellular basal metabolic rate decreases. As a result, renal tubular cell reabsorptive function decreases, and the kidney excretes a large amount of dilute urine. This

is termed *cold diuresis*, resulting in a decreased blood volume and progressive hemoconcentration.

Glucose Metabolism

- Blood glucose concentration commonly increases because pancreatic function, insulin activity, and/or response to insulin decrease, along with activated function of the autonomic nervous system in hypothermia. At the same time, hemoconcentration results in elevated serum glucose concentration.

Therapeutic Approach

Pre-Hospital Treatment

- Even if a patient is found down, cold, stiff, and cyanotic, the patient is not necessarily dead, and rescue efforts should not be given up while the patient is cold.
- As ventricular fibrillation or asystole may be induced by any stimuli, such as tracheal intubation, comatose patients should be treated with extreme care.
- The initial primary focus of prehospital treatment is to avoid further loss of heat. Removal of wet clothing and applying dry insulating covers and an aluminized space blanket may be used.
- The patient should be kept horizontal to minimize the circulatory and sympathetic change. Vigorous rubbing should be avoided because it induces vasodilation, which may be followed by hypotension or “rewarming shock.” Hot water bottles or hot packs may be used if available but should be used cautiously to avoid burn injury.
- Resuscitation using the ABCs—airway, breathing, circulation—of basic life support are implemented if needed.
- Warmed (42°C–46°C), humidified oxygen during bag-mask ventilation (20) and warmed intravenous fluids should be given if possible.
- Death should not be declared below 32°C.

In-Hospital Treatment

- Indicated monitoring includes an ECG, Doppler evaluation of pulses, and temperature.
- General laboratory studies include electrolytes, complete blood count, coagulation studies (prothrombin time and partial thromboplastin time), blood urea nitrogen, creatinine, amylase, calcium, magnesium, and glucose concentrations.
- Radiologic examinations are indicated.

TABLE 44.2

CAUSES OF HYPOTHERMIA

Clinical cause	Associated disorders
Central nervous system	Head trauma, tumor, stroke, Wernicke encephalopathy, Shapiro syndrome, Parkinson disease, multiple sclerosis, sarcoidosis, acute spinal cord transection, paraplegia
Metabolic	Hypoglycemia, hypothyroidism, hypoadrenalism, panhypopituitarism, diabetic ketoacidosis, anorexia nervosa
Integument	Burns, erythroderma, ichthyosis, psoriasis, exfoliative dermatitis
Infection	Sepsis
Chronic diseases	Chronic heart failure, chronic renal failure, chronic hepatic insufficiency, advanced age
Environmental exposure	Outdoor activities and physical or metabolic exhaustion, cold water immersion, inadequate indoor heating (particularly in the elderly and infirm), operating room
Pharmaceuticals/ drugs	Ethanol, muscle relaxants, phenothiazines, barbiturates, tricyclic antidepressants, lithium (toxic dose), α -adrenergic agonist (clonidine), anticholinergic drugs, β -adrenergic blocker

FIGURE 44.1. The electrocardiogram (ECG) shows atrial fibrillation with a very slow ventricular response, prominent (Osborne) J-waves (late, terminal upright deflection of QRS complex; best seen in leads V3–V6), and nonspecific QRS widening. (Adapted from O’Keefe J, Hammill S, Freed M, et al. *The Complete Guide to ECGs*. 2nd ed. Royal Oak, MI: Physicians’ Press; 2002.)

- Patients with hypothermia are usually dehydrated, which should be corrected with IV fluids warmed to 43°C.
- The glucose-containing solutions should be used with caution as hypothermic patients are usually hyperglycemic owing to hypoactivity of insulin.
- Techniques of rewarming are presented in Table 44.3.
- Percutaneous or open-chest cardiopulmonary bypass is recommended for pulseless hypothermic patients.
- Bronchopneumonia secondary to aspiration is a common complication. Oral intake of warm or hot drink should be avoided because obtunded, hypothermic patients may have suppressed airway protective mechanisms, including cough or gag reflexes.
- Prophylactic tracheal intubation may be considered if suppression of these reflexes is present. When the trachea is intubated, warmed (42°C–46°C), humidified oxygen should be administered.

HYPERTHERMIA

- Table 44.4 outlines the major causes, which may be classified as hyperthermia or fever.

Environmental Hyperthermia: Heat Stroke

- Heat stroke is a medical emergency, characterized by a high body temperature, altered mental status, and hot dry flushed skin.

- It may lead to multisystem organ dysfunction with hemorrhage and necrosis in the lungs, heart, liver, kidneys, brain, and intestines.
- Mortality in the last 50 years has remained between 10% and 50%.
- There are several heat-related illnesses (see Table 44.5).
 - *Heat syncope* is fainting due to peripheral vasodilation secondary to high ambient temperature.
 - *Heat cramp* refers to muscular cramping occurring during exercise in heat, which is related to electrolyte deficiency; it is usually benign.
 - *Heat exhaustion* or prostration refers to patient’s collapsing from dehydration, salt depletion, and hypovolemia. Anorexia, nausea, and vomiting frequently occur. Salt-depletion heat exhaustion usually occurs when an unacclimatized person exercises and replaces only water. Water-depletion heat exhaustion is usually observed in an acclimatized person who has inadequate water intake during exposure to extreme heat. Serum sodium concentration may be normal or mildly elevated. The core temperature may or may not be raised (usually mild to moderate, <38°C) and tissue damage does not occur.
 - *Heat stroke* occurs when the core body temperature rises against a failing thermoregulatory system and rectal temperature exceeds 40.6°C. Exertional heat stroke occurs in previously healthy young people exercising in hot and humid climates without being acclimatized. Nonexertional heat stroke occurs during extreme heat waves, the elderly being particularly vulnerable (Table 44.6).

TABLE 44.3**REWARMING METHODS**

Classification		Methods	Effects
Passive	External	Adding an insulating layer (e.g., blanket, sleeping bag)	0.1°C–0.7°C increase/h
Active	External	Increasing ambient temperature	Effective when body temperature is above 32°C
		Hot water bottles	1°C–4°C increase/h
		Heating blanket	Internal rewarming recommended to avoid rewarming shock
		Infrared lamp	
		Submersion in a warm water tank	5°C–7°C increase/h
	Internal (core)	Warmed crystalloid fluids or blood transfusion	1.5°C–2°C increase/h
		Gastric lavage	Warmed fluids administration required due to loss of circulatory blood volume caused by cold diuresis
		Rectal lavage	
		Cystic lavage	
		Airway rewarming	3°C–15°C increase/h
	(invasive)	Peritoneal dialysis	
		Thoracic cavity lavage	
		Hemodialysis	
		Cardiopulmonary bypass	
		Percutaneous cardiopulmonary support	

Temperature Regulation

- Normal heat production is primarily due to metabolic activity in the liver and skeletal muscle, with the liver generating most body heat at rest and muscle being the major source with exercise or shivering.

TABLE 44.4**HYPERTHERMIA AND FEVER****Hyperthermia**

Environmental exposure
 Malignant hyperthermia
 Neuroleptic malignant syndrome
 Thyroid storm
 Pheochromocytoma
 Serotonin syndrome

 Salicylates
 β -adrenergic blockers

Fever

Inflammatory disorders
 Infection
 Allergic reactions
 Collagen diseases
 Neoplasm
 Inherited and metabolic diseases
 Factitious fever

- Heat elimination occurs by four major mechanisms, as we have discussed in hypothermia.
- Heat stroke is mostly defined as a core temperature above 40.6°C, but neurologic impairment may occur at lower temperatures. Neurologic manifestations include slurred speech, delirium, stupor, lethargy, coma, seizures, ataxia, dysmetria, and dysarthria. Cerebral edema, and localized brain hemorrhages may occur with irreversible brain damage at above 42°C. Cerebellar impairment may persist after recovery.
- Cardiovascular manifestations include tachydysrhythmia and hypotension. Cardiac complications include myocardial pump failure, tachydysrhythmia, high cardiac output, and myocardial infarction. ECG abnormalities are also observed. Sinus tachycardia and QT prolongation are followed by non-specific ST-T wave changes, suggesting cardiac ischemia.
- Lactic acidosis may occur, and restoration of the circulating volume may lead to worsening lactic acidosis as skeletal muscle is reperfused. Patients typically hyperventilate to compensate for the acute acidosis with an acute respiratory alkalosis. This may lead to heat-induced tetany.
- Significant dehydration is noted in most patients with exertional heat stroke with elevated blood urea nitrogen and creatinine levels or hemoconcentration. Sodium, potassium, phosphate, calcium, and magnesium serum concentrations are frequently low in the early period. Sodium, potassium,

TABLE 44.5**HEAT SYNDROMES**

Syndrome	Temperature	Manifestation
Heat syncope	Normal	Faintness
Heat cramps	Normal	Muscle cramps
Heat exhaustion	Normal to 39°C	Faintness, weakness
Heat stroke	>40.6°C	Gross neurologic impairment

TABLE 44.6**EXERTIONAL AND NON-EXERTIONAL HEAT STROKE SYNDROMES**

	Exertional	Nonexertional
Age	Young	Elderly

Underlying process	None	Medical illness, drug therapy
Onset	Rapid	Slow
Sweating	Present	Absent

and magnesium are lost through increased sweating. Hypokalemia may be as a result of catecholamine release or may occur secondary to hyperventilation. Cellular death begins to occur throughout the body at temperatures above 42°C. Hyperkalemia may occur if significant skeletal muscle damage or cellular lysis develops. If significant rhabdomyolysis develops, injured cells release phosphate, which reacts with serum calcium and may lead to hypocalcemia.

- Renal dysfunction is well documented in exertional heat stroke, with the incidence of acute renal failure approximately 25%. Acute renal failure may be caused by direct heat damage, renal hypoperfusion, or rhabdomyolysis. The incidence of renal failure is about 35% with exertional heat stroke and about 5% in classic nonexertional heat stroke, with which rhabdomyolysis is less likely to coexist.
- Liver damage is very frequently seen and is probably related to splanchnic redistribution.
- Hematologic complications include hemolysis, thrombocytopenia, and DIC. Hemorrhagic complications may be petechial hemorrhages and ecchymoses, which may represent direct thermal injury or may be related to the development of DIC.
- Pulmonary edema may be caused by a limited cardiac function or may develop secondary to the acute respiratory distress syndrome. Pulmonary aspiration may be observed in obtunded patients.

Therapeutic Approach

- Heat stroke requires prompt oxygen therapy, rapid cooling, and cautious hydration.
- Tracheal intubation should be considered if the patient is obtunded or in respiratory distress.
- Oxygen delivery is often less than normal, and pulmonary shunt fraction is increased.
- Rapid cooling is accomplished by external techniques: immersion in ice water or application of cooling blankets, wetting the skin with water or alcohol, followed by the use of fans to facilitate evaporation and heat dissipation.
- Both techniques usually reduce core temperature below 40°C in 1 hour.
- Significant disadvantages of immersion are impairment of access to the patient and limited monitoring, intense vasoconstriction, and increased cardiac afterload.
- More aggressive cooling techniques include gastric lavage with iced saline, cold hemodialysis, and cardiopulmonary bypass.

- The efficacy of rapid infusion of large-volume ice-cold fluid (LVICF) intravenously with 30 mL/kg of LVICF (lactated Ringer solution at 4°C) over 30 minutes may decrease core temperature by 1.7°C immediately after infusion.
- Core body temperature should be monitored closely at the rectum, bladder, or tympanic membrane.
- Vital signs, neurologic functions, urine output, and laboratory measurements should also be monitored closely. Laboratory measurements include arterial blood gas and serum electrolyte concentrations, especially potassium, which may increase significantly and result in life-threatening hyperkalemia. Glucose–insulin therapy should be instituted emergently in patients with ECG changes.
- Volume deficit is not a prominent feature in classic nonexertional heat stroke. Central venous catheter and pulmonary artery catheter placement may be invaluable to assess volume depletion, peripheral vascular vasodilation, or primary myocardial dysfunction, especially in patients with limited cardiac reserve.
- Hypotension usually responds to intravenous fluids but, if an inotropic drug is needed, dobutamine is the drug of choice for heat stroke.
- Seizures occur commonly in heat stroke patients and should be treated with intravenous diazepam or other benzodiazepines.
- DIC may be treated with continuous infusion heparin therapy although its utility seems uncertain.

Malignant Hyperthermia and the Neuroleptic Malignant Syndrome

- Malignant hyperthermia (MH) and the neuroleptic malignant syndrome (NMS) are disorders of rising body temperature related to an imbalance between heat production and heat dissipation.
- Main features include hyperthermia, muscle rigidity, metabolic acidosis, and autonomic disturbances.
- Both MH and NMS are uniquely characterized by their association with various drugs, although they are distinctive from each other; associated drugs are listed in Table 44.7. An additive in commercial succinylcholine, chlorocresol, has been reported as an additional trigger in MH.
- The *in vitro* halothane–caffeine contracture test on skeletal muscle helps to identify susceptible individuals.
- For MH, the mortality rate was initially 70%; earlier diagnosis and use of dantrolene have reduced it to <5%.
- A decrease in mortality has been reported; NMS has had a 76% mortality and a 15% mortality since 1980.
- Free inbound ionized calcium can be released from the storage sites, which normally maintain skeletal muscle relaxation by sequestering calcium from the muscle contractile apparatus. The administration of anesthetics may unpredictably trigger rapid calcium release into the myoplasm, followed by the development of muscle contracture, rigidity, and increased muscle metabolic activity. This process can cause core body temperature to rise vigorously at a rate of 1°C every 5 minutes.
- A common pathophysiology of NMS and MH has been suggested based mainly on three points: (a) NMS and MH have clinical features in common, such as hyperthermia, rigidity, an elevated creatine kinase concentration, and a mortality rate

TABLE 44.7

DRUGS ASSOCIATED WITH MALIGNANT HYPERTHERMIA AND THE NEUROLEPTIC MALIGNANT SYNDROME

Classification	Associated drugs
MALIGNANT HYPERTHERMIA	
Volatile anesthetics	Halothane, cyclopropane, enflurane, methoxyflurane, isoflurane, sevoflurane, desflurane, diethyl ether
Depolarizing muscle relaxants	Succinylcholine, decamethonium
Antidysrhythmics	Lidocaine
NEUROLEPTIC MALIGNANT SYNDROME	
Phenothiazines	Fluphenazine, chlorpromazine, levomepromazine, thioridazine, trimeprazine, methotrimeprazine, trifluoperazine, prochlorperazine, promethazine, alimemazine
Butyrophenones	Haloperidol, bromperidol, droperidol
Thioxanthenes	Thiothixene, zuclopenthixol
Dibenzazepines	Loxapine
Dopamine-depleting drugs	Alpha-methyltyrosine, tetrabenazine, amoxapine
Dopamine agonist withdrawal	Levodopa, levodopa/carbidopa, amantadine
Serotonin dopamine antagonists	Risperidone
Serotonin-depleting drugs	Paroxetine

of 10% to 30%; (b) sodium dantrolene has been used successfully in both syndromes; and (c) abnormal findings have been observed in *in vitro* contractility tests in patients with either of the syndromes.

- MH may occur shortly after induction of anesthesia, at any time during the administration of anesthetics, or postoperatively.
- Trismus is the initial event in 50% of patients, and other early signs are tachycardia and hypercapnia due to increased metabolism. These are followed by whole-body rigidity and a marked increase in core body temperature.
- Sympathetic system overactivity produces tachycardia, hypertension, and mottled cyanosis. These symptoms precede hyperthermia, hyperkalemia, hypercalcemia, and lactic acidosis.
- Capnography may provide an early warning, as carbon dioxide production is remarkably increased while MH is in progress.
- Core body temperature can rise at a rate of 1°C every 5 minutes.
- Anesthesia should be aborted if these signs appear or if MH is suspected.
- Laboratory evaluation reveals increased serum myoglobin, creatine kinase (>20,000 U/L), lactate dehydrogenase, and aldolase levels. Dark urine reflects myoglobinemia and myoglobinuria.
- A clinical grading scale for the prediction of MH is summarized in Tables 44.8A and 44.8B.
- NMS should be suspected in patients given any neuroleptic drugs who subsequently develop signs of muscular rigidity, dystonia, or unexplained catatonic behavior, followed by

TABLE 44.8A

SCORING RULES FOR THE MALIGNANT HYPERTHERMIA (MH) CLINICAL GRADING SCALE

MH INDICATORS

Review the list of clinical indicators. If any indicator is present, add the points applicable for each indicator while observing the double-counting rule below, which applies to multiple indicators representing a single process.

If no indicator is present, the patient's MH score is zero.

DOUBLE-COUNTING

If more than one indicator represents a single process, *count only the indicator with the highest score*. Application of this rule prevents double-counting when one clinical process has more than one clinical manifestation.

Exception: The score for any relevant indicators in the final category of Table 44.8B ("other indicators") *should* be added to the total score without regard to double-counting.

MH SUSCEPTIBILITY INDICATORS

The italicized indicators listed below apply only to MH susceptibility. Do not use these indicators to score an MH event. To calculate the score for MH susceptibility, add the score of the italicized indicators below to the score for the highest-ranking MH event.

Positive family history of MH in relative of first degree

Positive family history of MH in relative not of first degree

Resting elevated serum creatinine kinase

Positive family history of MH together with another indicator from the patient's own anesthetic experience other than elevated serum creatine kinase

INTERPRETING THE RAW SCORE: MH RANK AND QUALITATIVE LIKELIHOOD

Raw score range	MH rank	Description of likelihood
0	1	Almost never
3—9	2	Unlikely
10—19	3	Somewhat less than likely
20—34	4	Somewhat greater than likely
35—49	5	Very likely
50+	6	Almost certain

TABLE 44.8B

CLINICAL INDICATORS FOR USE IN DETERMINING THE MALIGNANT HYPERTHERMIA (MH) RAW SCORE

Process	Indicator	Points
Process I: Rigidity	Generalized muscular rigidity (in absence of shivering due to hypothermia, or during or immediately following emergence from inhalational general anesthesia)	15
	Masseter spasm shortly following succinylcholine administration	15
Process II: Muscle breakdown	Elevated creatine kinase >20,000 IU after anesthetic that included succinylcholine	15
	Elevated creatine kinase >10,000 IU after anesthetic without succinylcholine	15
	Cola-colored urine in perioperative period	10
	Myoglobin in urine >60 µg/L	5
	Myoglobin in serum >170 µg/L	5
Process III: Respiratory acidosis	Blood/plasma/serum K >6 mEq/L (in absence of renal failure)	3
	PETCO ₂ >55 mm Hg with appropriately controlled ventilation	15
	Arterial PaCO ₂ >60 mm Hg with appropriately controlled ventilation	15
	PETCO ₂ >60 mm Hg 15 with spontaneous ventilation	15
	Arterial PaCO ₂ >65 mm Hg with spontaneous ventilation	15
	Inappropriate hypercarbia (in anesthesiologist's judgment)	15
Process IV: Temperature increase	Inappropriate tachypnea	10
	Inappropriately rapid increase in temperature (in anesthesiologist's judgment)	15
	Inappropriately increased temperature >38.8°C (101.8°F) in the preoperative period (in anesthesiologist's judgment)	10
Process V: Cardiac involvement	Inappropriate sinus tachycardia	3
	Ventricular tachycardia or ventricular fibrillation	3
Process VI: Family history (used to determine MH susceptibility only)	Positive MH family history in relative of first degree ^a	15
	Positive MH family history in relative not of first degree ^a	5
Other indicators that are not part of a single process ^b	Arterial base excess more negative than −8 mEq/L	10
	Arterial pH <7.25	10
	Rapid reversal of MH signs of metabolic and/or respiratory acidosis with IV dantrolene	5
	Positive MH family history together with another indicator from the patient's own anesthetic experience other than elevated resting serum creatine kinase ^a	10
	Resting elevated serum creatine kinase ^a (in patient with a family history of MH)	10

^aThese indicators should be used only for determining MH susceptibility.^bThese should be added without regard to double-counting.

hyperpyrexia. Other symptoms include unstable blood pressure, confusion, coma, and delirium (Table 44.9).

Complications

- Complications arising from MH and NMS are rhabdomyolysis (with renal failure), hepatic necrosis, and ventricular fibrillation. Cerebral edema with seizures is uncommon but may be seen. Patients with NMS are at risk for aspiration

pneumonia because of dystonia and the inability to handle secretions.

Therapeutic Approach

- Successful treatment of MH and NMS depend on prompt withdrawal of the suspected drugs. It may take 5 to 7 days to return to the patient's baseline because neuroleptics cannot be removed by dialysis, and blood concentrations decline slowly.
- General symptomatic treatment, such as hydration, nutrition, and reduction of fever, is essential.
- Dantrolene should be administered emergently to prevent further release of calcium from the sarcoplasmic reticulum. The dose is 2 mg/kg intravenously every 5 minutes to a total dose of 10 mg/kg until the episode terminates. Dantrolene also decreases temperature in NMS and thyroid storm.
- Acidosis should be treated aggressively with intravenous administration of bicarbonate, 2 to 4 mEq/kg.
- Hyperkalemia should be treated with insulin and glucose infusion and with diuresis.

TABLE 44.9

CRITERIA FOR GUIDANCE IN THE DIAGNOSIS OF NEUROLEPTIC MALIGNANT SYNDROME

Category	Manifestations
Major	Fever, rigidity, elevated creatine kinase concentration
Minor	Tachycardia, abnormal arterial pressure, tachypnea, altered consciousness, diaphoresis, leukocytosis

- Fever should be controlled by iced fluids, surface cooling, and cooling of body cavities with sterile iced fluids. Cold dialysis and cardiopulmonary bypass may also be applicable if other measures fail.
- Mannitol infusion—0.5 g/kg—with or without furosemide should be used to establish a diuresis and prevent the onset of acute renal failure from myoglobinuria.

- Further therapy is guided by blood gases, electrolytes, temperature, arrhythmia, muscle tone, and urinary output.
- Lab analyses include electrolytes, creatine kinase concentrations, liver enzymes, blood urea nitrogen, lactate, glucose, serum hemoglobin and myoglobin, coagulation profile, and urine hemoglobin and myoglobin.

CHAPTER 45 ■ EVALUATING THE ACUTE ABDOMEN

An acute abdomen is any problem in which the patient's pain or other physical findings originate from an abdominal lesion resulting in serious morbidity or mortality without appropriate therapy. Early recognition of the acute abdomen and initiation of definitive surgical or medical therapy often determine the outcome. A high index of suspicion is required in the critically ill patient who may not be able to give a lucid history, and physical findings may be masked by narcotics, steroids, and other therapy administered.

ANATOMY

Knowledge of the sensory nerve supply of the abdomen is particularly important in evaluating the abdomen in critically ill patients.

Visceral Pain

- Visceral pain is transmitted via both sympathetic and parasympathetic nerves.
- The pain is poorly localized, typically unpleasant, and associated with autonomic symptoms such as tachycardia, bradycardia, and diaphoresis.
- The primary stimulus is stretching of hollow viscera or solid organ capsules.
- Visceral pain shares common pathways and areas of the sensory cortex with somatic pain, which explains referred pain to remote dermatomes (e.g., shoulder pain caused by diaphragmatic irritation).
- Abdominal pain becomes more localized when the parietal peritoneum, with its rich somatic sensory supply, is affected by the underlying inflammatory process.
- Knowledge of the **blood supply** of the abdomen is also important given the extensive diagnostic and therapeutic applications of angiography in acute abdominal pathology.
- The foregut (esophagus to duodenum) is supplied by branches of the celiac trunk.
- The midgut (jejunum to distal transverse colon) is supplied by branches of the superior mesenteric artery (SMA).

- The hindgut (descending colon and rectum) is supplied by branches of the inferior mesenteric artery.
- **Collateral circulation** exists between branches of the mesenteric vessels.
- The **marginal artery of Drummond** connects the SMA and inferior mesenteric artery along the mesenteric border of the colon.
- The **arc of Riolan** connects the middle colic artery with the ascending branch of the left colic artery.
- The internal iliac artery contributes to colonic circulation through a connection between the middle and superior rectal arteries.
- An embolus tends to lodge distal to the origins of the most proximal branches of the SMA, namely the inferior pancreaticoduodenal, the middle colic, and the proximal jejunal branches. The proximal jejunum and the transverse colon are typically spared in acute ischemia due to SMA embolism compared to thrombosis.

HISTORY

- **A careful evaluation of the characteristics of abdominal pain is essential.** Its nature, onset, associated symptoms, radiation, and other characteristics are useful in localizing and delineating the cause. The history should include a complete surgical history, family history, and a list of medications. It should also include allergies, ethanol use, immunosuppressive drugs, and a history of human immunodeficiency virus (HIV), hepatitis, or chemotherapy.
- Diabetic and immune-suppressed patients, particularly those on steroids, can present with advanced intra-abdominal sepsis before peritoneal signs become obvious.
- Gastrointestinal bleeding or perforation may occur as a consequence of taking steroids or nonsteroidal anti-inflammatory agents.
- As we become more globalized, awareness of infectious disease from emerging countries is necessary for evaluation of disparate symptoms. The presence of a percutaneous endoscopic gastrostomy or other tubes should alert the physician

to the possibility of a problem related to tube misplacement or obstruction.

- **Abdominal symptoms can be masked by other disease processes.**
 - Diabetic ketoacidosis or syncope may have an underlying abdominal catastrophe as a precipitating factor.
 - Inferior myocardial infarction, pericarditis, and lower lobe pneumonia may present with upper abdominal pain.
 - Porphyria and sickle cell crises can mimic abdominal catastrophes, although they rarely cause admission to the intensive care unit.

PHYSICAL EXAMINATION

- Abdominal examination in the critically ill patient can be challenging, as many patients will be unconscious, intubated, combative, comatose, narcotized, or paralyzed. The standard routine of inspection—palpation, percussion, and auscultation—should be followed. Vital signs, including blood pressure (with the patient sitting if possible), pulse, respiratory rate, and rectal or core temperature, should be taken.
- Inspection of the abdomen can give many clues:
 - The Gray–Turner sign, flank ecchymosis, was initially described with hemorrhagic pancreatitis but can occur with other causes of retroperitoneal bleeding.
 - The Sister Mary Joseph nodule indicates abdominal or breast malignancy that spread along the round ligament to the umbilicus.
 - Dilated abdominal wall veins indicate advanced portal hypertension.
 - A large abdominal aortic aneurysm may be discerned as a pulsating upper abdominal mass in a thin patient.
 - Absent or hypoactive bowel sounds is a nonspecific sign as many patients will have ileus associated with their critical illness. Bowel sounds are frequently absent in paralyzed patients, despite the fact that muscular paralysis should not eliminate autonomic bowel function. Hyperactive sounds or “rushes” are most common with small-bowel obstruction. The presence of bowel sounds, however, does not always correlate with normal bowel function.
- The presence of guarding or rigidity indicates peritoneal irritation.
 - Rebound may not be present in a postoperative patient with significant abdominal pathology.
 - Patients’ response to the presence of blood in the peritoneal cavity can vary from guarding and rigidity to a soft abdomen.
 - In obese patients, assessment for abdominal wall rigidity is unreliable, and they may have groin or incisional hernias that are not easily discerned.
 - Patients with mesenteric ischemia have pain that is out of proportion to the findings of the physical exam.
 - Rectal and pelvic examinations are frequently avoided in the ICU; however, they are mandatory to discover low pelvic abscesses and masses, prostatic infection, and bloody stools.
- The physical examination of the acute abdomen should be performed by an experienced physician on a regular basis.
 - An isolated examination is not nearly as useful as **sequential examinations by the same observer** to carefully document

any progression of tenderness, muscular rigidity, and the overall trend toward improvement or deterioration.

- The physician who will ultimately make the decision whether surgical intervention is required should be involved as early as possible.
- The presence of abdominal distention in the setting of decreased urine output and increased ventilator pressures should lead to a possible diagnosis of **abdominal compartment syndrome** and immediately to a measurement of intra-abdominal pressures using bladder pressure manometry.

LABORATORY EVALUATION

- **Laboratory tests should be viewed as adjuncts in the evaluation of patients**, often providing useful information but rarely being diagnostic.
 - A hemogram, including hematocrit, hemoglobin, and white blood cell (WBC) count with differential
 - Urinalysis, including specific gravity and analysis for bacteria, bile, and reducing substances
 - Serum amylase, especially fractionated into isoenzymes, is helpful in diagnosing intra-abdominal catastrophe when it is elevated but is not specific.
 - Serum lipase is a more specific marker of acute pancreatitis than amylase and is less influenced by other intra-abdominal problems; calcium and phosphorus values are also helpful in determining the severity of pancreatitis.
 - Serum bilirubin elevation is associated with sepsis, resolving hematoma, hemolysis, and hepatobiliary disease.
 - Liver enzymes, such as serum glutamate oxaloacetic transaminase, serum glutamic pyruvic transaminase, and alkaline phosphatase, may be helpful but are rarely diagnostic by themselves.
- **Depending excessively on laboratory findings is costly and occasionally misleading.**
 - Severe sepsis can cause a leukopenia with a shift to the left that will be missed without a differential count.
 - Patients with indwelling Foley catheters often have asymptomatic bacteriuria and mild hematuria; a full workup of “benign bacteriuria” may delay the diagnosis of the true cause of sepsis.
- **Laboratory data are most useful in the management and correction of fluids, electrolytes, and acid-base derangements.** Persistent acidosis and arterial hypoxemia suggest severe metabolic problems that may be a reflection of unresolved third-space losses from untreated abdominal sepsis or ischemia. These causes are frequently overlooked in the early workup of these problems.

RADIOGRAPHIC STUDIES

- Although **plain portable radiographs** of the abdomen are obtained on most patients with suspicious abdominal findings, their yield is relatively low and their quality is frequently suboptimal.
 - Most useful is determining the position of intra-abdominal tubes such as nasogastric tubes and drains.
 - Examine abnormal intraluminal and extraluminal gas patterns.

THERAPY

- The absence of gas may be found with ischemic bowel.
- Small-bowel obstruction and colonic volvulus present with massive gaseous distention.
- An upright or left lateral decubitus film to discover air-fluid levels and free air above the liver should be obtained.
- A retrospective study of 1,000 patients presenting to the emergency room with acute abdominal pain compared the use of plain films to computed tomography (CT) scans.
 - 588 of 871 (68%) of abdominal radiographs were interpreted as nonspecific, no free air was found, and films were most sensitive for foreign bodies (90%) and bowel obstruction (49%).
 - CT was predictive of bowel obstruction in 75% and pancreatitis in 60%.
 - 120 patients had both exams: Abdominal films were negative in 20%, nonspecific in 76%, and abnormal in 4%.
- **Ultrasonography** has emerged as a dependable adjunctive diagnostic tool.
 - Can be brought to the bedside
 - Useful in demonstrating intra-abdominal blood or fluid and performing percutaneous drainage, such as percutaneous cholecystostomy
 - Less invasive and less expensive than CT scan
 - Limitations are as follows:
 - Acalculous cholecystitis
 - The gallbladder can be distended with poor contractility in patients admitted to an ICU for extended periods.
 - Ultrasound is not specific unless a radionuclide study using a hepatobiliary iminodiacetic acid (HIDA) scan confirms abnormal gallbladder filling.
 - Ultrasound can be difficult to interpret in patients with distended bowel gas
- **CT scan** has become the most widely used tool to examine the abdomen for abnormalities.
 - CT scanning is more accurate than any other modality for diagnosing intra-abdominal fluid collections.
 - It is especially useful in liver, splenic, renal, and retroperitoneal abscesses but may not be as useful as ultrasound in the diagnosis of right upper quadrant and pelvic masses.
 - Plain films have a low yield as compared to CT scan in the diagnoses of processes such as pneumatosis intestinalis, a finding very suggestive of bowel necrosis.
 - Increasingly useful as a therapeutic modality
 - CT drainage of abscesses, ascites, and pancreatic collections
 - CT-guided nephrostomy tube insertions
 - Optimal use of CT scan requires oral contrast, which may be difficult for the critically ill patient to ingest and retain and may be an aspiration risk.
 - CT scanning requires transporting the patient to the scanner accompanied by the nurse, therapist, and sometimes physician; the possibility exists of an untoward event during transport.
- A **Gastrografin swallow** is still an excellent tool to differentiate a gastric leak after gastric bypass surgery or persistent leak from a perforated ulcer.
- **Diagnostic peritoneal lavage** is still useful to drain tense ascites and determine the source and infectious nature of abdominal fluid. The presence of bacteria, bile, and >500 WBCs/mm³ can be inferred to indicate an acute abdominal process requiring immediate laparotomy.
- **Surgical consultation** should be obtained early in the evaluation of intra-abdominal problems as treatment in the acutely ill frequently requires surgical intervention. Acute abdominal catastrophe may be the first event in the precipitous cascade of multiple organ system failure. Unrecognized abdominal sepsis is associated with multiple organ system failure in 44% of cases. Early aggressive surgical therapy, vigorous fluid replacement, and appropriate antibiotic regimens are necessary.
 - Adequate volume resuscitation and electrolyte correction are vital to prepare the patient.
 - Patients who are volume-contracted may be hyponatremic, hypochloremic, hypokalemic, and alkalotic because of vomiting, nasogastric suctioning, and third-space losses.
 - Resuscitation with isotonic fluid, such as normal saline, is required to prevent anesthetic disaster.
 - Only after volume and salt repletion will their chloride-dependent alkalosis resolve.
 - Hypokalemia should be corrected cautiously until oliguria is resolved.
- **The specific management of disease entities should be based on well-established surgical principles.** However, the explosion of minimally invasive surgery has led to a new era in surgical intervention.
 - Acute cholecystitis
 - Can be treated conservatively for 24 to 48 hours
 - If the signs and symptoms do not improve within 48 hours or if cholangitis appears, an endoscopic retrograde cholangiopancreatography can be performed to drain the common duct.
 - A percutaneous cholecystostomy or a laparoscopic cholecystectomy can be performed in most cases.
 - Perforated ulcers can now be treated laparoscopically in some surgeons' hands.
 - Ruptured abdominal aneurysm can be addressed with endovascular aortic repair.
 - This repair can be performed under local anesthesia with bilateral groin cutdown, avoiding the significant morbidity of open procedures.
 - Initial studies imply that the overall morbidity, mortality, and ICU stay may be lower than that of open procedures.
- The use of **CT scan and ultrasonic-guided drainage** and catheter decompression of intra-abdominal abscesses had revolutionized care in some postoperative patients.
 - Results in excellent control of the septic source with a low morbidity
 - Often preferable to secondary exploratory laparotomy
 - If a patient persists in a downward clinical course, exploration with wide drainage of abscesses may be necessary.
- **Stress ulceration without perforation** may be prophylactically treated with antacids, H₂ blockers, and sucralfate, although aggressive pH control may lead to an increase in nosocomial pneumonia. Bleeding, though rare, requires operative intervention if it cannot be contained with conservative measures. This carries a high mortality rate of 50% but approaches 100% if multiple transfusions have created dilutional or hypothermic coagulopathies; the best treatment is prevention.
- **Antibiotics** are not a panacea for intra-abdominal sepsis, and abscesses will form despite adequate coverage. Usually

adjunctive to prevent systemic sepsis, the prolonged use of antibiotics for localized abscesses instead of surgical or radiologic drainage can lead to morbidity and increased mortality. Guidelines for the use of antimicrobial agents are published by several medical societies.

SPECIFIC DISEASE STATES

Any stable patient in an ICU developing sudden shock or sepsis must be examined closely for an intra-abdominal cause.

- **Appendicitis**, the most common abdominal condition in surgery, is rarely seen in the ICU.
- **Pancreatitis** and **acalculous cholecystitis** are seen, especially after open-heart surgery.
- **Ileus** and **colonic pseudo-obstruction** are frequent in elderly patients after orthopedic procedures.
- **Mechanical ventilation** carries a high risk for **gastrointestinal bleeding**, **ileus**, and **unrecognized perforation**.
- **Stress ulcer perforation** and **ileus** are insidious causes of respiratory failure and sepsis in any patient with a **spinal injury**.

Acquired Immunodeficiency Syndrome

Immunocompromised hosts require special attention when presenting either with abdominal pain or sepsis of unknown origin. Fever and nonspecific abdominal pain are frequently noted, although peritoneal signs may be lacking in severely immunocompromised patients.

- Acute abdominal pain is a complaint in 12% to 45% of patients with HIV infection presenting to the emergency room.
- Cytomegalovirus (CMV), gastroenteritis, lymphoma, Kaposi sarcoma, and mycobacterial disease were frequent causes of abdominal pain in HIV patients in early studies.
- There has been a significant reduction in these opportunistic infections, especially peritonitis secondary to atypical mycobacterium and fungi.
- The frequency of pulmonary, cardiac, gastrointestinal, and renal disease that is not directly related to the underlying HIV has increased.
- The HIV patient continues to present with non-HIV-related problems, such as appendicitis, diverticulitis, and pancreatitis.

Patients presenting with overt AIDS have a constellation of problems that are unique to this population. **Prognosis is somewhat dependent on the CD4 count and viral loads.** CD4 counts <200 cells/mm³, total lymphocyte count $<1,000$ cells/mm³, and viral loads $>75,000$ RNA copies/mL are associated with higher morbidity and mortality.

- Earlier studies reported increased morbidity and mortality in patients with AIDS, whereas recent data yield 10% to 19% operative mortality for emergency surgery.
- Acute appendicitis in AIDS patients may be routine or secondary to opportunistic organisms.
- WBC count may be low or normal.

Perforation

- Bowel perforation secondary to CMV or Kaposi sarcoma has decreased since the advent of retroviral therapy.

- Diligence is required to ensure perforation has not occurred.
- CMV perforations are more common in the ileum and colon secondary to ischemic lesion.
- Acute bowel obstruction suggests disseminated disease and has a poor prognosis if the cause is age-related.
- Recent data point to lymphoma and disseminated mycobacterial disease as causes.
- Colonic disease, especially **toxic megacolon**, has been seen with *Clostridium difficile* colitis, especially in patients with CMV infection. Megacolon can be a significant prognostic indicator in advanced age and may best be treated with colonoscopy for short-term management of the severely ill.
- **Acute hepatobiliary disease** secondary to opportunistic disease can present difficult diagnostic problems in patients with CD4 counts <100 cells/mm³. Acalculous cholecystitis is more common in HIV/AIDS patients than in the normal population.
- **Neutropenic patients with cancer** also present a diagnosis and therapeutic challenge. In patients who underwent emergency celiotomy for suspected intra-abdominal disease, the most common disease reported was neutropenic enteropathy (61%), with postoperative mortality up to 32%.

Biliary Disease

- Primary biliary tract disease in critically ill patients appears as calculous or acalculous cholecystitis. Calculous disease may present as acute cholecystitis, cholangitis, or pancreatitis. The typical presentation of right upper quadrant pain, a positive Murphy sign, and fever may be absent in critically ill patients. Leukocytosis is common, although nonspecific. The presence of stones in the gallbladder in patients with nonspecific symptoms is not pathognomonic of acute biliary disease.

Acute Acalculous Biliary Disease

- A concomitant of critical illness, it has been reported in 1% of surgical patients and 0.2% of postoperative cardiac patients.
- Risk factors include use of narcotics for more than 6 days, gastric suction, prolonged ileus with nothing by mouth, ventilatory support longer than 24 hours, multiple recent operations, more than 10 blood transfusions, open wound or abscesses, and intravenous hyperalimentation for more than 3 days.
- Presence of five of these risk factors in a patient with acute abdominal findings should lead to a search for acalculous biliary disease.
- Right upper quadrant pain may be present in 30%, peritonitis in only 24%; persistent fever is the most consistent finding.
- Up to 65% of patients with acalculous cholecystitis have elevated bilirubin; however, a control group of patients receiving multiple transfusions had similar hyperbilirubinemia.
- Liver enzymes are elevated in fewer than 50%.
- The presence of fever, mild elevation of bilirubin, sludge on ultrasound, and nonvisualization on HIDA are accurate indications of acute acalculous cholecystitis in critically ill patients.
- Treatment of choice is cholecystectomy if the patient is able to tolerate a major procedure.
- Use of percutaneous cholecystostomy has been reported in severely ill patients.
- The mortality rate is as high as 40% secondary to the multiplicity of the patient's problems.

Hepatobiliary Iminodiacetic Acid Scan

- 95% accurate in the diagnosis of acute cholecystitis
- Derivatives of iminodiacetic acid rapidly taken up by the hepatocytes and excreted into the bile even with elevations of bilirubin up to 6 g/dL
- Requires moving the critically ill patient to the radiology suite for up to 4 hours
- Caution urged in patients receiving hyperalimentation, which severely limits usefulness of the test.

Abscess

Intra-abdominal abscesses develop as a complication of secondary peritonitis that is the result of a perforation of a hollow viscus. Examples include colonic resection complicated by anastomotic leak, diverticular disease, appendicitis, inflammatory bowel disease, and malignancy.

- Abscess should be suspected in any patient deteriorating after abdominal surgery.
- The clinical picture can be vague, peritonitis is rare, and bowel function may be normal.
- Nonspecific manifestations such as fever, chills, malaise, and leukocytosis should raise the suspicion.
- Abscesses that incorporate the anterior abdominal wall are associated with a palpable tender mass.
- Retroperitoneal abscesses can develop from cecal perforation, lymphatic and hematogenous spread of bacteria, or infected pancreatic necrosis.
- Hiccup, unexplained pleural effusion, and a raised hemidiaphragm on chest radiograph may indicate subphrenic abscess.
- Diarrhea and urinary retention may indicate a pelvic abscess.
- CT scan, preferably with oral and intravenous contrast, is the standard diagnostic modality.
- Bedside ultrasonography may be useful in unstable patients.

The **bacterial flora** are related to the organ involved, the host defenses, and the duration of the critical illness. The flora of the normal stomach and duodenum are very sparse.

- Mainly swallowed oral organisms such as microaerophilic streptococci and *Streptococcus viridans*, lactobacillus, fusiform bacteria, and *Candida* species.
- Flora grow and change remarkably if there is gastric outlet obstruction, achlorhydria, or acid-suppressive therapy.
- Small-bowel flora consist mainly of Enterobacteriaceae, *Enterococcus* species, and anaerobic species.
- Colonic flora are extremely dense.
 - Account for one-sixth of the dry weight of stools
 - Contains both aerobic and anaerobic bacteria
 - Aerobic bacteria are much more abundant; primarily gram-negative (e.g., *Escherichia coli*, *Klebsiella* species, *Enterococcus* species, and *Proteus* species)
 - Anaerobic bacteria include *Bacteroides fragilis*, *Eubacterium* species, and *Bifidobacterium* species.
- Intra-abdominal abscesses are typically polymicrobial, but anaerobes are difficult to grow on cultures.
- Surgical consultation should be obtained, and **the decision to operate is based on individual patient conditions**. The efficacy of CT-guided percutaneous drainage of intra-abdominal abscesses has long been established. Antibiotic therapy is based on empiric coverage of gram-positive, gram-negative,

and anaerobic bacteria normally present within the gut rather than culture results. Antifungal agents are not given even if fungi are seen on cultures unless the patient is immunosuppressed or has recurrent intra-abdominal infection.

- **Mortality** from intra-abdominal sepsis is 24%, ranging from 7.5% for single abscess to 43% for patients with multiple abscesses and peritonitis. Mortality correlates directly with acute physiology score, malnutrition, age, and shock. Only early recognition, appropriate use of antibiotics, and prompt drainage can improve on these data.

Pneumoperitoneum

The most common cause of pneumoperitoneum is abdominal surgery. Free air may persist for weeks after laparotomy, although air from laparoscopy is frequently absent at 48 hours. Pneumoperitoneum in a patient who does not have a recent history of laparotomy or laparoscopy should be presumed to be due to a perforated viscus until proven otherwise.

- Perforation of the stomach or duodenum due to peptic ulcer disease is more likely to cause an obvious pneumoperitoneum than perforation of the colon due to diverticular disease.
- Other conditions that may cause pneumoperitoneum are a recent percutaneous endoscopic gastrostomy and barotrauma to the lung.
- Pneumoperitoneum has been observed in up to 10% of patients who suffer severe chest trauma with extra-alveolar air, such as pneumothorax and pneumomediastinum.

Pneumoperitoneum should be evaluated in the context of the patient's overall condition. In unconscious or paralyzed septic patients with no obvious source of sepsis, pneumoperitoneum should prompt an exploratory laparotomy. Diagnostic peritoneal lavage may be considered if the risk of operative exploration is too high or the index of suspicion is low.

Pseudo-Obstruction of the Colon

Isolated colonic ileus without mechanical obstruction was first described by Ogilvie.

- The abdomen is distended and tympanitic without signs of peritonitis, fever, or leukocytosis.
- Most common risk factors are old age, bed rest, prolonged narcotic use, mechanical ventilation, multiple trauma, abdominal and pelvic operations, orthopedic operations, and spinal cord injuries.
- The cause is unknown, but hyponatremia and hypokalemia may play a role in the development of this condition.
- On radiograph, the colon appears diffusely distended, including the rectum, and the small bowel is usually not seen.
- The cecum, being the widest segment of the colon, is at risk for necrosis and perforation if the diameter reaches 12 cm.
- **Mechanical obstruction should be ruled out** with a Hypaque enema; this hyperosmolar water-soluble enema helps to cleanse the colon and, unlike barium, does not interfere with a subsequent colonoscopy.

Initial management consists of decompressing the stomach and colon with nasogastric and rectal tubes. Electrolyte abnormalities, especially hypokalemia, should be promptly corrected. If there is no response to these measures,

neostigmine, a parasympathomimetic, may be given to stimulate colonic motility.

- 1 to 2 mg intravenously and can be repeated in 3 hours
- Should be done under cardiac monitoring as it may result in severe bradycardia
- Should not be given if the patient's baseline heart rate is <60 beats/minute, the systolic blood pressure is <90 mm Hg, or if there is a significant heart block or bronchospasm

The next step in management, if the previous measures fail, is colonoscopic decompression. This is **associated with a higher-than-normal risk of perforation**.

- Should be used gently and with the goal of decompression only
- Not necessary to advance the colonoscope all the way to the cecum
- Recurrence is seen in up to 40% of patients, and colonoscopy can be repeated.
- **Surgery is reserved for patients who fail all other measures and those with complications or impending cecal rupture (i.e., diameter > 12 cm).** The operation of choice is right hemicolectomy with primary ileocolic anastomosis if there is no evidence of necrosis or perforation, in which case an ileostomy with mucus fistula should be performed.

Abdominal Compartment Syndrome

The abdominal compartment syndrome (ACS) is a condition in which the intra-abdominal pressure rises to a point that impairs **respiratory, renal, and cardiovascular function**. The diagnosis of ACS is made when there is abdominal distention associated with high ventilator pressures, oliguria, and elevated urinary bladder pressures (>25–30 cm H₂O). It is believed that severe edema of the abdominal wall, bowel wall, and the retroperitoneum occurs as a result of massive fluid shifts associated with the severe systemic inflammation that accompanies reperfusion of tissues after shock states.

- Described mainly in the trauma population but can occur in any patient who receives a massive resuscitation for a profound shock state
- The abdomen not necessarily the site where the original pathology occurs (e.g., severe burns, sometimes described as secondary ACS).

Treatment

Treatment consists of abdominal decompression using a mid-line celiotomy and keeping the abdomen open using various dressing mechanisms over the bowel. For a detailed discussion of the ACS, see Chapter 39. More abdomens are now kept open if fascial closure is expected to increase abdominal pressure.

- Renal and pulmonary functions are not compromised, and the integrity of fascial edges is preserved.
- Gives the opportunity for frequent bedside washouts and debridements such as with infected pancreatic necrosis.

Once the swelling has resolved, the abdomen should be closed as soon as possible either by primary fascial closure or using one of the commercially available biologic or synthetic grafts. Prolongation of the open abdomen management is associated with increased risk of fistula formation.

Bariatric Surgery

- It is estimated that more than 130,000 bariatric procedures will be performed in the United States each year. Many of these patients have sleep apnea, hypoventilation, or other physiologic abnormalities that require ICU care in the immediate postoperative period. Anastomotic leak after gastric bypass and duodenal switch are potentially fatal, rapid recognition, diagnosis, and treatment are necessary to minimize patient risk.

- Abdominal pain is frequently not a major symptom, although shoulder (referred) pain may be present.
- The **hallmarks of dilatation and leak** are persistent tachycardia, tachypnea, fever, anxiety, and hiccups, usually accompanied by a mild leukocytosis with or without fever.
- Because this is also found in patients with **pulmonary emboli**, it is vital that the diagnosis of leak be made early.
- Immediate **Gastrografin swallow** with adequate volume of contrast should be performed
- The presence of a large gastric bubble without leak requires immediate decompression to prevent gastric perforation or an anastomotic disruption.
- A leak must be addressed immediately with drainage either percutaneously for small and contained leaks or operative intervention to attempt to repair and drain the area of concern.

Acute Mesenteric Ischemia

- The presence of physical signs indicating peritoneal irritation is extremely important because they portend impending or progressive gangrene and are associated with significant mortality. Leukocytosis out of proportion to the physical findings, elevated hematocrit, unexplained acidosis, and blood-tinged fluid on peritoneal lavage are all signs of advancing intestinal necrosis. **Numerous causes** exist for acute intestinal ischemia:
 - Embolus (50%–60%) or thrombus (25%–35%) of the SMA must be differentiated from nonmesenteric thrombosis (10%–20%) and acute mesenteric venous occlusions (5%).
 - Colonic and rectal ischemias have been reported after abdominal aortic aneurysmectomy in which the inferior mesenteric artery was ligated.
- A characteristic of gut ischemia is the disparity between the patient's pain and abdominal findings.
 - Common signs and symptoms include pain (75%–90%), nausea and vomiting (50%–60%), abdominal distention (56%–80%), peritoneal signs (60%), ileus (50%), and shock and fever (30%).
 - Upper gastrointestinal bleeding is less common.
 - Leukocytosis (WBC count of 20,000/mm³) is seen in fewer than 50% of patients.
 - A mild elevation in amylase is common.
 - Plain radiographs are useful to exclude the other processes; signs of intestinal ischemia on plain radiograph are a grave prognosticator with 90% mortality.
- **Patients at highest risk** are those older than 50 years with either valvular or atherosclerotic heart disease, congestive heart failure (especially if there is poor control with digitalis and diuretics), hypovolemia, hypotension of any cause,

recent myocardial infarction or cardiogenic shock, or cardiac arrhythmias. Dialysis patients seem to be at added risk for right colon ischemia.

- Once the diagnosis is suspected, **vigorous fluid resuscitation is necessary** to maintain adequate blood flow and pressure head in the mesenteric vessels. Occasionally, dextran has been used to expand plasma and to decrease sludging. Digitalis should be used cautiously. Gastrointestinal decompression with a nasogastric tube and proper hemodynamic monitoring are necessary to adequately resuscitate these precarious patients. Early heparinization should be used if immediate surgery is not undertaken.
- **CT scans** have improved in both availability and reliability and may demonstrate clot or ischemia. **Emergency selective arteriography** is still the keystone of the diagnostic and therapeutic approach to acute mesenteric ischemia.
 - Arteriography can differentiate occlusive from nonocclusive disease.
 - There are reports of successful thrombolysis of clot in the SMA; however, acute occlusion is best treated by immediate surgical restoration of circulation by embolectomy or aortosuperior mesenteric artery bypass.
 - Examination of the bowel for ischemia, which will require resection, is essential to avoid unnecessary morbidity and mortality.
- **Nonocclusive mesenteric ischemia** is diagnosed when mesenteric vasoconstriction on angiogram is seen in the patient with a clinical picture suggestive of intestinal ischemia.
 - Shock and vasopressors make interpretation of the arteriogram difficult.
 - Treatment is begun in the radiology suite by the administration of papaverine (30–60 mg/hour) through a catheter placed selectively in the SMA; it is continued for 24 hours, and an arteriogram is repeated.
 - Heparin may be used concomitantly.
 - If peritoneal signs are present and abdominal exploration is necessary to examine the viability of the bowel, vasodilators and local anesthetics can be injected directly into the base of the mesentery.

- **Systemic antibiotics are indicated** because of the high incidence of positive blood cultures resulting from compromised bowel, but may mask peritoneal signs.
- **Second-look operations** are frequently used at 24 to 48 hours to determine viability of remaining bowel, though survival is not necessarily improved by this technique.
- **Mortality** rate for acute mesenteric ischemia remains at 70% to 80%.
 - Embolus in the SMA is still associated with a 44% to 90% mortality rate.
 - Nonocclusive ischemia without peritoneal signs has a more favorable outcome
 - Peritonitis is associated with mortality rates of 60% to 90%.
 - Logistic regression yields an odds ratio of 22 for peritonitis and 14.9 for hypotension as independent predictors of mortality.
 - Death occurs from MSOF secondary to ischemia (65%), sepsis (25%), pulmonary failure (8%), and stroke (2%).
- High index of suspicion for ischemia followed by an early, aggressive, and rapid diagnostic workup seems to be the only method for improving this abysmal mortality rate.

SUMMARY

Acute abdominal problems are frequent among ICU patients. The physician must maintain a high level of suspicion that an abdominal problem is present when faced with a deteriorating critically ill patient. History and physical examination must guide the use of more invasive and expensive tests. Laboratory tests are usually adjunctive and rarely diagnostic. Radiographic procedures, especially ultrasound and CT scans, when appropriately used, can be helpful. Surgical consultation should be obtained early in a patient's course, because treatment frequently requires surgical intervention. Only by maintaining constant vigilance can critical care practitioners guide their patients through the multiple perturbations created by acute abdominal problems.

CHAPTER 46 ■ THE DIFFICULT POSTOPERATIVE ABDOMEN

The practice of surgery inevitably carries the risk of postoperative complications and difficult therapeutic choices. In this chapter, we address some of the most vexing operative dilemmas involved in the management of the postoperative abdomen. The core principles of careful surgical technique and meticulous patient management, including wound care, nutritional management, and timing of recurrent interventions, are key in treating these obstacles.

ADHESIONS

- Adhesive connections may occur between loops of bowel, intra-abdominal structures and the abdominal wall, and the pelvis and nearby structures (bowel, gynecologic organs, etc.).
- Most (94%–98%) of abdominal adhesions are acquired, either from operative therapy or via inflammatory processes (e.g., Crohn's disease, cancer).

- The remaining 2% to 6% of adhesions are congenital and largely consist of Ladd bands.
- In the reoperative abdomen, adhesions are present in 30% to 40% of patients.
- Adhesions result from trauma to tissues, relative ischemia, infection within the abdominal cavity, inflammatory processes, or the presence of foreign bodies such as suture, talc from gloves, and lint from sponges.
- **Adhesion formation** tends to follow predictable patterns, and the degree of adhesion formation is profoundly affected by the type of surgery performed.
 - Laparoscopic surgeries have been shown to have a 15% adhesion rate.
 - In open laparotomies, 50% result in adhesion formation.
 - Adhesions form more commonly after surgery to the small and large bowel than with other intra-abdominal organs, especially in surgeries involving bowel distal to the transverse colon or gynecologic organs.
 - Areas most frequently affected are the undersurface of the midline incision and at the operative site.
 - Owing to its tendency to migrate to regions of inflammation, the omentum is the most frequently involved organ (57%) and may be used to wrap anastomoses or to protect abdominal contents from a healing midline incision.
 - Small- and large-bowel adhesions continue to result in the highest morbidity and account for approximately 75% of postoperative bowel obstruction cases and 12% to 17% of hospital admissions after previous abdominal surgery.
 - One-fourth of these admissions occur within the first year after surgery, and 2% to 5% of small-bowel obstructions due to adhesions will require operative adhesiolysis.
- **To minimize adhesions**, principles of good surgical technique are the best defense.
 - Gentle tissue handling with strict hemostasis
 - Minimization of intraperitoneal trauma
 - Frequent irrigation to dilute or to remove contaminants
 - Use of small, nonreactive suture material
 - Raw surfaces or anastomoses should be protected by autologous tissue, either with a tongue of omentum or via mobilized local tissue flaps.

Barriers to Adhesiogenesis

- Despite meticulous technique and conscientious efforts to prevent adhesions, they will continue to form with attendant postoperative morbidity and mortality. Research efforts have focused on developing materials to minimize the occurrence and severity of adhesions. The most common method of decreasing the number and strength of adhesions is with one of a variety of barrier materials. Regardless of which product is ultimately chosen, the ideal barrier would be nonreactive in vivo, would be active during the key healing stages, and would then be reabsorbed by the body when no longer needed. Research interest in this area remains high as adhesion-related morbidity continues to plague surgical patients.

FISTULAS

- include such types as pancreatic fistulas, biliary fistulas, fistulas between two intra-abdominal organs (i.e., colovesical fistulas), and enterocutaneous fistulas. The natural history of a fistula begins as a leak from bowel or other intra-abdominal organ.
 - The ultimate **type of fistula** depends on whether the leak is uncontrolled, partially controlled, or well controlled.
 - Uncontrolled leak will result in peritonitis, which requires surgical exploration and correction.
 - Partially controlled leak may result in an intra-abdominal abscess, which will require definitive therapy.
 - Controlled leaks result in fistulas, the management of which can be a long-term challenge for both surgeon and patient.
-
- ### Enterocutaneous Fistulas

- An enterocutaneous fistula is an abnormal communication between lumen of bowel and the skin.
 - Spontaneous fistulas are uncommon, but causes may include malignancy, inflammatory processes such as Crohn's disease, or vascular insufficiency, as seen in radiation enteritis.
 - The iatrogenic fistula is the most common (accounts for 71%–90% of fistula's) resulting from inadvertent enterotomies, intra-abdominal infections, direct injury or bowel desiccation in the open abdomen, misplaced stitches, or anastomotic breakdown.
 - Impaired tissue perfusion from hypotension or vascular disease may predispose to this complication, as will infections, steroids, and malnutrition.
 - A seeming wound infection opened at bedside will result in copious drainage of discolored, watery material or frank succus.
 - Passage of gas from the midline wound is diagnostic of an enterocutaneous fistula.
 - Patients will usually demonstrate signs of advancing infection including increasing temperature and white blood cell count and persistent ileus.
 - Less commonly, patients may develop profound shock due to electrolyte imbalances and sepsis, necessitating emergent re-exploration. If the patient presents with drainage or an obvious fistula but is hemodynamically stable, conservative management is warranted, at least in the short term.
- ### Conservative Management of the Enterocutaneous Fistula

- Management is predicated on controlling output, managing electrolyte fluxes and nutritional deficiencies, and maximizing the potential for spontaneous closure (Fig. 46.1).
 - Aggressive fluid resuscitation and close monitoring of electrolyte balance are mandatory to maintain stability.
 - Nutritional replacement should begin immediately; this patient population is exceptionally prone to malnutrition from protein losses, increased metabolic demands, and limited or no oral intake.
 - Parenteral nutrition is nearly mandatory to provide early and aggressive nutritional repletion, to allow close management of electrolyte and protein balances, and to decrease volume transit past the fistula in the gastrointestinal tract.
 - Perhaps a greater challenge in this patient population is control of fistula output.

- A fistula is an abnormal communication between two spaces. In the abdomen, varieties of fistulas differ tremendously and

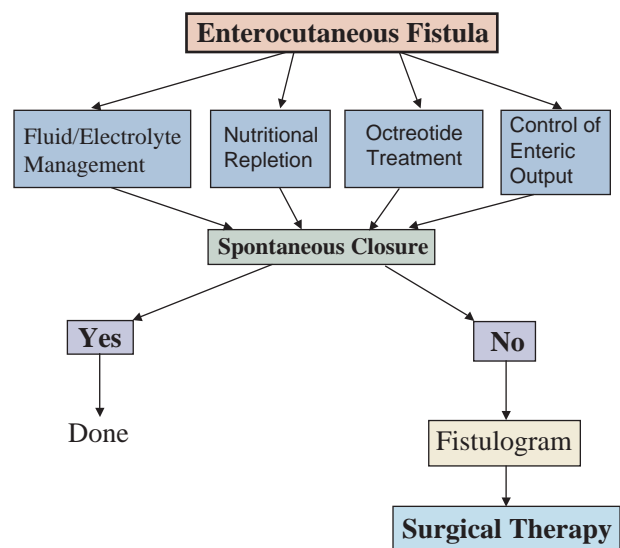

FIGURE 46.1. Management strategy for enterocutaneous fistulas.

- Enteric contents are extremely caustic to the skin and surrounding tissues.
- An immediate goal is to isolate enteric contents from the skin.
- For a simple enterocutaneous fistula, a stoma appliance may be all that is needed.
- Fistulas present in open wound beds, including on granulating abdomens, are not amenable to the placement of a simple stoma appliance.
- In these situations, a close association between the surgeon, patient, and wound care nurse/enterostomal therapist is mandatory to control fistula output.
- Once initial control is achieved, it may be possible to close fistulas surgically or to skin-graft the region.

Spontaneous Closure

- The goal of conservative therapy is to achieve spontaneous closure of the fistula, which is **dependent largely on inherent characteristics of the fistula**.
- Most fistulas that close without intervention will do so in the first 3 to 6 weeks.
- Fistulas with **long tracts and narrow mouths** are most likely to resolve.
- **Low-output fistulas**, defined as having an output <500 mL/day, have a higher likelihood of closure.
- A fistula that is not closed by 3 months is unlikely to close without surgical therapy.
- Additionally, many **patient factors** have been associated with failure of the fistula to close spontaneously. Factors that will virtually ensure patency of the fistula include the following:
 - Presence of a **foreign body** in the fistula tract
 - Close association between the fistula and an abscess
 - Association with a **malignancy**
 - **Distal bowel obstruction** leading to increased pressure and transit through the fistulous tract
 - **Epithelialization** of the tract
 - Short neck with wide fistula mouth
 - Long-standing fistulas with high outputs, which are unlikely to close spontaneously

- The patient and surgeon are not completely at the mercy of physiology and chance while awaiting spontaneous closure.
- A positive nitrogen balance and a transferrin level >200 mg/dL are associated with successful closure.
- Use of octreotide or other somatostatin analogue (100 µg intravenously every 8 hours) may decrease secretion in the gastrointestinal tract.
 - Somatostatin inhibits the secretion of most gastrointestinal hormones.
 - Enhances fluid and electrolyte absorption, thereby decreasing intraluminal volume and potentially decreasing fistula output.
 - Despite the theoretical benefits of somatostatin use, clinical studies have revealed mixed results on effectiveness.
 - As side effects are relatively mild, including gastrointestinal discomfort and increased biliary sludge, we recommend trying a somatostatin analogue in conjunction with other conservative therapies while waiting for a fistula to close spontaneously.
 - However, somatostatin analogues should not be relied on as a primary therapy to close fistulas.

Surgical Therapy

If after approximately 3 months a fistula has failed to resolve, the likelihood of closure without operative intervention is poor.

Criteria for Closure

- Defining the fistula tract via fistulogram to detect the length of the tract, tortuosity, tract diameter, and which segment of the gastrointestinal tract is involved.
- A computed tomography scan may also be helpful in defining intra-abdominal abscesses, malignancy, and hernias.
- It is imperative that the patient's nutrition be maximized at the time of repair.
- Fistula output should be controlled, as healthy skin at the time of operation will improve the success of abdominal wall reconstruction.

By delaying operative repair until all criteria are met, successful closure rates improve from 50% to 94%, and mortality decreases from 50% to 4%.

Operative Intervention

- Extensive, dense adhesions may make access to the fistula very difficult.
- Risk of multiple enterotomies in approaching the segment involved in fistulization
- Attempts to oversew the fistula primarily may be appealing due to simplicity and avoidance of an anastomosis but has a dismal failure rate and often results in a larger fistula.
- **Definitive surgical therapy** remains complete lysis of intra-abdominal adhesions and resection of the involved segment with an anastomosis performed between two healthy segments of intestine.
- The complete lysis of adhesions allows careful inspection of small bowel to rule out downstream obstruction or other pathology.

The Open Granulating Abdomen

- A superior option for the patient is the **split-thickness skin graft**.
 - Skin graft rarely results in fistula closure.

- Decreases the metabolic demands in an already stressed body
- Provides a good base for appliances to control fistula output
- In general, the split-thickness skin graft, with or without fistula closure, is more successful in low-output fistulas.
- High-output fistulas will stress a fistula repair, leading to recurrent fistulization, or will interfere with adherence of the grafted skin and ultimately digest the skin graft.

The Pancreatic Fistula

- The pancreatic fistula is of an entirely different nature.
- Most often result from trauma or iatrogenic injury, though a small percentage will be the result of pancreatitis.
- The **cardinal principles** of management are diagnosis of the fistula and wide drainage.
- A pancreatic fistula may drain **100 to 1,000 mL of fluid per day**; the resulting **pancreatic ascites** may cause abdominal pain, fevers, and a plethora of vague symptoms including abdominal bloating, hiccups, intolerance to oral intake, and abscess.
- Pancreatic fluid contains a large amount of **bicarbonate** compared to plasma (70–90 mEq/L) and may lead to **nonanion gap metabolic acidosis**.
- All patients respond differently to a pancreatic leak, and whereas some may present in profound shock, other patients may tolerate large-output pancreatic fistulas with few signs or symptoms.
- Variability in clinical presentation is poorly understood but is likely due to the degree of enzymatic activation of the leaking fluid.
- The most common method of diagnosis is by computed tomography scan.
- If the patient is of reasonable body habitus and transport is hazardous, an ultrasound may provide equivalent information.
- For most patients, the **initial treatment is simply drainage**.
 - In the modern era, interventional radiology is invaluable in placing these drains.
 - If at initial operation, there is concern for postoperative leak; wide drainage with a closed-system drain should be established before closing the patient's abdomen.
 - Wide drainage of pancreatic secretions should allow time for the patient to stabilize and prevent damage to other abdominal organs.
 - Frequently, patience to allow long-term drainage to resolve will permit spontaneous closure of the pancreatic fistula.
- Adjuncts such as **total parenteral nutrition and octreotide** may be helpful in decreasing secretory stimulation to the pancreas.
 - Octreotide, administered 100 μ g subcutaneously every 8 hours begun immediately after procedures deemed at high risk for pancreatic fistulas may help reduce fistula output, lower serum amylase and lipase levels, and help earlier return of positive nitrogen balance.
 - It is reasonable to pursue this therapy for a time-limited course (approximately 1 week) to improve chances of non-operative resolution.
- Depending on the cause of the fistula, intervention may be indicated on an earlier basis.
- If drainage fails to resolve the fistula, an imaging study should be pursued to define the duct and to determine whether an obstructive process is mandating fistula patency.
 - Magnetic resonance cholangiopancreatography and endoscopic retrograde cholangiopancreatography may provide equivalent information.
 - Endoscopic retrograde cholangiopancreatography is preferred; it allows the opportunity to identify pathology of the pancreatic duct and intervene.
- Stenting of a proximal obstruction may be adequate to allow prograde drainage of pancreatic secretions and closure of the fistula.
- When all less-invasive therapies fail, exploratory laparotomy remains the gold standard for definitive therapy.
 - Options at laparotomy depend on the level of the injury.
 - Primary duct repair is unlikely in most circumstances.
 - A distal duct fistula (perhaps secondary to a splenectomy) is well treated by distal pancreatectomy.
 - If the leaking duct is sufficiently large, as is seen in relation to a ductal obstruction, a pancreaticojejunostomy may be performed to allow for a low-resistance drainage pathway.
 - Pancreatic fistulas involving the proximal duct are most often iatrogenic or related to trauma and are troublesome to deal with, in light of other major structures in the region.
 - A pancreaticoduodenectomy (Whipple procedure) will resect the leaking portion of pancreas and allow reconstruction.
 - The Whipple procedure should be entertained only in patients with good physiologic reserve.
 - As noted, an attempt at conservative therapy and complete preoperative imaging and optimization are mandatory as these procedures are a major commitment for surgeon and patient.
 - Despite the wealth of surgical options, most pancreatic fistulas will resolve with appropriate drainage, and thus, surgical correction is an end-stage option for correction of the fistula.

ABDOMINAL COMPARTMENT SYNDROME

Since its first description in the 1980s, abdominal compartment syndrome has become an increasingly recognized clinical entity. Although classically described as a primary entity, in current surgical therapy it is usually seen after a **massive fluid resuscitation** from trauma, burns, intraoperative resuscitation, pancreatitis, or sepsis. As the abdomen is a limited potential space, increasing interstitial edema and free fluid in the abdomen result in increased intra-abdominal pressure, which is transmitted to organs in both the thorax and abdomen.

- Capillary leak occurs secondary to sepsis or reperfusion injury in the splanchnic circulation and results in massive interstitial edema.
- In operative cases requiring large-volume resuscitations, the abdomen is frequently left open postoperatively until edema decreases enough to allow tension-free primary closure.
- In this way, compartment syndrome and its sequelae are avoided.

Management

- Conservative management with drains is generally pursued for up to 6 months and has a success rate of up to 97%.

- The first clue to abdominal compartment syndrome is a distended and tense abdomen, but the key to diagnosis is a high index of suspicion.

The Physiologic Effects

- Compression of the inferior vena cava by abdominal contents and fluid results in decreased preload and a subsequent **decrease in cardiac output**.
- This ultimately leads to increased systemic vascular resistance and decreased stroke volume.
- Clinically, patients will become increasingly tachycardic and hypotensive.
- Increased abdominal volume also places pressure on the diaphragm, resulting in **high peak ventilatory pressures** (>30–35 mm Hg) and decreased ventilation with hypercapnia and hypoxemia.
- If ventilated with a pressure-control ventilatory method, the patient will demonstrate low tidal volumes.
- Compression of the ureters and bladder and renal vein compression leads to **diminished urine output** and renal injury and **elevated bladder pressures** (>25–30 mm Hg).
- **Bladder pressure** may be transduced for definitive diagnosis.
 - An arterial pressure line is attached to the patient's Foley catheter.
 - Approximately 60 mL of sterile saline is introduced.
 - Abdominal pressures >15 mm Hg are indicative of abdominal compartment syndrome.
 - When the transduced pressure reaches 25 to 30 mm Hg, a decompressive laparotomy is indicated as therapy for abdominal compartment syndrome.
 - Decompressive laparotomy may be indicated at lower intra-abdominal pressures depending on the patient's clinical condition.
- After decompressing the abdominal contents, the abdomen is left open with a **temporary abdominal closure** until swelling diminishes enough to allow closure.
 - Decompressive laparotomy for abdominal compartment syndrome is lifesaving.
 - Associated with a 42% to 68% mortality rate although this is dependent on the severity score.

The Open Abdomen

- Two increasingly recognized trends in surgery have led to a change in perspective over the last 20 years, where the open abdomen is no longer a catastrophe but rather a tool in the surgeon's armamentarium.
 - Primary and secondary abdominal compartment syndrome
 - "Damage control laparotomies" have become increasingly common in treating major abdominal trauma.
- **Damage control laparotomy** is aimed at limiting intraoperative times for deteriorating patients.
 - Allows transfer to the intensive care unit for vigorous resuscitation
 - Major vascular hemorrhage is controlled, either by ligation or packing.
 - Gross bowel contamination is controlled through ligation, often leaving the gastrointestinal tract in discontinuity.

"THE BLOODY VICIOUS CYCLE"

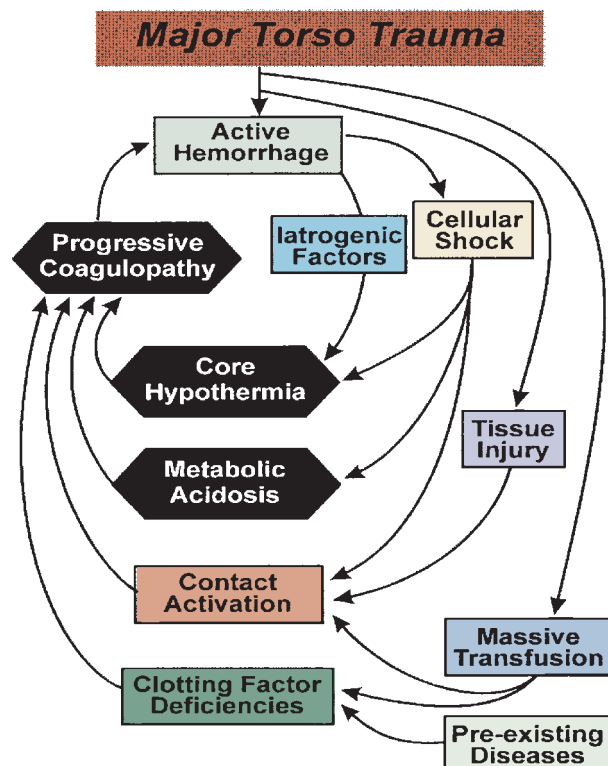

FIGURE 46.2. The "bloody vicious cycle" of coagulopathy, hypothermia, and metabolic acidosis.

- The abdomen is then closed in a rapid and temporary manner, with a plan to return when the patient is more stable to effect definitive repair.
- An aggressive strategy for treatment of patients who develop the deadly triad of coagulopathy, hypothermia, and metabolic acidosis (Fig. 46.2)

Management

Management of the open abdomen involves three primary decision-making stages—initial operative management, decision to close primarily versus a planned ventral hernia, and definitive closure of the planned ventral hernia.

- The original temporary abdominal dressing is known as the Bogota bag initially described from its use in Colombia during the 1980s and consists of covering the abdominal contents with a sterile saline bag to protect the bowel until re-exploration.
- A derivation of the Bogota bag is a widely used method of temporary abdominal closure in current practice.
 - A plastic drape, such as a sterile cassette cover, is placed over the bowels to prevent them from injury and under the fascia to contain the abdominal contents.
 - A sponge or blue towel, with two large Jackson-Pratt drains (Cardinal Health, McGaw Park, IL), is then placed over the plastic drape to allow egress of blood and edema fluid.
 - An adhesive drape is placed over the abdomen to maintain sterility, contain contents, and prevent free drainage of fluid (Fig. 46.3)
- After an appropriate resuscitation period, typically 24 to 48 hours, the patient is returned to the operating room.

FIGURE 46.3. A temporary abdominal closure, using a sterile cassette cover and drains, as used in our practice.

- If definitive therapy is complete, the decision to close primarily depends on the quantity of intra-abdominal edema and the quality of the fascia.
- **Whenever possible, primary tension-free closure of fascia is ideal.**
- High-tension closures not only result in elevated intra-abdominal pressures but lead to ischemia of the involved fascia with subsequent breakdown and the risk of dehiscence.
- If it is not possible to close the fascia, or if further trips to the operating room are indicated, the surgeon should choose a temporary closure that prevents lateral retraction of the fascia and facilitates later primary closure.
- **Vacuum-assisted fascial closure**, most commonly by KCI (KCI Wound VAC System, Kinetic Concepts, Inc., San Antonio, TX) involves a pie-crusted plastic drape with incorporated sponge, a separate wound sponge, and adhesive dressing with suction tubing.
 - The sponge suction provides constant medial tension, without disrupting the fascia, to prevent lateral retraction.
- Management of the patient's volume status may be as important as the method of temporary closure in allowing later reapproximation of the fascia. Regardless of which method is chosen, most studies have indicated a high rate of primary closure if the patient has a net negative fluid balance at the time of operation.
- Net negative volume balance is extremely difficult to achieve in critically ill trauma patients requiring large-volume resuscitations.
- A large percentage of these patients will go on to planned giant ventral hernias.

Short Bowel Syndrome

- Short bowel is an outcome of intra-abdominal catastrophe resulting in extensive surgical resection. Short bowel is defined as a **gastrointestinal length of 2 m or less**. The cause may vary greatly between children and adults. Regardless of the cause, a patient's ultimate outcome is largely determined by the length

of remaining small bowel and the presence or absence of the colon.

- Children most commonly end with short gut syndrome after a congenital or neonatal process such as necrotizing enterocolitis, intestinal atresia, volvulus, or gastroschisis.
- Adults acquire short gut syndrome after extensive surgical resection necessitated by malignancy, trauma, obstruction, or vascular insufficiency.
- Presence of the colon can extend the functional capacity of the remaining bowel.
- To have the **potential for enteral autonomy**, a patient requires at least 150 cm of small bowel or 60 to 90 cm if the colon is present.
- Presence of the **ileocecal valve** is also important in maintaining hydration and modulating gastrointestinal transit time.
- There may be difficulty meeting nutritional requirements and dependence on parenteral nutrition.
- Patients will complain of weight loss, diarrhea, and steatorrhea.
- Gastric emptying abnormalities and rapid transit times are due to short intestinal length.
- Dehydration is a constant threat if the colon is absent due to an inability to reabsorb the approximately 4 L of gastrointestinal secretions per day.
- Loss of absorption results in deficiencies in B₁₂, fat-soluble vitamins, and bile salts.
- Patients are also prone to cholelithiasis and nephrolithiasis due to altered absorption of bile salts and oxalate, peptic ulcers due to increased gastric secretions, liver dysfunction and line sepsis from parenteral nutrition.

Management

- A surgeon's role in managing short gut starts in the operating room with the very first incision.
 - At the initial operation, make every effort to preserve bowel length and the ileocecal valve.
 - In some cases, it may be safest to limit resection and return at a later date to inspect marginally viable bowel.
 - Initial postoperative therapy is often supportive, as this patient population is critically ill after emerging from the operating room.
- Early central venous access with immediate institution of parenteral nutrition aids in healing and prevents malnutrition.
- The long-term management of short gut patients then requires a multidisciplinary team involving physicians and nurses, nutritionists, patients, and their families.
- Patients with short gut generally fall into two groups: those with insufficient length (usually <45–60 cm) who require life-long parenteral nutrition and those with adequate length to potentially adapt and become partially or totally enterally independent.
 - Adaptation is a process whereby the absorptive surface of the gut alters to increase digestive capacity and improve nutritional potential.
 - In most cases, the ability is dependent on time and the nature of the remaining bowel.
 - The ileum is capable of adapting to many jejunal functions, but the reverse is less successful.
 - Recombinant growth hormone has been used to improve adaptation by promoting mucosal hyperplasia and increasing villous surface area.

- The process is further enhanced by high-carbohydrate, low-fat diets.
- Glutamine has also been proven beneficial and works synergistically with growth hormone.
- Glutamine, and trophic feeds, stimulate enterocytes and enhance cell proliferation.
- Even in patients who are completely parenterally dependent, low-rate trophic feeds maintain mucosal health.
- Preservation of colonic length improves fluid reabsorption, leading to a more normal bowel regimen and improving the success of adaptation and weaning from parenteral nutrition.
- Conservative therapies such as medication and diet modification are the first line of therapy.
- If inadequate, segmental interposition (surgery) may be attempted:
 - Approximately 10 cm of small bowel is reversed and interposed in the gastrointestinal tract. The antiperistaltic flow slows transit time.
 - When small bowel length is inadequate, a colonic limb may be interposed; this option is much less favored and rarely performed.
- Creation of an artificial valve is also a possibility for those lacking a native ileocecal valve.
- Surgical therapy for short bowel syndrome is pursued infrequently and is generally referred to tertiary centers with extensive experience managing these challenging patients.
- In some cases, patients may have adequate remaining length for enteral independence but suffer from poor function secondary to obstruction, pseudo-obstruction, or dilation.
- A final option in pursuit of enteral independence is **small bowel transplantation**.

Radiation Enteritis

Of patients undergoing abdominal and pelvic radiation, 50% to 75% will have some symptoms related to the therapy in the months to years after treatment. The most common symptoms are vague abdominal pain, diarrhea, rectal bleeding, and tenesmus. In 1% to 15%, bothersome symptoms will progress into actual radiation enteritis.

- The incidence of injury is dependent on such factors as volume of irradiated small bowel, total dose delivered, and dose per fraction, and type of radiation being delivered.
- Symptoms most commonly occur during therapy and may be abrogated by decreasing the radiation dose by 10%.
- In the case of late radiation enteritis, workup should include dismissing recurrence of the initial neoplasm.
- Affected bowels may develop strictures, perforate, or develop fistulas.
- Sitz baths and stool softeners are effective initial treatments for rectal and anal symptoms.
- Opiates, antispasmodics, and anticholinergics will decrease diarrhea.
- Steroid enemas and sucralfate (by mouth or by rectum) can diminish irritation of the mucosa, which results in rectal pain and bleeding.
- If malnourished from chronic enteritis, total parenteral nutrition may be necessary, especially if operative intervention is entertained.

Techniques to Diminish or Prevent Radiation Injury

- Simple nonsurgical methods include patient positioning, multiple field techniques, and bladder distention.
- Intra-operative efforts are designed to decrease the volume of small bowel included in the radiation field postoperatively.

Treatment of Radiation Enteritis Complications

- The most common indication for surgery remains obstruction, but other indications include excessive bleeding, intractable diarrhea, pain, fistulas, and persistent abscess.
- Any surgical intervention should use the least invasive procedure required to address the issue.
- Excessive handling and adhesiolysis of radiated tissues commonly results in unplanned enterotomies and may interrupt an already tenuous blood supply.
- If dense adhesions prevent access to the involved segment, a gastrointestinal bypass may be necessary; this will predispose a patient to blind loop syndrome and bleeding but may be a better option than attempting to mobilize frozen bowel.
- Chronic proctopathy may include rectal pain and bleeding and affects 2% to 5% of patients.
 - First-line therapies of sucralfate and steroid enemas are of limited benefit.
 - Endoscopic coagulation of bleeding with electrocautery or laser has been successful but requires multiple treatment sessions.
- The most effective nonoperative therapy remains the topical application of 4% formalin, with 85% of patients responding after two instillations or less.
- Strictures should undergo serial dilation; if unsuccessful or the indication is intractable pain, severe incontinence, or profound bleeding, a diverting colostomy may be necessary.
- In worst case situations, abdominoperineal resection may be pursued.
- In the event of fistulas, the fistula tract and involved tissue at either end must be resected and the sites closed.
- An interposition flap of omentum or muscle should then be placed to protect the repair sites.

CHAPTER 47 ■ CRITICAL CARE OF HEPATOPANCREATOBILIARY SURGERY PATIENTS

- Hepatopancreatobiliary (HPB) surgery is composed of surgery of the liver, bile duct, and pancreas, and may include portal decompressive procedures for complications of portal hypertension. Patients are admitted to the intensive care unit (ICU) for a variety of reasons following HPB surgery, including maintenance or restoration of normal physiology immediately after extensive surgery and the subsequent management of complications that develop. Recurring issues that are relatively specific to HPB surgery patients will be discussed.

LIVER ANATOMY AND PHYSIOLOGY

Liver anatomy has been described by various methods, surgical anatomy is based on the segmental nature of vascular and bile duct distribution.

- The liver is approximately 4% to 5% of total body weight but responsible for **20% to 25% of body oxygen consumption** and 20% of total energy expenditure.
- Liver has a dual blood supply, 75% from the portal vein and 25% from the hepatic artery.
 - Total blood flow to the liver is approximately 1.5 L/minute/1.73 m².
 - There is autoregulation of hepatic arterial flow but not of the portal venous system.
 - Decreasing portal venous flow increases hepatic arterial flow; with complete portal occlusion or diversion, hepatic arterial flow does not completely compensate, and total liver blood flow is diminished.
 - Portal flow is increased by food intake, bile salts, secretin, pentagastrin, vasoactive intestinal peptide (VIP), glucagon, isoproterenol, prostaglandin E₁, E₂, and papaverine.
 - Serotonin, angiotensin, vasopressin, nitrates, and somatostatin decrease portal flow.
- The portal pedicle divides into right and left branches and supplies the liver in a segmental fashion.
- Venous drainage is through the hepatic veins, which drain directly into the inferior vena cava.
- **Hepatic segmentation** is based on the distribution of the portal pedicles and their relation to the hepatic veins. The three hepatic veins run in the portal scissurae and divide the liver into four sectors, which are, in turn, divided by the portal pedicles running in the hepatic scissurae. Segmental anatomy becomes important in considering surgical resection when essentially any segment or combination of segments can be resected if attention is paid to maintaining vascular and biliary continuity to the remaining segments.
- Common liver resections are performed that may require ICU admission after surgery.
 - Right or left hepatectomy, about 50% of liver volume is removed.
 - Right or left trisectionectomy, up to 80% of the liver is removed.
 - If <40% of the liver is resected in patients with normal underlying liver function, then relatively little derangement of liver physiology is noted.
- The liver performs many functions, including uptake, storage, and eventual distribution of nutrients from the blood or gastrointestinal tract, as well as synthesis, metabolism, and elimination of a variety of endogenous and exogenous substrates and toxins (including narcotics and other drugs).
- **Bile**, composed of inorganic ions and organic solutes, is formed at the canalicular membrane of the hepatocyte, as well as in the bile ductules, and is secreted by an active process that is relatively independent of blood flow.
 - The major organic components of bile are the conjugated bile acids, cholesterol, phospholipid, bile pigments, and protein.
 - Approximately 600 to 1,000 mL of bile is produced per day.
 - Bile secretory pressure is 10 to 20 cm saline, with maximal secretory pressures of 30 to 35 cm in the presence of complete biliary obstruction.
 - Bilirubin, a degradation product of heme, is eliminated almost entirely in the bile.
 - Complete obstruction of one of the right or left hepatic ducts alone will cause marked liver enzyme abnormalities, but rarely causes jaundice.
- The liver synthesizes many of the major human plasma proteins including albumin, γ -globulin, and many of the coagulation proteins.
- Liver dysfunction can have a profound effect on coagulation.
 - In obstructive jaundice, there is decreased activity of factors II, V, VII, IX, and X, secondary to a lack of **vitamin K-dependent** posttranslational modification.
 - Reversal of coagulation abnormalities by exogenous administration of vitamin K allows differentiation between synthetic dysfunction and lack of vitamin K absorption secondary to obstructive jaundice.
- After resection, there is a reduction in functional liver mass and potential ischemia/reperfusion injury to the liver remnant.
 - Reduction below 25% functional liver volume has been associated with an increased risk of both liver failure and mortality in patients with normal presurgical liver function.
 - Preoperative portal vein embolization (PVE) of the liver to be resected is done percutaneously.
 - Diversion of portal flow and its hepatotrophic factors to the future liver remnant (FLR) causes growth and hypertrophy

of about 30% over a 6-week period and has been shown to reduce the complications associated with subsequent extended liver resections.

SURGICAL PROCEDURES

Liver Resection

- The liver is a tremendously vascular organ, intra- or post-operative complications are often related to excessive blood loss. While liver resection may be performed, in many cases without the need for interruption of blood flow to the liver, it is sometimes necessary to reduce blood flow to prevent excessive blood loss.
- Selective inflow control can be established by division or occlusion of the vascular structures supplying the segment(s) of liver to be removed.
 - This maintains blood flow to the segment of the liver being preserved, but is generally only useful in smaller resections.
- **Total inflow occlusion** (Pringle maneuver) clamps the entire inflow of the liver at the hepatoduodenal ligament, and has been shown to reduce blood loss during the parenchymal transection phase of the resection.
 - **Warm ischemic injury** is a concern, but abundant data show that the normal liver can tolerate inflow occlusion up to 1 hour; this may also hold true for some cirrhotic livers.
 - Clamp times are expected to be <30 minutes for formal hepatectomies, but may be higher for more complex parenchymal transections.
 - In such cases, total occlusion is carried out in 15-minute increments with 5-minute reperfusion intervals.
 - **Ischemic preconditioning** involves inflow occlusion for 10 minutes, 15 minutes reperfusion, and then sustained clamping for up to 1 hour.
 - Intermittent clamping is associated with more blood loss than ischemic preconditioning; however, the protective results of ischemic preconditioning in ischemia reperfusion injury have not been uniform across age groups, and may not be as effective in livers that have been exposed to pre-operative chemotherapy.
- **Total vascular isolation** of the liver with both inflow occlusion and occlusion of the supra- and infrahepatic vena cava can be useful for technically demanding cases where the vena cava or proximal hepatic veins are involved with tumor.
 - Safe for up to 60 minutes in normal liver, but can be accompanied by varying degrees of hemodynamic instability.
 - When required, we carry out as much of the operation as possible prior to isolation of the liver to reduce the ischemic time and the period of hemodynamic instability.
- The most troublesome bleeding sources during liver resection are usually from hepatic vein branches, which may be minimized by maintaining the central venous pressure (CVP) below 5 mm Hg during the period of hepatic transection.
 - Cooperation of the anesthetist in minimizing volume loading, and occasionally using pharmacologic agents to reduce CVP, is essential.
- If total vascular isolation is to be used, volume loading prior to caval clamping is required to avoid an acute decrease in cardiac output at the time the clamps are applied.
- Knowledge of the **details of intraoperative conduct** of the operation is therefore important to the physicians who are to manage the postoperative care of the liver resection patient in the ICU setting.
 - Was inflow occlusion or vascular isolation required, and for how long? Prolonged clamp times are associated with greater liver dysfunction.
 - Was the patient maintained with a low CVP throughout the course of the surgery? The patient may need volume expansion on arrival to the ICU.
 - How much liver remains, and is it normal? If the percentage of remaining liver is <25% in normal livers or <40% in cirrhotic livers or livers with bile duct obstruction, then the chance of liver failure and the need for its management are higher.
 - Was there significant blood or fluid requirements? Patients may need a period of ventilation while fluid shifts and equilibrates.

Pancreatic and Bile Duct Surgery

In general, procedures on the pancreas or biliary tree should not be associated with major intraoperative hemodynamic changes or alterations in physiology. The more common indications for admission to the ICU after pancreatic or biliary surgery are either an underlying medical condition or the development of a postoperative complication.

- With **portal vein resection or repair**, it is more likely that the patient will require ICU care.
 - Technical difficulties can arise in which damage occurs to, or resection is required of, the portal vein.
 - Requires variable durations of portal venous outflow obstruction from the gut, which are usually short and well tolerated, but can increase the amount of fluid third-spaced into the bowel wall.
 - Can lead to massive transfusion requirements and hypotension.
- Pancreatic or bile leaks, which can lead to sepsis, will be discussed later in the chapter.

Portal Decompressive Procedures

- Surgical portal decompressive procedures, although a rarity since the introduction of the **transjugular intrahepatic portosystemic shunt (TIPS)**, remain indicated in select patients with variceal bleeding and preserved liver function who have failed medical management and are not transplant candidates.
 - The high-pressure portal system is surgically connected to the low-pressure caval circulation.
 - Reduction of portal flow in patients with borderline liver function can precipitate liver dysfunction or failure.
 - The fraction of portal flow diverted into the systemic circulation is not cleared by the liver until it returns by the arterial circulation.
 - Shunts that divert most or all of the portal flow are more likely to induce encephalopathy than those shunts that are selective or partial.

- One special case scenario is **Budd-Chiari syndrome**, in which the hepatic venous outflow is obstructed, usually due to thrombosis secondary to a hypercoagulable state.
- Blood inflow cannot exit through the blocked hepatic veins.
- A functional side-to-side shunt is performed (portacaval, mesocaval) that allows hepatic arterial blood to flow into the sinusoids, exit through the portal vein, and then through the shunt into the systemic circulation.
- It is not uncommon for liver function to deteriorate initially after the shunt is performed, with subsequent gradual improvement and liver regeneration.
- In some cases, the shunt may **precipitate acute liver failure**, making urgent liver transplantation the only option.

IMMEDIATE POSTOPERATIVE MANAGEMENT

- Postoperative fluid management is important in the care of patients after major hepatobiliary surgery. Most liver resections are performed with low central venous pressure and low intravascular volume to minimize bleeding; postoperatively, these patients may have signs of hypovolemia with low urine output and low blood pressure. Volume re-expansion should be gentle, as partial liver resection leads to hypoalbuminemia, and pulmonary edema and ascites can develop with aggressive resuscitation.
- Physiology is similar to patients with cirrhosis.
- **Albumin**, if the serum albumin is <2.9 mg/dL, may be useful in the resuscitation of patients after liver resection.
- Fresh frozen plasma can be used for volume expansion; however, it is generally reserved for abnormalities in coagulation.
- Serial **lactate levels** are helpful in the postoperative management of patients after liver resection.
- Elevated lactic acid levels may be a sign of hypovolemia, but the lack of response to volume can indicate liver dysfunction.
- After liver resection, **glucose metabolism** is altered due to both a reduction in functional liver mass and the relative dysfunction of the remaining liver secondary to ischemia reperfusion injury if vascular control has been used during the procedure.
- Normally, as glycogen stores are depleted, the liver uses gluconeogenesis to provide glucose.
- Resulting from altered hepatic physiology, hypoglycemia may occur, although lethal hypoglycemia is rare.
- Tight glucose control to reduce risk of sepsis requires closer monitoring and may necessitate reduced insulin dosing to prevent hypoglycemia after major liver resection.
- Patients who have undergone shunt surgery require a different approach than patients undergoing other types of hepatobiliary surgery.
- More aggressive fluid management is required immediately postoperatively to maintain **circulating intravascular volume** and reduce the risk of shunt thrombosis.
- Maintenance fluid should be 0.45% saline solution with 5% dextrose to provide the liver with carbohydrate.
- After the immediate postoperative period, patients are also at risk for ascites formation, so excessive sodium should be minimized and additional volume expansion—if needed—should be albumin or fresh frozen plasma.
- Diuretics, a combination of 100 mg of spironolactone for every 40 mg of Lasix, can be reinstituted after the immediate postoperative period.
- Antibiotics are administered for 48 hours postoperatively to minimize infection from bacterial translocation.
- **Encephalopathy** is rare in patients after liver resection, unless they are in liver failure or have preexisting liver disease.
- The presence of asterixis can be an early sign.
- Treat with lactulose and dietary protein restriction.
- Infection, dehydration, and bleeding, as well as narcotic use can trigger decompensation that leads to encephalopathy.

Hypophosphatemia

- The exact mechanism of the hypophosphatemia seen after hepatic resection remains unclear.
- Utilization during liver regeneration and a renal wasting mechanism has been proposed.
- Clinical consequences include respiratory depression, diaphragmatic insufficiency, seizures, and cardiac irritability.
- Hepatocellular regeneration is dependent on adenosine triphosphate (ATP) and may be impaired if phosphate is not repleted.
- Significant postoperative hypophosphatemia (<2.5 mg/dL) increases complications after liver resection.
- Phosphate should be replaced with potassium or sodium phosphate preparations, or added to parenteral nutrition solutions.

Liver Function: Assessment and Support

Liver function should be carefully monitored after major liver resections and shunt surgery, as liver failure is a risk in any major hepatobiliary surgery.

- Risk increases with the extent of hepatectomy and with preoperative liver disease or cirrhosis.
- **Liver function tests** may not show elevation until the patient has significant liver failure.
- Mechanical injury and partial devascularization elevates transaminases in the 200 to 300 units/dL range post resection.
- Prothrombin time and lactate are helpful in evaluating early postoperative liver dysfunction.
- Elevated total and indirect bilirubin are also useful indicators of postoperative liver dysfunction. However, isolated elevation of total bilirubin in the presence of normal liver function can have other etiologies.
- Perioperative blood transfusions can lead to hemolysis and direct **hyperbilirubinemia**.
- Bile leaks or obstruction can also lead to an elevated serum bilirubin.
- Many popular anesthetics, antibiotics, and other drugs can cause hepatotoxicity and elevation of the serum bilirubin and need to be reduced or stopped if liver failure occurs.

When postoperative liver dysfunction develops, it is important to exclude sepsis, drug toxicity, biliary obstruction or leak, and anatomic causes of liver failure.

- Ultrasound can evaluate for portal vein, hepatic arterial, or hepatic vein thrombosis or obstruction, which may be amenable to surgical intervention.

- In the absence of these conditions, liver failure is likely related to a preexisting liver disease and/or the extent of resection.
- Treatment is then supportive, with correction of coagulopathy, encephalopathy, and ascites.
- Systemic antibiotics or gut decontamination may be beneficial, since the liver Kupffer cells play a role in decreasing bacterial translocation from the portal blood flow, and patients with liver failure or biliary leak or obstruction may have an increased risk of bacteremia and sepsis.

Although definitive clinical data are lacking, both **N-acetylcysteine** and **prostaglandin (PG) E₁** have been used to ameliorate postoperative liver damage in both liver resection and transplant patients.

- **N-acetylcysteine** is given as a continuous IV infusion, 40 mL of 10% solution mixed in 250 mL D5W, over 16 hours.
 - Decrease liver injury after acetaminophen overdose.
 - Lessen ischemia reperfusion injury of the liver.
- **Prostaglandin** is given as a continuous IV infusion, starting at 0.15 $\mu\text{g/kg/hour}$, titrated up to 1 $\mu\text{g/kg/hour}$ based on systemic hypotension.
 - Linked to improvement of ischemia reperfusion injury and liver damage.

Coagulopathy

Coagulopathy is common after liver resection.

- Increase in prothrombin time directly proportional to the extent of liver resection.
- Attributed to impaired synthesis and clearance of clotting factors, inhibitors, and regulatory proteins.
- Underlying liver disease and cirrhosis often have **thrombocytopenia and qualitative platelet defects**.
- Intraoperative hypothermia and perioperative transfusions, while not routine, are not uncommon during major hepatobiliary surgery, and can contribute to postoperative coagulopathy.

Because of the vascular nature of hepatobiliary surgery combined with postoperative coagulopathy from decreased liver function, serial hemoglobin and prothrombin levels should be followed for postoperative bleeding.

- In general, we would obtain a hematocrit and international normalized ratio (INR) on ICU arrival and then repeat them, every 6 hours, for the next 24 hours.
- The surgeon should be notified of excessive bloody output from the drains, increasing abdominal distention, or hemodynamic instability.
- If INR goes above 2.0 it should be corrected both with vitamin K and fresh frozen plasma.
- Any patient who is bleeding should have his or her coagulopathy completely corrected.
- For severe bleeding, both aprotinin (currently not available until further safety studies are done) and activated factor VII are safe in patients during and after liver resection.
- Patients who fail to stop bleeding after correction of their coagulopathy require return to the operating room for exploration.
- The surgical team should be made aware of any patient who requires transfusion immediately after surgery.
- Once the postoperative coagulopathy has resolved or stabilized, all patients should be given subcutaneous heparin or low-molecular-weight heparin with sequential compression

devices to prevent the formation of deep venous thrombosis.

Pain Management and Sedation

Major hepatobiliary surgery can result in significant pain after surgery.

- Resultant from the large subcostal incision
- Altered pharmacokinetics, metabolism of many common medications, and coagulopathy, in particular after partial liver resection or shunt surgery, can make postoperative pain management a challenging proposition.
- With narcotics and sedatives that require hepatic clearance, oversedation is a common problem that arises in the ICU after liver resection.
- A standard dose of narcotics given to a patient who has had 80% of the liver resected may well cause prolonged respiratory depression and signs and symptoms of encephalopathy.
- **Narcotics should be used at the minimum dose required to achieve pain control.**
- After liver resection, basal rates on patient-controlled anesthesia pumps should be avoided, as metabolism of narcotics is difficult to forecast.
- **Benzodiazepines** also have altered clearance after liver resection, and should be administered at a **lower dose** or, if possible, avoided altogether.
- In patients requiring ongoing endotracheal intubation and mechanical ventilation, the level of sedation can be more easily titrated and reversed with sedative agents such as propofol rather than narcotics.
- **Epidural** pain management may be the optimal analgesic technique after liver resection.
 - Contraindicated in many patients because of postoperative coagulopathy
 - Good pain control with small risk of oversedation requiring naloxone in living donor partial hepatic resection
 - Useful in select patients who do not have underlying liver disease and who are not undergoing extensive resections.

Nutrition

- The role of the liver in protein and carbohydrate metabolism makes proper postoperative nutrition imperative after major hepatobiliary surgery, in particular after partial liver resection when liver function is temporarily reduced.
 - Preoperative biliary obstruction, malignancy, and cirrhosis are higher risk for nutrition-related complications after major liver or bile duct surgery.
 - Preoperative nutritional risk factors associated with postoperative complications include weight loss >14% lean body mass over 6 months, serum albumin <3 g/dL, hematocrit <30%, total body potassium <85% of normal, <25th percentile for midarm circumference, and skin test anergy.
 - Preoperative bilirubin, albumin, prealbumin, prothrombin time, and transferrin, as well as replacement of vitamin and trace mineral deficits, may also be important preoperatively.
- As with most critically ill patients, **early enteral nutrition has been associated with improved outcomes.**

- In hepatobiliary surgery, both enteral and parenteral nutrition have been associated with improved outcomes, especially in high-risk patients.
- Parenteral nutrition has an increased risk of wound infection and catheter sepsis.
- Enteral nutrition improves gut flora, prevents gastrointestinal atrophy and loss of immunocompetence.
- In patients who have undergone routine liver resection or shunt surgery, low-volume enteral feeds can be started almost immediately after surgery.
- Unless the feeding tube is placed distal to the anastomosis, hepaticojejunostomies or pancreatic surgery must await the return of bowel function prior to starting feeds.
- Consult with the operating surgeon before starting enteral feeds in any patient, particularly those with enteric reconstruction.
- Patients with major pancreatic surgery (pancreaticoduodenectomy, subtotal or total pancreatectomy) may require pancreatic enzyme supplementation with enteral feeds or when resuming oral intake.
- Patients with **chronic liver disease or cirrhosis** often have severe metabolic derangements that make nutritional management difficult.
 - Depletion of fat-soluble vitamins, in particular vitamin K, leads to coagulopathy and diminished antioxidant response.
 - Chronic liver disease stimulates a catabolic state with proteolysis and cachexia.
 - Protein loss can be exacerbated by dietary restriction for encephalopathy.
 - Branched-chain amino acids do not reduce encephalopathy.
 - Cirrhosis patients have abnormal glucose tolerance and insulin levels, along with elevated ammonia levels, hypophosphatemia, and hypoalbuminemia.
 - All Child's B or C cirrhotic patients should be fed enterally when hospitalized.
 - The caloric needs of these patients are increased, and goal kcal is 25 to 25 kcal/kg/day, with administration of protein at 1 to 1.5 g/kg dry weight in nonencephalopathic patients and 0.5 g/kg dry weight in encephalopathic patients.
 - Patients with ascites need sodium restriction of 2 g/day and a fluid restriction of 1 to 1.5 L/day, in combination with diuretics if tolerated.
- **Patients with preoperative obstructive jaundice**
 - Such patients often have decreased hepatic protein synthesis and catabolism as well as chronic, low-grade endotoxemia and sepsis.
 - Malabsorption of fat and fat-soluble vitamins from obstruction of bile flow, leads to weight loss, anorexia, coagulopathy, and a diminished antioxidant response.
 - Mandatory biliary decompression prior to surgery is controversial but allows malnutrition and sepsis to resolve.
 - Two weeks of alimentation (both parenteral and enteral) **prior to operation** is associated with a lower risk of infection, morbidity, and mortality.
 - Standard nutrition is acceptable as hepatic dysfunction is usually not present.
 - A low-fat diet and replacement of fat-soluble vitamins is appropriate in patients where bile flow is not restored.
 - Medium-chain triglyceride absorption is not bile salt-dependent.
- Partial liver resections also cause metabolic abnormalities secondary to the regenerating liver.

- Postoperative parenteral nutrition should be supplemented with protein and fat, but low on glucose to improve hepatic regeneration.
- Hepatic mitochondria switch to **fat from glucose** as their preferred energy source in hepatic regeneration.
- Hypertonic glucose and insulin infusions should be avoided immediately after resection, as hyperglycemia and insulinemia suppress fatty acid release and decrease ketone body production by the liver.
- The evidence for administration of fat/ketone bodies or infusions of glucose and insulin directly into the portal vein after liver resection to accelerate regeneration is lacking.
- General goals are 30 kcal/kg/day, with 1.0 to 1.5 g/kg protein; glucose approximating 5 mg/kg/minute, and fat should not exceed 30% of the calories.
- Patients with cancer may need an increase of up to 35 kcal/kg/day and 2 g/kg protein.

Renal Failure

- Acute renal failure occurs in 10% of major hepatobiliary surgery patients and significantly increases postoperative mortality.
- Risk factors include postoperative sepsis, preoperative uremia, preoperative anemia, malignant disease, and preoperative jaundice.
- About 10% of patients with preoperative obstructive jaundice develop postoperative renal failure.
 - Both dehydration and endotoxin production from bile duct obstruction have been postulated to cause renal failure in these patients.
 - Mannitol, bile salts, hydration, and lactulose may decrease endotoxin absorption, and may be beneficial in the prevention of renal failure.
 - Preoperative biliary drainage helps lessen the perioperative inflammatory response.
- Adequate hydration, treatment of sepsis, and avoidance of nephrotoxic drugs are mandatory.
- Supportive care and dialysis are needed until renal function returns.
- Patients with advanced cirrhosis or postoperative liver failure can develop **hepatorenal syndrome (HRS)**.
 - This outcome is more significant in the acute care of patients with liver failure or after liver transplantation.
 - Hepatorenal syndrome is a diagnosis of exclusion, with decreased renal function associated with urine sodium <10 mg/dL combined with urine osmolality greater than plasma osmolality that does not respond to volume administration.
 - The cause is likely multifactorial, but is primarily related to circulatory disturbances in patients with advanced liver disease, reduced liver function, and portal hypertension.
 - Systemic vasodilatation and low mean arterial pressure result in renal vasoconstriction and a reduction in the glomerular filtration rate.
 - Although liver transplantation remains the only cure for HRS, vasoconstrictors, albumin infusions, and transhepatic portosystemic shunts are able to reduce HRS and may prevent its development in patients with spontaneous bacterial peritonitis.

POSTOPERATIVE COMPLICATIONS FOLLOWING LIVER RESECTION

- The morbidity associated with liver resection is reported to range between 30.7% and 47.7%.
- In addition to the standard complications associated with all major operations, liver resection is associated with specific problems including bleeding, bile leaks, liver insufficiency, ascites, pleural effusions, and infections. Risk factors of complications following liver resection include increased blood loss, increased number of segments resected, increased preoperative bilirubin, increased prothrombin time, prolonged operative time, resection of segment VIII, diabetes, and concomitant surgical procedures.

Mortality

- The in-hospital mortality due to liver resection has decreased over the last two decades, and high-volume centers have reported rates of 0% to 5% despite increased mean age and comorbidities.
 - This decrease is attributed to improved surgical technique, intraoperative anesthesia management, and perioperative care.
 - Risk factors include hypoalbuminemia, thrombocytopenia, preoperative total bilirubin >6 mg/dL, serum creatinine >1.5 mg/dL, cholangitis, major hepatic resection, increased number of segments resected, synchronous abdominal procedure, major comorbid illness, diabetes mellitus, and blood transfusion requirements.
 - Specific surgical strategies to decrease mortality include minimizing blood loss and transfusions, and avoiding ischemic injury to the remnant liver.
 - Specific posthepatectomy strategies include minimizing ongoing liver injury by maintaining tissue oxygenation, early nutritional support to facilitate liver regeneration, and replenishing phosphate levels.

Bleeding

- Bleeding was once the “Achilles heel” of liver resection surgery but has decreased dramatically over the last two decades due to a better appreciation of liver anatomy, surgical technique, and improved anesthesia management.
 - Estimated blood loss has decreased from 750 mL to 300 mL and perioperative transfusion rates from 28.3% to 17.3%.
 - Risk factors for increased bleeding from liver resection include cirrhosis, portal hypertension, increased segments resected, coagulopathy, thrombocytopenia, and elevated central venous pressure during resection.
 - Strategies include appropriate patient selection—especially avoiding resection in patients with portal hypertension—and maintenance of central venous pressure under 6 mm Hg, Pringle maneuver, preoperative correction of coagulopathy and thrombocytopenia, use of fibrin sealant on raw liver surfaces, use of intraoperative ultrasound to locate the hepatic venous branches, and utilization of selective hepatic vascular exclusion.

Bile Leak

- Biliary leaks occur in 3.6% to 17% of liver resection cases and are associated with increased mortality and concomitant complications.
 - Risk factors include older age, preoperative leukocytosis, left-sided hepatectomy, prolonged operative time, resection for peripheral cholangiocarcinoma, and resection of segment IV.
 - For hepatocellular carcinoma (HCC) resection, risk factors for bile leaks included central tumor location and preoperative transarterial chemoembolization (TACE).
 - The efficacy of fibrin glue to decrease bile leak is debatable.
- Most bile leaks following liver resections without biliary reconstructions are small and can be managed nonoperatively.
 - If a drain was not placed during the procedure, a percutaneous drain prevents abdominal sepsis and controls the leak.
 - Broad-spectrum antibiotics are started for fevers, leukocytosis, or positive bile cultures.
 - Persistent drainage for 2 to 3 days of more than 100 mL of bilious fluid confirms an active leak, and is managed with endoscopic retrograde cholangiopancreatography (ERCP), sphincterotomy, and stent placement.
 - These measures may define the location of the leak and facilitate enteric biliary drainage and leak closure.
 - When leaks are at the resected hepatic duct stump, a stent traversing the leak may further facilitate leak closure, although the main principle of treatment is to reduce the pressure in the biliary tree and allow spontaneous closure.
 - Early endoscopic management of biliary leaks can minimize hospital length of stay and are not associated with late biliary complications.
 - Endoscopically placed nasobiliary tubes to decompress the biliary system allows easy repeat cholangiograms and later removal.
 - Although most leaks will close with time with these measures, they may persist for months.
- Around 0% to 32% of patients ultimately require reoperation because the leak cannot be controlled, and these procedures are associated with a high mortality rate.
 - Biliary enteric drainage is performed on patients in whom ERCP cannot be performed for technical reasons, or with persistent leaking despite ERCP.
 - Important factors contributing to a good outcome are early reoperation, control of the biliary fistula before surgery, and utilization of healthy bile duct edges for enteric anastomosis.
- Hemobilia may complicate bile leaks or liver resections or may occur secondary to trauma.
 - Hemobilia is an open communication from a branch of the hepatic artery to the biliary tree and leads to intermittent, and sometimes exsanguinating, gastrointestinal (GI) bleeding.
 - Identification is made when blood is seen exiting the ampulla when endoscopy is performed for upper GI bleeding.
 - Computed tomography (CT) scanning with arterial phase contrast can localize the bleeding within the liver; however, management is by angiographic embolization.

Liver Failure and Dysfunction

- **Liver failure** complicates liver resection in up to 12% of cases, and occurs when inadequate functional liver volume is left after resection. This complication occurs primarily in patients undergoing resection for hepatocellular carcinoma with underlying liver disease, and is often a consequence of patient selection and choice of operation.
- Risk factors for hepatic insufficiency in cirrhotics include major resections, especially right lobectomy, portal hypertension, long-standing jaundice, Childs-Pugh Turcotte (CPT) score greater than A, and hepatic steatosis.
- Preoperative chemotherapy, routine in colorectal cancer metastases, with newer agents such as irinotecan, oxaliplatin, and Avastin cause an increase in both hepatic steatosis as well as steatohepatitis, which can contribute to postoperative liver dysfunction.
- By assessing the patient's **functional liver status**, the surgeon can estimate the maximum amount of liver mass that can be resected while preserving adequate functional liver volume.
 - In a normal liver, up to 75% of total liver volume can be resected safely.
 - In general, Child-Pugh class C is a contraindication to any sort of resection.
 - Early Child's class B patients without portal hypertension may undergo minor resections—from wedge resection to a single segmentectomy—but may be better served by nonsurgical local ablation techniques.
 - Child-Pugh class A patients who are considered for major hepatectomy—resection of four or more segments—should undergo assessment of both liver and physiologic status.
 - Model for End-Stage Liver Disease (MELD) score ≥ 11 predicts liver failure following HCC resection.
 - Portal hypertension, defined as a hepatic vein pressure gradient (HVPG) > 10 mm Hg, and as suggested by signs such as esophageal varices, anatomic portosystemic shunts, and ascites, has been associated with increased morbidity and mortality following major resection.
 - Thrombocytopenia with platelet counts $< 100,000$ cells/ μ L has been associated with in-hospital mortality following liver resection.
 - The indocyanine green (ICG) clearance test, commonly used in Asia, is one method of quantifying liver function.
 - ICG retention at 15 minutes (ICGR15) of $< 20\%$ allows safe, limited liver resection.
 - A value $< 14\%$ is associated with near-zero operative mortality.
 - In Child-Pugh class A patients with right-sided lesions curable by major resection but whose liver reserve may be inadequate, preoperative ipsilateral portal vein embolization increases the remnant contralateral liver volume.
 - This is generally performed in patients with a predicted function liver remnant of $< 25\%$ in noncirrhotics or $< 40\%$ in patients with significant fibrosis and/or cirrhosis.
- Liver failure following liver resection presents clinically with encephalopathy and asterixis.
 - Severe cases appear similar to fulminant liver failure, presenting with marked acidosis, jaundice, and hemodynamic instability; the patient ultimately succumbs to multiorgan failure and sepsis.

- In mild cases, treatment is supportive, with judicious fluid management, optimization of tissue oxygenation, infection prophylaxis, and nutritional support if recovery is prolonged.
- The goal in the mild and salvageable cases is to promote immediate liver functional recovery from the insults inherent to liver resection; to promote liver regeneration with nutritional and electrolyte repletion, particularly phosphate; and to minimize the chance of infectious complications.
- N-acetylcysteine may improve hepatic oxygen delivery and extraction in patients for non-acetaminophen-induced liver failure.

Ascites and Pleural Effusion

- Ascites occurs in up to 9% of liver resections and is associated with decreased survival, as it is a surrogate marker of liver insufficiency and because of its potential contribution to prerenal insufficiency.
 - Risk factors for both ascites and pleural effusion include right lobectomy, diabetes mellitus, poor nutritional status and hypoalbuminemia, left-sided cardiac insufficiency, and liver and renal insufficiency.
- Pleural effusion, usually occurring on the right side and frequently accompanying ascites, is found following liver resection in 3.8% to 21% of cases and is usually asymptomatic, requiring no treatment.
 - Effusion may develop from underlying ascites that crosses the diaphragm.
 - The same pathophysiologic processes of fluid overload and hypoproteinemia that cause ascites may also contribute to the development of pleural effusion.
 - Risk factors specifically associated with pleural effusion include resection for HCC with underlying liver disease, subphrenic collections, postoperative liver insufficiency with ascites, and duration of inflow occlusion.
 - Strategies to prevent postresection ascites and pleural effusion include avoiding overhydration, including gentle diuresis; preventing renal insufficiency by avoiding nephrotoxic drugs and hypotension; early detection and treatment of infection; maintaining adequate nutrition; and the use of perioperative drains. The appropriate selection of patients and resection to maintain adequate liver function, especially in patients with hepatomas and underlying liver disease, will minimize the risk of liver failure and subsequent ascites.

COMPLICATIONS FOLLOWING BILE DUCT RESECTION/RECONSTRUCTION

- Perhaps the most extensive hepatobiliary operations are performed for proximal extrahepatic cholangiocarcinomas, with mounting evidence demonstrating significantly improved survival following extended liver and bile duct resections and reconstructions.
- Perioperative mortality following extended liver and biliary resections ranges from 1.3% to 16%. Complications following these procedures occur in 51% to 81%, and many patients have multiple complications.

- Complications include **bile duct leaks, bleeding, liver failure, pleural effusions, wound infection, and sepsis.**
- Each of these complications can also be found in liver resections alone, share the same risk factors, and can be approached with the same preventative strategy and treatment.
- Liver failure following extended resections for obstructive cholangiocarcinoma may have a unique pathophysiology and, hence, preventative strategy.
- Prolonged biliary obstruction causes significant hepatocellular dysfunction, with up to 27.6% liver failure in patients who undergo extended liver and biliary resections and reconstructions, this is frequently fatal.
- Resection of up to 75% of the liver and vascular reconstruction that requires an increased duration of ischemia is often necessary to resect hilar cholangiocarcinoma.
- Strategies to optimize functional liver volume prior to extended liver resections are essential.
- Preoperatively biliary decompression, using percutaneous transhepatic cholangiocatheterization, is somewhat controversial.
 - May introduce infectious agents into an otherwise sterile biliary tree
 - May be avoided in patients who can undergo surgery within 2 to 3 weeks after the onset of jaundice
- Contralateral portal vein embolization may be performed to increase the remnant liver volume prior to resection.
- Decreased liver failure rates are observed when these are employed.

COMPLICATIONS FOLLOWING PANCREATIC SURGERY

- The mortality rate following pancreaticoduodenectomy (PD) ranges between 2.7% and 6.9%.
- Risk factors for perioperative mortality include elevated serum bilirubin, the diameter of the pancreatic duct, increased intraoperative blood loss, pancreatic fistulae, and older age.
- Complications are seen to occur in 22.1% to 30.2% of PDs, and include **pancreatic fistulae, delayed gastric emptying, bleeding, abdominal abscesses, and wound infections.**
- **Pancreatic fistulae** are a dreaded complication of PD, occurring in 12% to 18% of patients.
 - Risk factors for pancreatic fistulae include small duct size, soft pancreas texture, duration of surgery >8 hours, diabetes mellitus, lower creatinine clearance, preoperative jaundice, and increased intraoperative blood loss.
 - Pancreatic fistulae are associated with a mortality rate ranging to 19%.
 - Patients often die secondary to massive erosive *bleeding* from sepsis and pancreatic enzyme accumulation.
 - **Bleeding** occurs in 1% to 8.8% of PD patients and carry a mortality rate of 47% to 50%.
 - Strategies to prevent pancreatic fistulae following PD, including the use of octreotide, fibrin sealants, pancreatic stents, and different methods and sites of pancreatic anastomosis, have not proven effective.
 - Pancreatic fistulae are initially detected on postoperative day 6 as abdominal pain, fever, nausea/vomiting, and leukocytosis.
 - Fistulae are then confirmed by CT scan demonstrating fluid collection behind the pancreatic anastomosis, elevated serum amylase, drain output >50 mL/day, and drain amylase 10-fold greater than serum amylase.
- Management is initially conservative, with bowel rest, total parenteral nutrition, antibiotics, and monitoring of clinical signs and symptoms and drain output.
 - If repeat imaging demonstrates increased accumulation of fluid and the patient does not respond to conservative measures, another drain may be placed percutaneously to prevent progression to abdominal sepsis.
 - About 80% to 90% of patients seal pancreatic fistulae with these measures.
 - Uncontrolled leaks and abdominal sepsis may require surgery, usually for completion pancreatectomy.
- Life-threatening erosive intra-abdominal **bleeding can occur**, usually from the stump of the gastroduodenal artery, small arterial branches to the pancreas or, rarely, the portal vein occurs in a small group of patients.
 - This presents with signs and symptoms of sepsis and hypovolemia, such as fever, abdominal pain, hypotension, anemia, and bloody drain output.
 - Patients are treated by rapid resuscitation and angiography for potential **embolization** of the bleeding arterial branch.
 - If arterial bleeding cannot be controlled in this manner, or if the bleeding is venous, the patient is explored for hemostasis and completion pancreatectomy.
 - Surgery in this setting is associated with a high mortality of up to 36%.

CHAPTER 48 ■ CRITICAL CARE OF THE THORACIC SURGICAL PATIENT

Thoracic surgical patients are among the most complicated admissions to intensive care due to their preoperative status, variety of operations, airway and pleural appliances, and requirements for postoperative interventions. Information transfer is key, including operative procedure, the expected medical course, and the predictable potential complications.

PREOPERATIVE CONSIDERATIONS: IDENTIFYING THE HIGH-RISK PATIENT

- The patient undergoing thoracic surgery is frequently older, with concurrent medical problems and often debilitated owing to cancer and associated malnutrition.
- Pulmonary abnormalities commonly arise from prior occupational exposure, tobacco use, or a primary disease process. History of asthma, wheezing, or allergic airway responses identify patients in whom bronchodilator management may be needed in the postoperative period.
- With severe chronic obstruction, the best predictors of postoperative ventilation requirements are arterial $pO_2 < 70\%$ of that predicted for age and the presence of dyspnea at rest.
- Factors associated with postoperative pneumonia after elective surgery include low preoperative serum albumin values, high American Society of Anesthesiologists physical status classification, smoking history, prolonged preoperative stay, longer operative procedure, and thoracic or upper abdominal site for surgery.
- **Preoperative pulmonary function tests**
 - By themselves are not reliable predictors of postoperative pulmonary function. The forced expiratory volume in 1 second (FEV_1) is an indicator of effective cough and ability to clear secretions. A postoperative FEV_1 is affected by inspiratory muscle strength, elastic recoil, and degree of obstructive air trapping, as well as any surgical removal of lung tissue.
 - FEV_1 decrease may not be proportional to the extent of resection with an obstructed lobar or mainstem bronchus.
 - An FEV_1 of 800 mL is commonly used as a cutoff value for a postpneumonectomy.
 - Forced vital capacity and functional residual capacity (FRC) can fall to $< 60\%$ of preoperative values on the first postoperative day; return to baseline can take up to 14 days.
 - Any decline in FRC contributes to physiologic shunting and hypoxemia.
- **Advanced age** is frequently cited as a surgical risk factor.
 - Elderly patients have a number of age-related changes in pulmonary function, including decreased elastic recoil and progressive stiffening of the chest wall, increase in the ratio of FRC to total lung capacity, and diminished vital capacity and FEV_1 .

- The activity of upper-airway reflexes is blunted, which may result in impaired clearance of secretions and the ability to protect the airway.
- **Obesity** results in decreases in FRC and expiratory reserve volume.
 - The expiratory reserve volume drops below closing volume, resulting in perfused, unventilated segments of lung and a widened alveolar-arterial (A-a) pO_2 gradient.
 - Patients are more likely to cough poorly, retain secretions, and develop basilar atelectasis.
- **Cigarette smoking** contributes to perioperative morbidity via its effects on the cardiovascular system, mucus secretion and clearance, and small-airway narrowing.
 - Cessation should occur at least 8 weeks prior to elective surgery.
 - Smoking cessation *just prior* to surgery may actually increase the risk of postoperative pulmonary complications, probably due to transient increases in sputum volume.
 - Expectations of postoperative respiratory failure allow increased awareness of unanticipated cardiovascular or respiratory deterioration.
- A very large patient population from the Veterans Affairs Medical Centers provided a database to learn what factors play a role in predicting postoperative respiratory failure.
 - These factors are all assigned a point status (Table 48.1); more points increase the probability of postoperative respiratory failure (Table 48.2).
 - Women were excluded from data collection in this study, but the factors noted do not have gender specificity.

OPERATING ROOM EVENTS THAT AFFECT INTENSIVE CARE UNIT CARE

- The pace of postoperative recovery depends on the amount and types of anesthetic agents given as premedication and during the operative procedure. Anesthetic delivery is constrained by patient factors.
 - The need for high inspired oxygen concentrations, particularly during one-lung anesthesia, limits the ability to use nitrous oxide and an early extubation goal limits the use of opioids.
 - Regional techniques (spinal, epidural) can supplement general anesthesia but are generally not applicable because of the difficulty in providing a high enough spinal level.
 - Controlled ventilation is necessary to sustain respiration during open thorax procedures.
 - An awake, comfortable, and extubated patient at the end of the procedure avoids stress on fresh suture lines from positive pressure ventilation and coughing or bucking.

TABLE 48.1**RESPIRATORY FAILURE RISK INDEX**

Preoperative predictor	Point value
Type of surgery	
Abdominal aortic aneurysm	27
Thoracic procedure	21
Neurosurgery, upper abdominal or peripheral vascular	14
Neck procedure	11
Emergency surgery	11
Albumin (<30 g/L)	9
Blood urea nitrogen (>30 mg/dL)	8
Partially or fully dependent functional status	7
History of chronic obstructive pulmonary disease	6
Age (y)	
≥70	6
60–69	4

Adapted from Arozullah AM, Daley J, Henderson WG, et al. Multifactorial risk index for predicting postoperative respiratory failure in men after major noncardiac surgery. *Ann Surg.* 2000;332:242–253.

- **Selective endobronchial intubation** isolates the right and left airways to permit operation on a quiet, collapsed lung. One-lung ventilation alters the ventilation/perfusion relationship, as blood to the unventilated lung causes a right-to-left shunt, thus reducing arterial saturation.
 - The nonoperative side is used for selective intubation in lobectomies and pneumonectomies.
 - In pediatric patients, very small adults, and laryngectomy patients, a bronchial blocker can be placed under fiberoptic guidance in place of selective intubation.
 - Collapse and hypoxic pulmonary vasoconstriction limit perfusion of the unventilated lung.
 - The double-lumen endotracheal tube (DLETT) is large and has the potential to cause airway trauma and edema. It may shift its position and suctioning through it is difficult; it is usually replaced by a single-lumen tube when continued mechanical ventilation is required post-operatively.
 - Selective intubation may be continued to protect against soilage (pus or blood) and provide alternate positive end-

expiratory pressure (PEEP) to a lung of different compliance in emphysematous patients undergoing single-lung transplantation.

- A flexible tube changer and a pediatric fiberoptic bronchoscope are essential tools that should be available in the ICU for placement and adjustment of double-lumen tubes.

IMMEDIATE POSTOPERATIVE ISSUES

- Usual postoperative monitoring includes intermittent blood pressure determinations, continuous electrocardiography, and pulse oximetry. In selected patients, assessing intravascular volume status and cardiopulmonary function may be facilitated with central venous pressure or pulmonary artery catheters. A checklist of immediate considerations in the postoperative thoracic patient is helpful (Table 48.3).
- **Chest tubes** are inserted to drain the surgical site, except in pneumonectomy patients where the standard practice is to avoid a chest tube. The patient will arrive with at least one chest tube; daily chest radiographs are usually obtained while chest tubes are in place.
 - Air leak from the thorax is demonstrated by bubbles in the water seal bottle.
 - Tube(s) should drain blood and some clots; large quantities suggest continued bleeding.
 - Should never be clamped owing to risk of unrecognized bleeding or tension pneumothorax.
 - Except for those in pneumonectomy spaces, are set to –20 cm H₂O of suction.
 - A chest radiograph will confirm endotracheal, nasogastric, and chest tube placement and identify any pneumothorax, mediastinal shift, or significant atelectasis.
 - Routine chest radiographs are not necessary after an uncomplicated removal of chest tubes.
- Hourly output from chest tubes should be recorded and the operative team notified if drainage is >100 mL/hour for more than 4 hours, or if >200 mL in any 1-hour observation period.
 - Expected drainage from major procedures in the first 24 hours is roughly 300 to 600 mL, tapering to <200 mL by the second day.
 - The level of fluid in the water seal chamber should fluctuate with each respiration (assuming no air leak) and serves as confirmation of chest tube patency.

TABLE 48.2**RESPIRATORY FAILURE RISK INDEX SCORES AND OUTCOMES**

Class	Point total	N (%)	Predicted probability of PRF (%)	Observed phase I (% RF)	PRF phase II (% RF)
1	≤10	39,567 (48%)	0.5	0.5	0.5
2	11–19	18,809 (23%)	2.2	2.1	1.8
3	20–27	13,865 (17%)	5.0	5.3	4.2
4	28–40	7,976 (10%)	11.6	11.9	10.1
5	>40	1,502 (2%)	30.5	30.9	26.6

PRF, postoperative respiratory failure; RF, respiratory failure.

Phase I indicates patients enrolled between October 1, 1991, and December 31, 1993, and phase II indicates patients enrolled between January 1, 1994, and August 31, 1995.

TABLE 48.3

IMMEDIATE ICU CONSIDERATIONS IN THE THORACIC SURGICAL PATIENT

Preparation

- Supplemental oxygen or mechanical ventilator ready.
- Bedside monitoring: ECG, pulse oximetry; possible arterial, central, or PA line.
- Infusion pumps if inotropes, vasopressors, or vasodilators in use.
- Wall suction to connect to pleural drainage system.

On arrival in ICU

- Connect patient to bedside monitors and ventilator (if needed).
- Check and secure all connections to chest tubes and assess function.
- Auscultate breath sounds and observe chest excursion; suction if necessary.
- Assess adequacy of circulation (BP, HR, pulse oximetry).
- Assess adequacy of oxygenation and ventilation (via ABG or noninvasive devices).
- Consider need for lung-protective ventilation if trauma/sepsis/operative issues.
- Fluid management: confirm need for continued maintenance fluid; generally keep “dry.”
- Monitor inputs and outputs; label all chest tubes and chart outputs.
- Control pain with intravenous analgesics and/or regional anesthetics/analgesics.
- Order any necessary laboratory studies and chest radiograph.

Information to be obtained from operating room team

- Patient name, age, gender, and brief history.
- Operation performed and any major problems encountered.
- Circulatory and ventilatory requirements as determined in OR.
- Current drug infusions and titration plans; timing and dose antibiotics.
- Anesthetic agents given and plans for awakening/extubation (if relevant).
- Fluids and blood products given; urine output during case.
- Estimated blood loss, assessment of hemostasis at closing, and blood products available including surgical salvage if any.
- Laboratory results (e.g., ABGs, Hct) obtained during operating room.

ICU, intensive care unit; ECG, electrocardiogram; PA, pulmonary artery; BP, blood pressure; HR, heart rate; ABG, arterial blood gas; OR, operating room; Hct, hematocrit.

- Most pulmonary resections have mild to moderate air leaks, which are problems only if the lung does not completely expand or a significant amount of tidal volume is lost.
- Additional pleural drainage or changes in mechanical ventilation may be required to minimize the air leak and optimize ventilation. Ventilation techniques such as smaller volumes at higher rates, pressure-controlled inverse ratio ventilation, or high-frequency oscillation may sometimes minimize leaks.
- Once all air leaks resolve and drainage is <100 mL/24 hours, chest tubes may be removed during the expiratory phase of ventilation or while the patient performs a Valsalva maneuver.

TABLE 48.4

INDICATIONS FOR CONTINUED POSTOPERATIVE VENTILATION

Airway compromise due to edema or bleeding
 Inadequate pulmonary reserve after surgery
 Compromised myocardial function, especially with perioperative infarction
 Expected large fluid shifts with thoracoabdominal procedures
 Severe neurologic impairment
 Continued bleeding with likelihood of return to operating room
 Esophageal surgery patients (risk for reflux and aspiration—delay extubation until airway reflexes have fully recovered as for full stomach intubation)

- PEEP is sometimes used in an effort to decrease postoperative drain output, especially from mediastinal drains in cardiac patients.

Extubation and Airway Concerns

- Extubation can often be accomplished in the operating room, but continued ventilation may be necessary in the presence of concurrent cardiac illness, inability to protect the airway, malnutrition, or coexisting lung disease.
- Endotracheal intubation for 24 hours postoperatively decreases pneumonia from silent aspiration and decreases the operative mortality rate in high-risk patients.
- Measurement of maximal inspiratory pressure (often called negative inspiratory force, is helpful in determining respiratory muscle strength, particularly after thymectomy for myasthenia gravis and after long-acting neuromuscular blocking agents intraoperatively.
- Ideally, the patient should be awake and following instructions and have an adequate gag reflex (signifying airway protection) and cough (for secretion clearance).
- Measured extubation parameters include a respiratory rate to tidal volume (f/Vt) ratio of <100, a maximal inspiratory pressure >25 cm H₂O, and oxygen saturation >92% on FiO₂ <50% at PEEP <5 cm H₂O. Although many patients will not meet these criteria, it is usually best to attempt weaning and extubation rather than risk the complications of continued mechanical ventilation.
- Indications for continued ventilator support are presented in Table 48.4.
- **High-frequency jet ventilation** has a role in the operating room during “shared airway” procedures (i.e., laryngoscopy, bronchoscopy, microlaryngeal procedures, and airway surgery). In the intensive care unit, particularly for hypoxemic respiratory failure, its role is poorly defined except for the case of a bronchopleural fistula. High-frequency jet ventilation allows ventilation at lower airway pressures, minimizing air passing through the fistula and promoting healing. With decreased pulmonary compliance, the benefit of lowering airway pressure may be lost.

Postoperative Fluid Management

- Thoracic surgery patients present unique issues in fluid management due to the potential for pulmonary edema that

affects 4% to 27% of patients. Procedures involving the mediastinum experience even more profound fluid shifts. Operative, insensible (600–1,200 mL/day in a 70-kg adult), and interstitial and intracavitary (6 to 8 mL/kg/h) losses provide valuable information when anticipating needs.

- Intraoperative handling of the lung, fresh frozen plasma, prolonged one-lung ventilation, collapse and re-expansion of the lung, and increases in postresection pulmonary artery pressures prime the lung for a more profound inflammatory response and potential fluid accumulation.
- Traditional markers include urine output (usually >0.5 mL/kg/hour), mental status, blood pressure, heart rate, blood lactate level, capillary refill time, venous oxygen saturation, filling pressures, and cardiac performance. If a state of poor perfusion persists, invasive devices allowing for precise hemodynamic monitoring and oxygen consumption need consideration to establish goals of therapy.
- Resection patients, especially right-sided pneumonectomy with high ventilatory pressures during surgery, are at increased risk for postpneumonectomy pulmonary edema and crystalloid infusion is ideally limited to 20 mL/kg for the first 24 hours.

Pain Management

- The pain after thoracotomy is one of the most intense of any surgical procedure. Adequate pain control is important not only to ensure patient comfort but also to avoid potential complications and reduce the risk of long-term postthoracotomy pain.
- Without satisfactory pain relief, the patient is unable to breathe deeply, which decreases vital capacity and functional residual capacity. Splinting also occurs, making it more difficult to clear secretions and increases the likelihood of developing respiratory failure.
- Pain elevates catecholamine levels and increases myocardial oxygen consumption.
- **Pain management options**
 - The mainstay of postoperative pain control is systemic analgesics in the form of **opioids**; intravenous route provides the most predictable responses but side effects like respiratory depression, nausea/vomiting, and ileus are an issue.
 - **Nonopiate medications** such as nonsteroidal anti-inflammatory drugs—including the parenteral prostaglandin inhibitor, ketorolac—are reasonable adjuncts. Nonsteroidal anti-inflammatory drugs may exacerbate renal dysfunction and pose a risk with postoperative healing.
 - **Neuraxial opioids and local anesthetics** via the epidural or intrathecal route provide excellent regional pain control. Epidural catheters are the preferred route when local anesthetics, either with or without opioids, are infused in this manner. Pulmonary complications decrease relative to that with systemic opioids, and initiation prior to the operation allows for better postoperative pain management. Hypotension due to sympathetic blockade is a potential side effect when local anesthetics such as bupivacaine are administered, and it may be necessary to decrease the dose or eliminate the local anesthetic from the infusion completely.
 - **Intercostal and paravertebral nerve blocks** may be performed intraoperatively or postoperatively, lasting up to 12 hours; repetitive dosing may be needed and can be accomplished with cryoablation of the intercostal nerves during the surgery. Intercostal nerve blocks are relatively contraindicated in postpneumonectomy patients due to the risks of entering and contaminating the empty chest cavity; splinting on the pneumonectomy side may actually reduce atelectasis in the remaining lung.
- **Intrapleural catheters** inserted in the posterior pleural cavity can deliver local anesthetic such as bupivacaine or lidocaine via intermittent bolus or continuous infusion. Not a viable option in the setting of pleural effusion or pleural fibrosis. Complications include technical difficulties during placement, pneumothorax, toxicity to the anesthetic, and tachyphylaxis to the local anesthetic with time.
- Transcutaneous electrical nerve stimulation, heat and cold application, music therapy, and relaxation are additional techniques.
- Prolonged mechanical ventilation may benefit from dexmedetomidine.

Specific Patient Populations

- **Thoracic trauma:** Patients are typically evaluated and treated for acute, life-threatening injuries prior to their arrival in the ICU. Typical blunt injuries to the chest include rib fractures, flail chest, hemothorax, pneumothorax, tension pneumothorax, pulmonary contusion, cardiac contusion, and aortic disruption. Penetrating trauma such as gunshots and stabbings are less predictable in terms of the injuries generated and therefore require a case-by-case assessment in terms of management issues. Uncontrolled hemoptysis or cavitory lesions after penetrating injury require emergent surgical intervention. Mortality increases in thoracic trauma with increasing age, lower Glasgow coma scale scores, liver injury, splenic injury, more than five rib fractures, and long-bone fractures. Mortality rates typically are between 9% and 20% in the United States; with out-of-hospital traumatic arrest, <10% survive to hospital discharge. Maintaining a high degree of vigilance is paramount for diagnosing potential missed injuries.
- **Rib fractures**
 - The most common type of chest trauma, by themselves are rarely life-threatening but may serve as indicators for more severe intrathoracic or intra-abdominal injuries.
 - Pain may be significant and impairs usual respiratory mechanics, leading to splinting, hypoventilation, atelectasis, and potentially pneumonia as pulmonary toilet is compromised.
 - First and/or second rib fractures indicate a large transfer of energy to the thoracic cage and should raise further suspicion for other intrathoracic problems such as aortic rupture or tear.
 - The implications of age begin at 45 years; those with four or more rib fractures have more in-hospital complications such as increased ventilator and ICU days.
 - For the elderly, defined as 65 years of age and older, mortality increases by 19% with each rib fracture and the risk of pneumonia by 27%.
 - Epidural analgesia is associated with a decreased incidence of nosocomial pneumonia and shorter duration of mechanical ventilation in patients with three or more rib fractures.

- **Flail chest** occurs when two or more adjacent ribs are fractured at two or more sites leading to a paradoxical movement during inspiration, manifested as an inward collapse. Pain control is important to avoid splinting and to facilitate pulmonary toilet. Positive pressure ventilation, whether invasive or noninvasive, may be required to stent open the affected lung region and thereby avoid atelectasis.
- **Hemothorax** is a collection of blood in the pleural cavity. Large collections, >200 mL, of blood are needed to be seen on chest radiograph. The mainstays of therapy are ensuring adequate circulating blood volume and tube thoracostomy to drain blood from the pleural space. Inadequate hemothorax drainage may progress to empyema or fibrothorax.
- Thoracotomy is required if bleeding continues at a significant rate, defined as initial 1,500 mL out or 250 mL/hour for 4 hours or if the patient's vital signs suddenly decompensate.
- Retained hemothorax can be addressed with further large-diameter tube thoracostomy, open thoracotomy, or video-assisted thoracoscopy. Less invasive than thoracotomy and just as effective, video-assisted thoracoscopy is the intervention of choice unless there are extensive adhesions. Early surgical drainage decreases the duration of tube drainage, hospital stay and cost.
- Fibrinolytic therapy offers a possible alternative, especially if the time from injury to therapy is delayed, with a response rate of up to 92% in terms of resolution.
- **Pneumothorax** is the accumulation of air, originating from the lung, between the visceral and parietal pleura and is the most common complication of trauma.
- Treatment with tube thoracostomy is indicated when the size is >20% on chest x-ray, the patient is on positive pressure ventilation, or there are signs and symptoms of hypoxia and dyspnea.
- If after tube placement the lung does not completely re-expand and there is a persistent air leak, it is important to search for a more severe tracheal or bronchial injury, as this situation would require surgical intervention.
- **Tension pneumothorax**, a life-threatening condition requiring immediate therapy, occurs when air accumulates under pressure, causing impaired venous return and cardiac output. Ipsilateral absence of breath sounds and tracheal and mediastinal deviation away from that side are the hallmarks, especially in the presence of severe hypotension. Initial therapy includes needle decompression, followed by tube thoracostomy.
- **Pulmonary contusion** is a result of blunt force transmitted across the thorax. The mechanism is related to compression and re-expansion of the lung tissue, leading to capillary disruption with interstitial and intra-alveolar edema, decreased compliance, and hypoxemia due to a shunt physiology. Care is largely supportive in this population, with close attention to pain management and pulmonary toilet.
- **Cardiac contusion** is a potential complication of blunt chest trauma; its exact incidence is unclear, as different studies used varying criteria to make the diagnosis. It is typically well tolerated in mildly injured patients but may lead to fatal arrhythmias or cardiogenic shock if severe.
- Motor vehicle accidents are the most common cause; with rapid deceleration, the heart moves freely and can strike the internal sternum with a substantial amount of force.

TABLE 48.5**ELECTROCARDIOGRAPHIC FINDINGS IN CARDIAC CONTUSION**

Nonspecific abnormalities
Pericarditis-like ST-segment elevation or PTa depression
Prolonged QT interval
Myocardial injury
New Q wave
ST-T segment elevation or depression
Conduction disorders
Right bundle branch block

Adapted from Sybrandy KC, Cramer MJM, Burgersdijk C. Diagnosing cardiac contusion: old wisdom and new insights. *Heart*. 2003;89:485–489.

- Biomarkers Troponin I and T are specific to the myocardium and may avoid false-positives by relying solely on creatine kinase as patients often have diffuse muscular damage.
- Treatment involves cardiac monitoring and stabilization of the traumatically induced injuries, supporting blood pressure and cardiac output as indicated. Electrocardiographic findings in cardiac contusion are presented in Table 48.5. Echocardiographic findings in this same setting are presented in Table 48.6. A therapeutic algorithm for blunt chest trauma is presented in Figure 48.1.
- **Aortic disruption:** Only 13% to 15% of these patients reach the hospital alive; those who do have a 30% chance of subsequent rupture and death. Diagnostic modalities include chest radiograph, aortography (the gold standard), computed tomography scan, and transesophageal echocardiography. Treatment is immediate repair of the injury.

- **Lung volume reduction surgery** is used to improve the pulmonary dynamics of patients with severe emphysema by palliating dyspnea and improving functional status. This population is prone to more postsurgical complications than most other thoracic surgery patients due to their underlying fragile nature. Anticipated complications include arrhythmias, prolonged respiratory failure, air leaks, pneumonia, and ICU readmission.
- **Esophageal surgery** patients undergo procedures that traumatize the lung, the interposed stomach, and the diaphragm. Patients who undergo esophageal resection for carcinoma tend to be malnourished. Increasing patient age and decreasing performance on spirometry predict increased risk of pulmonary complications including atelectasis, pneumonia, aspiration, and retained secretions.
 - Aspiration risk is minimized by having patients undergo a thorough swallowing evaluation, including radiographic testing, prior to initiating oral intake.
 - The most dangerous complication, occurring in as many as 11% of patients, is leakage from the surgical site. Risk factors include high estimated intraoperative blood loss, cervical location of the anastomosis, and the development of postoperative adult respiratory distress syndrome. Use of thoracic epidural analgesia is associated with a decreased occurrence rate. Mortality is historically high, but improved with modern surgical techniques. Early identification is important, and endoscopy provides a safe method for determining the integrity of the graft and whether surgery is necessary to avoid loss of the graft.

Respiratory Therapy

- Thoracic patients often have significant underlying chronic obstructive pulmonary disease, impaired mucociliary clearance, excessive secretions, and/or increased closing volumes, all of which predispose to atelectasis.
- The respiratory therapist plays an important role in providing secretion management and chest physiotherapy (percussion and vibration) and should begin as soon as the patient has recovered sufficiently from anesthesia to cooperate.
- Other modalities include adequate hydration, aerosolized bronchodilators, humidified oxygen, and early treatment of tracheobronchial tree infection. Mucolytic agents (such as N-acetylcysteine) help with thick secretions but may cause bronchospasm.
- Oral or nasotracheal suctioning is used in selected extubated patients, but discomfort and the possibility of complications (hypoxemia, vagal-mediated bradycardia, or cardiac arrest) limit routine use. Inadequate clearance of secretions often requires flexible bronchoscopy, which is of greatest benefit in the extubated patient who cannot adequately be suctioned.
- A mini-tracheostomy (bedside percutaneous cricothyroidotomy for suctioning) can provide access to the lower airway in patients with thick secretions.
- If pulmonary parenchymal involvement is confined to one lung, altering body position and use of specialized beds can improve gas exchange by changing the relationships between ventilation and perfusion.

TABLE 48.7

POSTOPERATIVE COMPLICATIONS AFTER ANY THORACIC PROCEDURE

Airway edema/stridor
 Arrhythmias (especially atrial fibrillation, multifocal atrial tachycardia)
 Arytenoid dislocation
 Aspiration of gastric contents
 Atelectasis
 Bronchospasm
 Bronchopleural fistula
 Chylothorax
 Congestive heart failure
 Deep venous thrombosis
 Empyema
 Hemorrhage
 Hemothorax
 Infection (superficial, deep)
 Lobar collapse
 Lobar torsion
 Myocardial infarction
 Pain and splinting
 Pleural effusion
 Pneumothorax
 Pulmonary embolus
 Re-expansion pulmonary edema
 Respiratory failure
 Retaining secretions
 Subcutaneous emphysema
 Tension pneumothorax

Complications

- **Laryngeal and glottic edema** frequently occur after airway manipulation or intubation with a double-lumen endotracheal tube (Table 48.7). A critical airway may be converted to an adequate airway by the administration of Heliox, a helium and oxygen mixture. Upright or sitting position, racemic epinephrine and corticosteroids are traditional treatments used. Serious laryngeal edema can be detected by an absent cuff leak. If there are any doubts, the endotracheal tube should be removed only under direct laryngoscopic or fiberoptic observation, with a percutaneous tracheostomy set immediately at hand.
- The **recurrent laryngeal nerves** branch from the vagus nerves as they enter the chest. Injury can result from excessive traction, aggressive dissection, or the operative sacrifice of these nerves. Mediastinoscopy, anterior mediastinotomy, left pulmonary resection with subaortic exenteration, and resections of mediastinal tumors are common operations in which the recurrent laryngeal nerve may be damaged.
 - Early airway and laryngeal edema may allow adequate coaptation of the vocal cords, preventing identification of injury until after ICU discharge, when ineffective cough or aspiration of secretions becomes apparent.
 - If there is permanent damage, injection with Teflon may be considered.
- Aggressive chest physiotherapy, careful airway management, and temporary avoidance of oral feeding may eliminate the need for intervention until nerve function has recovered.
- Intermittent noisy inspiration and painful swallowing suggest **arytenoid dislocation**, an uncommon cause of postextubation respiratory failure. Treatment consists of surgical reduction, before the cricoarytenoid joint becomes fibrosed in poor position.
- Postoperative **air leaks** most often result from distal fistulae between tiny bronchioles or respiratory units and the pleural cavity. Repositioning or insertion of chest tubes into undrained spaces ensure complete expansion of the lung help them close.
 - A substantial persistent air leak or incomplete expansion of the lung suggests a significant bronchopleural fistula. Major proximal airway problems such as failure of the anastomosis, disruption of a bronchial closure, or retained secretions or foreign bodies can be identified by bronchoscopy.
 - Any fistula within the first 7 postoperative days is likely to be due to a technical problem.
 - Fistulae at 1 to 6 weeks are more often due to an empyema or local peribronchial abscess.
 - Late fistulae, >6 months after the operation, are frequently due to recurrent carcinoma.
- **Early postoperative bronchopleural fistula in a pneumonectomy patient** is a surgical emergency. A chest radiograph will show loss of fluid from the pneumonectomy space. Typical presentation is sudden expectoration of copious amounts of pink, frothy sputum, which may be misdiagnosed as pulmonary edema.
 - The patient should be positioned with the operated or pneumonectomy side down to trap remaining fluid in the pneumonectomy space and prevent drowning.
 - Management will likely include bronchoscopy and immediate reoperation.
- **Empyema** is initially treated with closed tube drainage and antibiotic therapy.
 - Any bronchopleural fistula is identified and treated.
 - A chest radiograph helps to determine whether the mediastinum is fixed or whether it has shifted and compressed the contralateral remaining lung. If the mediastinum is stable, open drainage in the form of rib resection and marsupialization of the pneumonectomy cavity (Clagett window or Eloesser flap) may be performed.
 - With time, the cavity shrinks in size, and the window or flap may be closed.
- **Postoperative hypoxemia** is common and may be due to sepsis, adult respiratory distress syndrome, pneumonia, or pulmonary embolization.
 - If pulmonary embolization is suspected, ventilation/perfusion scanning, spiral computed tomography, or pulmonary angiography should be done and treatment initiated. If anticoagulation or lytic therapy is contraindicated, an inferior vena caval filter should be placed.
 - Systemic tumor emboli, though uncommon, may be seen after pulmonary resections for primary bronchogenic carcinomas or metastatic sarcomas.
- **Massive postoperative hemorrhage** from the pulmonary vein or artery and requiring emergent reoperation can present

TABLE 48.8

COMPLICATIONS OF SPECIFIC THORACIC PROCEDURES

Procedure	Complications
Anterior mediastinotomy (Chamberlain)	Damage to recurrent laryngeal nerve (particularly left)
Bronchoscopy/mediastinoscopy	Bleeding from major vessels if torn, air leak with biopsy of bronchus
Bronchopleural fistula repair	Persistent leak, dehiscence
Bronchopulmonary lavage	Respiratory distress/contralateral spillage
Bullectomy	Tension pneumothorax, air leak
Chest wall reconstruction	Blood loss, altered chest wall compliance, unstable chest, infection of prosthetic material
Clagett window	Air leak
Collis-Belsey	Gastric leak, splenic injury
Decortication	Blood loss, air leak(s)
Esophageal dilatation	Esophageal perforation, pleural effusion, airway obstruction
Esophagoscopy	Esophageal perforation
Esophagogastrectomy	Third-spacing of fluids, anastomotic leak, gastric devascularization, splenic injury, gastric torsion
Heller myotomy	Esophageal tear
Lobectomy	Bronchial leak, lobar collapse, lobar torsion
Mediastinal tumor excision	Airway obstruction with sedation/anesthesia, damage to recurrent laryngeal nerve
Nissen fundoplication	Esophageal obstruction (with tight wrap), splenic injury
Pectus repair	Costochondritis, unstable sternum
Pleuroscopy	Pharyngeal laceration, air leak
Pneumonectomy	Atrial arrhythmias (atrial fibrillation, MAT), mediastinal shift, cardiac torsion, air embolism, disrupted bronchus
Thoracic aortic aneurysm	Paraplegia, bleeding, aortobronchial fistula, esophageal injury
Thymectomy	In myasthenics, possible weakness and respiratory failure
Lung transplant	Rejection (day 5), reperfusion injury, infection, overdistention of native lung, dehiscence
Tracheal resection	Fixed neck flexion postoperatively, dehiscence, air leak

MAT, multifocal atrial tachycardia.

as significant shock. Slower hemorrhage results from small bleeding vessels in the mediastinum or chest wall.

PULMONARY PARENCHYMAL COMPLICATIONS

- **Tracheoesophageal fistula:** A communication occurs between the anterior esophageal wall and membranous (posterior) wall of the trachea after prolonged intubation due to pressure exerted from the cuff of the endotracheal or tracheostomy tube leading to tissue necrosis.
 - Tracheoesophageal fistula should be suspected when feedings are aspirated from the airway.
 - Surgical revision is definitive therapy but may not be practical in patients still requiring positive pressure ventilation.
 - Stenting of the esophagus allows for temporary sealing of the fistula until the patient is a suitable candidate for final surgical repair.
- **Tracheoinnominate fistula:** A rare life-threatening complication with massive bleeding, it is seen 48 hours or more after tracheostomy requires urgent action.
 - Initial steps include hyperinflation of the tracheostomy cuff or direct arterial compression with a finger to tamponade the bleeding.
 - Bronchoscopy is the diagnostic procedure of choice, followed by surgery to divide the innominate artery, with subsequent separation of the trachea from the divided artery by viable tissue.
- **Atelectasis** is the most common complication after thoracic surgery.
 - Potential contributors include hypoventilation, splinting, bronchospasm, poor cough, retained secretions, pneumothorax, and trauma to the lung during the surgical procedure.
 - Symptoms include fever, tachypnea, arrhythmias, hypoxia, or respiratory failure.
 - Efforts to avoid atelectasis include frequent suctioning of the tracheobronchial tree, chest percussion and postural drainage, humidification of inspired gases, frequent patient rotation, bronchodilators, pain control, coughing, deep breathing, bronchoscopy for removal of mucus plugs or secretions, invasive or noninvasive positive pressure ventilation, and early ambulation.
 - Chest physiotherapy uses clapping and vibration to stimulate coughing and move secretions, potentially decreasing hospital costs due to shorter lengths of stay; incentive spirometry does not provide the same benefit.
- **Lobar collapse and torsion**
 - Lobar collapse most commonly occurs in either the right upper lobe after double-lumen endotracheal intubation or in the right middle lobe after right upper lobectomy.

- Lobar torsion occurs as the result of a lung segment twisting about its hilar structures with infarction occurring if the process is not recognized and treated. The right middle lobe and lingula are at greatest risk after thoracotomy.

PLEURAL COMPLICATIONS

- Pneumothorax occurs as described earlier.
- **Pleural effusions** should be evaluated via thoracentesis if persistent. If the fluid is transudative, the underlying cause needs to be addressed. Exudative fluid induces a high suspicion for empyema. If pleural effusions and pneumothoraces do not

resolve, more definitive therapy such as pleurodesis needs to be entertained.

- **Thoracic duct injury** is a known complication after dissection in the posterior mediastinum and may result in chylothorax, high in triglycerides and chylomicrons. The leakage site is localized with lymphangiography or computed tomography scanning, and the clinical situation will dictate the type of management. Management initially includes chest tube drainage and parenteral nutrition to decrease thoracic duct output, with surgery reserved for failure of conservative management.
- Complications of specific thoracic procedures are presented in Table 48.8.

CHAPTER 49 ■ POSTOPERATIVE MANAGEMENT OF THE ADULT CARDIOVASCULAR PATIENT

CARDIOPULMONARY BYPASS (CPB)

- Development of the heart–lung machine over the last 50 years has made complex repairs of intracardiac structures and the great vessels feasible. The most basic components are a venous cannula, a venous reservoir, a pump, an oxygenator, a heat exchanger, a filter, and an arterial cannula (Fig. 49.1). A cardioplegia delivery system, ultrafiltration unit, cardiectomy suction system, left ventricular vent, and cell saver system are some of the other components.
- Interaction between the patient's blood and the large plastic surface area of the CPB circuit triggers the inflammatory cascade; this activates plasma enzyme systems and blood cells, dilutes plasma proteins, causes coagulopathy, produces emboli, and leads to release of an array of vasoactive mediators that affect vascular motor tone and endothelial permeability (Table 49.1).
- The post-CPB inflammation is typically self-limited; vasomotor mediators reach peak levels within 24 hours of surgery and subside over ensuing days.

Immediate Concerns

- Almost all patients are in a state of controlled shock because of fluid shifts and changes in vascular tone. A checklist is useful to ensure that essential tasks are accomplished within the first 30 minutes of a patient's arrival in the ICU (Table 49.2).
- The first step should be a quick assessment of the ABCs (airway, breathing, circulation), electrocardiogram, and pressure measurement catheters to verify that they are connected and calibrated.

- Sign-out of patient information from the perioperative team to the ICU team ensures the safe transition of care. Important details may include ease of intubation, perioperative ventricular function, inotropic and vasopressor requirement, optimal

volume status, completeness of revascularization, and suspected coagulopathy.

- Mechanical ventilation is continued and significant arterial-alveolar (A-a) gradients are common; hence high concentrations of oxygen (70%–80%) are routine until adequate oxygenation is confirmed. Tidal volume in the absence of acute lung injury is set at 8 mL/kg of predicted body weight.
- Although affected by severe atherosclerosis, skin temperature, pulse amplitude, and capillary refill time provide essential information about the adequacy of cardiac output. Palpable peripheral pulses are an excellent indicator of systemic perfusion. Mental status and central nervous system assessment is also part of the initial exam.
- A portable chest radiograph is obtained to determine the proper placement of the endotracheal tube, monitoring catheters, and nasogastric tube. Look closely for evidence of a pneumothorax, hemothorax, and areas of lung collapse or atelectasis.

Initial Therapy

- The first hour is a critical and unstable time. The goals are to maintain adequate systemic perfusion, adequate oxygenation and ventilation, and control cardiac rate and rhythm.
- Hypothermia, especially below 35.5°C, reduces the threshold for ventricular tachycardia or fibrillation; serum potassium

levels should be maintained in the 4.5- to 5.0-mmol/L range to prevent ventricular irritability. Avoid correcting acidosis with rapid IV sodium bicarbonate that can acutely lower serum potassium.

- Monitor closely for inappropriate diuresis, which occurs commonly after CPB and may require rapid replacement of crystalloid and electrolyte losses. Mediastinal drain output is also closely observed. If rapid hemorrhage is suspected, transfusion therapy is initiated and the operating team should be made aware of any massive hemorrhage.

The First 8 Hours after Cardiopulmonary Bypass

- The *golden period* frequently follows when the patient's hemodynamics are adequate and the patient is relatively stable. Cardiorespiratory performance should be optimized so that the decreasing cardiac function that characterizes the following 16 hours does not jeopardize end organ perfusion. Inotropes should be cautiously weaned despite adequate hemodynamics in anticipation of this deterioration.
- Nonemergent cardiovascular surgery patients can usually be extubated safely during this period. The major criteria for extubation are adequate central nervous system function, stable hemodynamics without malignant arrhythmias, normothermia, low A-a gradient, adequate pulmonary mechanics, and

no ongoing mediastinal hemorrhage. Early extubation is not suitable for patients with deep hypothermic circulatory arrest, long CPB periods, poor ventricular function, unstable hemodynamics, or a large anticipated transfusion requirement.

The Next 16 Hours after Cardiopulmonary Bypass

- Changes in heart compliance
 - Clinically, the heart seems to become noncompliant or “stiff” leading to reduced cardiac output at any given filling pressure. One usually observes a rise in pulmonary artery pressure and pulmonary artery occlusion pressure (PAOP), and a reduction in the systemic arterial pressure, cardiac output, and mixed venous oxygen saturation.
 - Patients with a low cardiac output syndrome before the onset of changes in compliance often develop hemodynamic instability.
- Time course
 - The usual time course is a steady deterioration in cardiac performance between the 8th to 12th hours following CPB. The condition stabilizes and generally persists over the next 12 to 24 hours, followed by a gradual improvement over the next 48 hours.
 - Once unstable, far more interventions are required to return to a steady state than if problems are anticipated and

stability maintained. Even if cardiac output remains low during this time, it is better tolerated than marked swings in hemodynamics.

- Optimizing the determinants of cardiac output
 - Heart rate and rhythm. The ventricles are stiff and non-compliant, so slower heart rates do not necessarily lead to increased filling and improved stroke volume. Optimal heart rates of 90 to 110 beats/minute are typically necessary. Atrial fibrillation may be poorly tolerated as the noncompliant ventricles depend on atrial contraction for filling; sinus rhythm should be restored.
 - Volume loading to a PAOP beyond 12 to 14 mm Hg is unlikely to lead to significant increases in stroke volume due to noncompliance (unless the patient has an underlying stiff myocardium). Once in this range, attention should be turned to other determinants of cardiac output to improve cardiac performance.
 - Afterload reduction improves cardiac performance without increasing myocardial oxygen consumption (MVO₂), but institute cautiously to avoid hypotension. Renal function in older patients may be particularly sensitive to decreases in perfusion pressure. Patients with recent right ventricular infarcts and right ventricular stunning are also sensitive to hypotension.
- Patients with a relatively normal cardiac output before surgery often poorly tolerate a cardiac index <2.0 L/minute/m², venous PO₂ <30 mm Hg, or SVO₂ <50%. Although costly in terms of MVO₂, enhancement of cardiac contractility is an effective method to augment cardiac output until reversible cardiac dysfunction related to CPB and reperfusion effects have resolved. Moderate doses of inotropes are generally well tolerated by completely revascularized patients and those with valvular disease, but can cause myocardial ischemia in incompletely revascularized patients. Myocardial ischemia
 - Increases in heart rate, filling pressures, and contractility to support patients during this period may cause myocardial ischemia from increased MVO₂.
 - An electrocardiogram should be obtained immediately after surgery and as clinically indicated thereafter. Continuous telemetry should be monitored closely for ischemic changes in the ST segment.
 - Cardiac enzymes are usually not helpful in this early period because they typically rise in all cardiovascular surgery patients. Although, an unusually high enzyme level or a sudden change in the usual pattern of enzyme leak may be useful.
 - If acute graft closure is suspected after a coronary artery bypass, echocardiography should show a new segmental wall motion abnormality. Comparison with intraoperative transesophageal studies is particularly useful. If bypass graft failure of a large myocardial territory is suspected, coronary angiography with either percutaneous or open surgical re-intervention may be indicated.

The Second 24 Hours after Cardiopulmonary Bypass

- Cardiovascular function typically improves; small increases in the mixed venous oxygen saturation (SVO₂) and cardiac output, together with a noticeable decrease in fluid requirements, herald this recovery phase. Invasive monitoring with

arterial and pulmonary artery catheters should be maintained until patients demonstrate recovery.

- Patients with normal preoperative systolic ventricular function usually tolerate weaning of inotropes, the amount of active intervention is largely determined by the function of other organ systems such as the lungs and kidneys. Patients with preoperative decompensated left ventricular function should have slow wean inotropes, active diuresis, and substitution of oral afterload-reducing drugs, particularly angiotensin-converting enzyme (ACE) inhibitors.
- If not extubated in the early postoperative period, the patient should be continuously re-evaluated for extubation to limit their risk for ventilator-associated complications.
- For patients who have undergone routine elective procedures, transfer to a step-down telemetry ward may be considered. Important criteria include adequate central nervous system (CNS) function, no or trivial requirement for inotropes, no dependence on temporary pacemaker leads, and good pulmonary toilet.

The Third 24 Hours after Cardiopulmonary Bypass

- Patient care is focused on the transition from ICU to ward care. Compliance in the left ventricle should improve rapidly accompanied by a decrease in interstitial pulmonary water. Improved cardiac performance at lower filling pressure can be anticipated. Mobilization of third-spaced fluid occurs, and active diuresis should be instituted as is physical rehabilitation with emphasis on pulmonary toilet and early ambulation.
- Oral medications oriented more toward long-term cardiovascular risk reduction, such as β -blockers, aspirin, and statins, are started. ACE inhibitors are favored in patients with valvular heart disease, particularly those with adverse left ventricular remodeling preoperatively. IV insulin is transitioned to long-acting subcutaneous regimens.

Catheters and Tubes

- Mediastinal drains, pacing wires, arterial lines, Foley catheters, and pulmonary artery catheters often can be removed. If continuous invasive cardiac monitoring is still necessary, a central venous pressure (CVP) catheter will measure right ventricular filling pressure. The association of CVP and PAOP will be known by this point (although this may change), and left heart filling pressures can be estimated. Venous saturation from the superior caval–atrial junction correlate closely with the SVO_2 in the absence of a left-to-right shunt.

Arrhythmias

- Despite rapid improvements in this period, atrial arrhythmias including flutter and fibrillation are prominent. The atrial contribution to cardiac output remains high and a rapid heart rate may not be well tolerated.
- Patients undergoing elective cardiovascular procedures are frequently on β -blockers preoperatively. Amiodarone and atorvastatin have also shown promise for prophylaxis against atrial fibrillation. Postoperatively, all patients are begun on low-dose metoprolol as soon as inotropes are discontinued and up-titrated as the blood pressure and heart rate permit. For patients with depressed left ventricular function who

require prolonged inotropic support, amiodarone may be used for arrhythmia prophylaxis.

- The mainstays of atrial fibrillation treatment in the hemodynamically stable patient include diuresis, aggressive repletion of serum potassium and magnesium, IV amiodarone loading, and IV β -blockers.
- IV calcium channel blockers and procainamide are used occasionally in certain circumstances. Procainamide is useful in heart transplant recipients who are still on inotropic support to avoid long-acting agents such as amiodarone, which may have a prolonged slowing effect on sinus and atrioventricular node function.
- Hemodynamic instability with the onset of atrial fibrillation should be treated with synchronized direct-current cardioversion. Whenever feasible, rapid atrial pacing should be attempted to suppress by overdrive pacing atrial flutter with a 2:1 block.

Monitoring and Managing Cardiovascular Performance

Arterial Blood Pressure

- Most adults require a mean arterial pressure (MAP) of at least 50 to 55 mm Hg for overall systemic perfusion, especially cerebral and renal perfusion. Older patients, particularly with severe atherosclerotic disease, may require a MAP of 65 mm Hg or higher depending on their baseline.
- Pulse pressure is a useful indicator of systemic perfusion and left ventricular ejection volume. Poorer ventricular ejection is observed when the dicrotic notch is at the base of the arterial pressure trace compared to when it is located midway up the down slope of the tracing, resulting in a larger area under the arterial pressure curve.
- Harmonic augmentation characterized by a sharp, spiked arterial pressure tracing with virtually no dicrotic notch suggests an increase in peripheral vascular tone.
- A central arterial pressure reading provides a better and more reliable assessment of overall hemodynamic function and cardiac output.

Heart Rate and Rhythm

- Normally, the atrial contraction or “kick” contributes approximately 5% of the cardiac output. However, in the postoperative patient, this may be as high as 30%. Minimizing the incidence of atrial fibrillation and maintaining sinus rhythm are as important after cardiovascular surgery.

Pacemakers

- Temporary epicardial atrial and ventricular pacing wires are commonly placed at the completion of cardiovascular procedures and can be invaluable both diagnostically and therapeutically. Heart rates of 90 to 110 beats/minute are important to optimize cardiac output of poorly compliant ventricles immediately following cardiovascular surgery and can also suppress premature ventricular beats. Patients with temporary heart block following surgery can have A-V synchrony restored with dual-mode pacing/sensing (DDD) pacemakers.
- An atrial pacing wire may be needed to determine the cardiac rhythm and differentiate supraventricular tachycardia. Simply connect the atrial pacing wire to the right arm ECG

limb lead and observe the rhythm of leads I, II, or III. The contour of the left and right atrial waveforms is another way of determining sinus rhythm.

Ventricular Preload

- The load that determines resting muscle length is primarily manipulated by fluid administration. Maintain cardiac preload at an adequate but not excessive level with the left ventricular end-diastolic pressure (PAOP) between 12 and 14 mm Hg.

Fluid Administration

- Increasing right and left ventricular filling pressures to their upper limits (16–20 mm Hg) exacerbates several problems that are difficult to manage later, especially pulmonary dysfunction. Immediately after CPB, colloid oncotic pressure is reduced by as much as 50% and returns to normal over a 2-week period of time. In addition, neutrophil and endothelial activation following CPB increase pulmonary vascular permeability, promoting increased pulmonary interstitial water accumulation and pulmonary edema.

Crystalloids and Colloids

- The focus of this debate concerns the administration of crystalloid versus colloid (blood products, albumin, or hydroxyethyl starch) solutions. Sole reliance on crystalloid solutions such as Ringer lactate may result in an inordinate amount of fluid administration to maintain adequate preload. In patients without hemorrhage we use up to 2 L of crystalloid, before 5% albumin is given.
- When the hematocrit is low (<22%) and the patient is bleeding or is hemodynamically unstable, blood products are indicated. If coagulation factors are abnormal and bleeding continues, fresh frozen plasma and platelets should be considered. The threshold to give blood is lowered in patients with incomplete revascularization, low cardiac output, and signs of inadequate oxygen delivery such as low mixed venous oxygen saturation, that is, $\text{S}\overline{\text{V}}\text{O}_2$.

Ventricular Afterload

- Afterload reduction offers the most efficient means to improve cardiac output at little or no expense to myocardial oxygen demand; judicious volume loading should be performed to avoid hypotension and hemodynamic collapse. Especially in patients with severely depressed systolic ventricular function, the ejection fraction can be dramatically improved by a reduction in systemic vascular resistance (SVR) and peripheral vascular resistance (PVR). The extent of afterload reduction that is necessary greatly depends on ventricular performance.

Vasodilators

- Nicardipine hydrochloride (1–15 mg/h), a peripheral acting calcium channel blocker, acts as a direct systemic arterial vasodilator. It is our primary afterload-reducing agent because it is reasonably evanescent, avoids cyanide toxicity, and is less associated with pulmonary artery shunting and ventilation–perfusion (V-Q) mismatch than sodium nitroprusside.
- Sodium nitroprusside increases venous capacitance and directly vasodilates the systemic and pulmonary arterioles. Its advantage is its fast onset of action (15–20 s), allowing rapid titration (0.3–10 $\mu\text{g/kg/min}$). It can be associated with

cyanide toxicity as well as pulmonary artery shunting and V-Q mismatch.

- Nitroglycerin (0.5–2 $\mu\text{g/kg/min}$) is a venous and arterial vasodilator but primarily a preload-reducing agent with mild afterload-reducing effects including on the coronary arterial tree. An additional advantage with right ventricular failure is its effects on the pulmonary vasculature. It decreases myocardial oxygen consumption and may be especially useful with incomplete revascularization.

Pulmonary Artery Vasodilators

- Right ventricular failure may be the primary cause of low cardiac output in patients who have after right ventricular myocardial infarction, heart transplantation, pulmonary endarterectomy, or CPB in patients with a long-standing history of congestive heart failure.
- The inhaled prostacyclin analogue iloprost is our preferred specific pulmonary artery vasodilator. An important advantage is its ease of administration, it can be delivered intermittently by a nebulizer to either intubated or extubated patients.
- Inhaled nitric oxide has vasodilatory activity restricted to the pulmonary artery tree because of its short half-life but requires continuous delivery by a specialized system and can be used only in intubated patients.
- Hypercapnia and hypoxia should be strictly avoided with marginal or severe right ventricular dysfunction due to their pulmonary vasoconstrictive effects. High FiO_2 can be considered a form of pulmonary vasodilator in this subset of patients.

Vasoconstrictors

- Vasodilation is especially common after prolonged CPB, a period of circulatory arrest, or preoperative treatment with ACE inhibitors. Vasoconstrictors are first-line treatment for low SVR with adequate volume and contractility.
- Phenylephrine hydrochloride (20–180 $\mu\text{g/min}$), an α -specific catecholamine, acts as a pure peripheral vasoconstrictor. It has a relatively short half-life and can be easily titrated for goal parameters, such as mean arterial blood pressure.
- Vasopressin (1–10 units/h) also acts as a pure peripheral vasoconstrictor. Because of its longer half-life, it is less suited for minute-to-minute changes in blood pressure but may be particularly useful in patients treated preoperatively with ACE inhibitors. Its mechanism of action is synergistic with norepinephrine.

Contractility

- The specific conditions under which the operation was conducted, including repairs performed, completeness of revascularization, length of cardiopulmonary bypass, and myocardial preservation can profoundly influence myocardial contractility.

Inotropes

- Few pharmacologic agents affect only one determinant of cardiac performance; this is especially true of inotropes. A major goal after CPB is to gain cardiac output with as little increase in myocardial oxygen consumption as possible.
- Epinephrine (0.01–0.10 $\mu\text{g/kg/min}$), can be particularly useful to support right ventricular function. Above these levels it also has vasoconstrictor and chronotropic effects.

- Norepinephrine (0.01–0.10 $\mu\text{g/kg/min}$), has stronger vasoconstrictor effects in this range and is associated with improved coronary and splanchnic blood flow.
- Isoproterenol (0.005 and 0.02 $\mu\text{g/kg}$) is a relatively weak inotrope with primarily chronotropic properties. Used primarily in heart transplant to achieve tachycardia of 100 to 120 beats/minute because of the normal coronary arteries, diastolic dysfunction, and right ventricular distention common in this population.
- Milrinone (optional 50 $\mu\text{g/kg}$ loading dose, then 0.1–0.75 $\mu\text{g/kg/min}$) is a phosphodiesterase inhibitor with potent inotropic and vasodilatory effects commonly used in patients with pre-existing ventricular systolic dysfunction. It is frequently given in combination with a vasoconstrictor agent.
- Dopamine hydrochloride (3–5 $\mu\text{g/kg/min}$) can be used to decrease SVR and augment cardiac contractility when a more potent catecholamine is not required. In this dosage range, it also stimulates dopaminergic receptors in the kidney enhancing renal perfusion, although prevention of renal failure has not been documented.
- Dobutamine (3–5 $\mu\text{g/kg/min}$) has inotropic and vasodilatory effects similar to milrinone. At higher doses, it has α stimulatory effects and acts as a vasoconstrictor.

Cardiac Output and Cardiac Index

- A pulmonary artery catheter measures cardiac output by thermodilution, facilitates calculation of SVR, PVR, pulmonary and intracardiac shunts, and estimates left ventricular end-diastolic pressure (LVEDP) by PAOP. Cardiac output should always be normalized by conversion to cardiac index.
- An index of 2.0 L/minute/ m^2 or more is usually sufficient to maintain end organ performance. Chronic low cardiac output pathology may tolerate a lower index in the immediate postoperative period.
- Higher body temperature, agitation, or other concomitant conditions such as sepsis, may lead to cardiac index requirements >2.0 L/minute/ m^2 . Postoperative stress normally produces cardiac indices approaching 3.5 to 4.0 L/minute/ m^2 .

Mixed Venous Saturation

- Continuous display of $\text{S}\bar{\text{V}}\text{O}_2$ affords one the opportunity to observe acute and gradual changes in cardiac performance, increasing oxygen consumption ($\dot{\text{V}}\text{O}_2$), or both.
- Acute changes in $\dot{\text{V}}\text{O}_2$ and cardiac performance are especially demonstrable during episodes of agitation, tracheal suctioning, and rapid extracellular volume shifts.
- $\text{S}\bar{\text{V}}\text{O}_2$ varies with cardiac output, hemoglobin, SaO_2 , and oxygen consumption and is a balance between oxygen delivery and oxygen consumption.
- Equipment used to measure physiologic parameters such as the arterial pressure and $\text{S}\bar{\text{V}}\text{O}_2$ must be calibrated regularly.

Serum Lactate

- As an indicator of anaerobic metabolism, serum lactate can provide information about the adequacy of cardiac performance in meeting the body's oxygen requirement. Several problems, however, limit its ability to assess cardiac performance.
- On arrival to the ICU, lactate values may range between normal (<2.0 mmol/L) to as high as 8 to 9 mmol/L. As body temperature normalizes, serum lactate may actually rise despite improving hemodynamics because underperfused

vascular beds open and release lactate into the systemic circulation.

- The difficulty is whether to attribute a rise in serum lactate to a washout phenomenon or to a diminution of cardiac performance. Evaluation of the cardiac index, $\text{S}\bar{\text{V}}\text{O}_2$, and SVR in conjunction with serial serum lactate determinations helps to resolve this dilemma. Lactate levels should decrease after 8 hours if perfusion is adequate.

Serum Ionized Calcium and Potassium

- Serial measurement of Ca^{2+} is especially helpful when solutions containing protein such as blood, fresh frozen plasma, albumin, or plasma protein solutions are administered. Protein binds calcium and may diminish that which is available for myocardial function.
- Maintenance of adequate serum potassium is crucial, especially after the usually brisk diuresis following CPB and in conjunction with diuretic therapy. Potassium chloride should be considered a first-line agent for prevention and treatment of arrhythmias.

Urine Output

- Initially brisk, urine output alone should not be relied on to judge cardiac performance as it is influenced by numerous variables including high serum glucose, denatured plasma protein fractions, and diuretics during CPB.
- Later, urine output may be influenced by stress hormones such as antidiuretic hormone, aldosterone, and cortisol, which conserve intravascular volume.
- Almost all patients have excess total body water but intravascular volume is variable because of third-spacing related to increased capillary permeability and post-CPB inflammation.
- Diuretic therapy is directed to low normal filling pressures, as long as hemodynamics are not compromised, to minimize interstitial lung water and improve pulmonary function. Diuresis should be performed cautiously when ventricular compliance is poor, especially with concentric ventricular hypertrophy, and cardiac function may be especially preload dependent.

Special Concerns

- Bleeding
 - Severe postoperative bleeding occurs in 3% to 5% of patients who undergo CPB.
- Causes
 - Inadequate surgical hemostasis should always be suspected.
 - At least half have acquired hemostatic defects including activation of fibrinolysis, decreased clotting factors, and transient platelet dysfunction.
 - Preoperative use of antiplatelet agents such as clopidogrel and aspirin are associated with increased postoperative transfusion requirements.
- Treatment
 - Antifibrinolytic agents, such as epsilon aminocaproic acid, are begun intraoperatively to decrease transfusions in high-risk subpopulations. No evidence supports use in the postoperative period. Aprotinin is not available.
 - Recombinant activated factor VII and XIII replacement is an emerging strategy.

- Isolated activated partial thromboplastin time elevation may indicate heparin rebound reversible with protamine sulfate administration.
- Point-of-care platelet function assays may be useful for directing platelet transfusion, even in patients without thrombocytopenia.
- Blood loss of >3 mL/kg/hour for several consecutive hours prompts a return to the operating room. Evacuation of the mediastinal hematoma frequently improves coagulopathy even when no surgical bleeding is identified. Brisk hemorrhage should be re-explored even before coagulopathy is corrected to prevent cardiac tamponade and hemodynamic collapse.
- **Cardiac tamponade.** Two fairly reliable signs of cardiac tamponade are increased or exaggerated cycling of the systolic blood pressure during positive pressure ventilation, and equalization of right and left atrial and pulmonary artery diastolic pressures. Blood clots on the acute margin of the right ventricle may substantially affect cardiac performance without atrial pressure equalization. A reduction in \bar{SVO}_2 and decreased urine output will also be observed. The diagnosis may be suspected with abrupt cessation of drain output and confirmed by echocardiography. In severe low-output states, tamponade must be ruled out by exploration in the operating room or a limited opening of the chest at bedside. Percutaneous drainage is not useful in the immediate postoperative period.
- **Thrombocytopenia**
 - Platelet counts <100,000/ μ L are common and managed by removal of offending agents. Causes include platelet activation and consumption during CPB, mechanical destruction by intravascular devices, and inadequate production.
 - If counts fall more than 50% or a thrombotic event occurs between 4 and 14 days of heparin exposure, heparin-induced thrombocytopenia (HIT) should be excluded. If diagnosed or strongly suspected, a nonheparin anticoagulant such as lepirudin or bivalirudin should be considered to prevent thrombotic complications.
 - For patients who require long-term anticoagulation for DVT, warfarin can be started once platelet levels are in the normal range.
- **Ventilator management**
 - Ventilator management after cardiac surgery is directed toward optimizing pulmonary function without compromising hemodynamics. Acute hemodynamic changes may indicate patient distress. Patient dyssynchrony with the ventilator should prompt assessment of sedation and analgesia.
 - Positive end-expiratory pressure (PEEP) above 8 to 10 cm H_2O , may affect chamber filling and decrease cardiac performance. With high PEEP, intravascular volume may be necessary to raise the effective LVEDP, though the amount of pressure transmitted through diseased lungs may vary.
 - Nitroprusside and to a lesser extent nicardipine in heavy smokers or patients with severe chronic lung disease may increase pulmonary shunting and cause hypoxia. Bronchodilators and PEEP rarely correct this and alternative agents such as nitroglycerin (3–5 μ g/kg/min) or hydralazine should be used.
 - Acute respiratory distress syndrome (ARDS) is much less frequent due, in part, to shorter CPB times and the use of membrane oxygenators. When ARDS does occur, it may be accompanied by multiple organ dysfunction syndrome or sepsis.
- **Diuretics**
 - Diuresis is desirable during the recovery period to reverse hemodilution and improve pulmonary function, but should always be closely monitored. A 24-hour diuresis goal is set with reassessments to avoid hypovolemia.
 - Excessive diuresis of 500 to 1,500 mL over several hours may rapidly deplete intravascular volume, reduce cardiac performance and promote increased SVR.
 - Relatively small doses of furosemide (10–20 mg) every 4 to 8 hours as needed spares the patient rapid volume shifts and produces a gradual negative fluid balance. In patients with marginal ventricular or renal function, a continuous infusion at doses up to 20 mg/hour may be necessary.
 - Intermittent doses of thiazide diuretics are a useful adjunct to therapy.
- **Renal failure**
 - Acute tubular necrosis may develop with an extremely low cardiac output or hypotension during the first 24 hours after CPB. Most respond to adequate volume maintenance and diuretic therapy and can be kept in a nonoliguric renal failure. Some, especially those with a preoperative creatinine clearance <50 mL/minute, may develop oliguric or anuric renal failure.
 - **Diuretics.** Patients with oliguria should be given a test bolus of furosemide (60–120 mg) and be evaluated for a urine response >50 mL/hour. A continuous infusion up to 20 mg/hour with intermittent doses of thiazide diuretics usually maintains urine output and avoids gross volume overload. Avoiding hypovolemia is also essential.
 - **Ultrafiltration.** Patients with renal failure and volume overload who fail initial diuretic therapy may be candidates for ultrafiltration to remove excess salt and water without clinically significant effects on hemodynamics or electrolyte balance. Standard central or peripheral venous catheters can be used for access.
 - **Dialysis.** Intravascular volume overload and inadequate clearance of potassium are the principal indications for dialysis. The overall goal is to remove excess water and solutes while maintaining cardiovascular stability, this is best achieved with continuous venovenous hemodialysis (CVVHD). CVVHD offers good clearance and accurate control of ultrafiltration that is adaptable to the patient's hemodynamic requirements. Average filter life is 16 to 24 hours, heparin should be administered to prolong filter life if postoperative bleeding is not a concern.
 - Patients should be transitioned to conventional hemodialysis only after a significant period of myocardial recovery. Blood flow rates of at least 200 mL/hour are required and result in large volume shifts over a several-hour period.
- **Central nervous system complications**
 - The incidence of cerebrovascular accidents (CVAs) with focal neurologic sequelae is 2% to 5% but may be lower with advancements in intraoperative technique including routine use of epiaortic ultrasound. Advanced age, history of CVA, peripheral vascular disease, valvular surgery, and procedures requiring a period of circulatory arrest are associated with a higher incidence of central nervous system events.
 - Patients should be continuously assessed for focal motor deficits and the ability to comprehend and follow simple

commands. Focal deficits should prompt noncontrast computed tomography (CT) of the brain to rule out hemorrhagic mass lesions. Magnetic resonance imaging (MRI) may be useful to identify smaller embolic foci. Fresh post-CPB patients are usually poor candidates for thrombolysis because of their risk for bleeding. The treatment for major embolic CNS events is usually supportive. Higher blood pressures may lead to greater perfusion through collaterals in patients with severe occlusive cerebrovascular disease.

- **Untoward psychological and cognitive sequelae** are more prevalent than focal CVAs. The precise cause of neuropsychological complications remains unclear, however microemboli, especially air, are related to both severe and subtle postoperative neuropsychological deficits.
- **Delirium.** Postcardiotomy delirium is typically preceded by a lucid interval, usually 36 to 48 hours from the time patients awaken from anesthesia. This syndrome is characterized by confusion, disorientation, and disordered thinking and perception. Severe manifestations may include visual and auditory illusions, hallucinations, and paranoid ideation. Treatment consists of undisturbed rest, frequent reorientation, ensuring patient safety, reassurance to both the patient and family, and haloperidol. Avoid benzodiazepines because of the paradoxical excitatory response seen occasionally in the elderly. Subtle changes in mentation and thinking processes occur frequently during the first few weeks after surgery and usually resolve by the sixth postoperative month.
- **Sedation and paralysis**
 - Shivering, agitation, or both can cause a marked increase in $\dot{V}O_2$ and reduction in $\dot{S}\dot{V}O_2$, especially in low cardiac output states. Once gross neurologic function is assessed in the immediate postoperative period, these are best treated with narcotic agents. Meperidine is particularly efficacious, although its mechanism is unknown.
 - If early extubation is expected, propofol has a short half-life and is useful for temporary sedation. A combination of narcotic and benzodiazepine infusions are used for prolonged periods of mechanical ventilation. Fentanyl has limited effects on myocardial contractility and the peripheral vasculature.
 - In rare instances, such as severe pulmonary artery hypertension and right heart failure, a paralytic agent may be indicated to prevent any respiratory effort, which can trigger increased pulmonary artery pressures and precipitate hemodynamic collapse. Because of their association with critical illness neuropathy, we prefer to avoid paralytic agents and treat these patients with deep sedation. When required, vecuronium has a lesser chronotropic effect than pancuronium.
- **Mechanical cardiac assistance**
 - **Intra-aortic balloon pumps (IABP).** When patients fail to respond to moderately high-dose inotropic drug combinations such as epinephrine and milrinone, IABP therapy should be considered early and can be instituted at the bedside by a percutaneous technique. The IABP improves cardiac performance primarily by afterload reduction and augmentation of systemic diastolic pressure, thereby increasing coronary artery perfusion pressure. Its main contraindications are aortic insufficiency and aortoiliac occlusive disease. Complications and adverse effects include platelet consumption, catheter sepsis, and lower extremity ischemic complications.

- **Ventricular assist devices (VAD) and total artificial hearts.** VADs replace the function of either or both ventricles until myocardial recovery occurs or cardiac transplantation can be performed. End-stage congestive heart failure patients who are not transplant candidates may have a VAD placed as destination therapy. Currently, total artificial heart therapy remains experimental and is limited to research protocols.
- In some cases, extracorporeal membrane oxygenation (ECMO) is indicated for profound cardiorespiratory failure.
- **Blood glucose control**
 - For cardiac surgery patients, tight blood glucose control (blood glucose 80–110 mg/dL) reduces the incidence of mediastinitis, atrial fibrillation, ischemia, length of stay, hospital costs, and mortality in both diabetic and nondiabetic patients. Nearly all adult patients require an intravenous insulin infusion through the immediate postoperative period if normoglycemia is to be maintained.
 - Once taking an oral diet, the patient is transitioned to a long-acting insulin formulation to cover basal needs and fast-acting insulin based on the percentage of meals consumed.
- **Catheter sepsis**
 - Bloodstream infections have particularly significant implications in cardiovascular surgery patients as prosthetic intravascular devices are frequently implanted during surgery and multiple invasive monitoring catheters are used.
 - The incidence of sepsis increases when invasive monitoring catheters are left in place longer than 72 hours, for straightforward cases they should be removed by this time. All peripheral lines are changed with transfer to the intermediate care floor.
 - The critically ill, who require prolonged invasive monitoring, are observed closely for signs of sepsis such as fever and leukocytosis, with a low threshold to remove old lines. Rewiring catheters is avoided, new catheter insertion at a different site is preferred.
- **Clinical pathways**
 - Coronary artery bypass grafting (CABG) procedures were among the first to benefit from clinical pathways to improve the continuity and coordination of care. CABG procedures are common, usually elective, have typical recovery milestones, and require coordination of multidisciplinary provider teams, which make pathways extremely useful to support both clinical and administrative management. Pathways for other cardiovascular procedures including heart valve surgery and transplantation have been developed as well.
 - When successfully implemented, they encourage the use of clinical guidelines, follow a timeline, improve multidisciplinary teamwork, reduce variations in patient care, and improve clinical outcomes.
 - It is important that clinical pathways not discourage personalized care and that they function well even in the face of unexpected changes in a patient's condition.
- **Cardiac surgery databases**
 - Institutional and multi-institutional databases are useful tools to track outcomes following cardiovascular operations, conduct clinical research, and guide continuous quality improvement. The data collected is clinical, administrative, or both.

- Data is also used by various regulatory bodies and third-party payers to monitor health care quality and costs; in the future it will also be used for pay-for-performance initiatives.
- The Society of Thoracic Surgeons Cardiac Database is the largest clinical cardiothoracic surgery database in the world and currently has more than 500 participating sites. This allows risk modeling for common procedures and provides individual institutions with comparative outcomes data and national benchmarks.
- All databases are limited by the variable quality of collected data, which in many instances is self-reported. Comparison of outcomes is also subject to selection bias not corrected by imprecise risk models.

Special Clinical Scenarios

- Off-pump coronary artery bypass (OPCAB) surgery
 - OPCAB avoids diffuse inflammatory response, multiorgan dysfunction, and neurocognitive complications that may follow after CPB (Table 49.3).
 - There are several important differences for expedited care after OPCAB surgery.
 - Decreased need for inotropic support, most likely from avoidance of global ischemia and reduced myocardial stunning.
 - Euvolemia is more likely in the immediate postoperative period as systemic inflammatory response and capillary leak related to CPB are avoided.
 - A relatively hypercoagulable state as opposed to the coagulopathy typical after CPB. This reduces postoperative hem-

orrhage and transfusion requirements but has the potential to adversely affect graft patency. In addition to daily aspirin as with conventional CABG, clopidogrel (75 mg/d) is started once chest tube drainage has been low for 3 consecutive hours.

- Persistent or massive hemorrhage is more likely surgical and not related to factor or platelet deficiency.
- One of the major benefits to the healthcare system benefits is the potential for reduced resource use, especially length of mechanical ventilation and ICU stay.
- Thoracic aortic surgery
 - Patients undergoing surgery for disorders of the thoracic aorta present critical care providers with several unique challenges, including neurologic complications, hemodynamic disturbances, and malperfusion syndromes. Several of these conditions are caused by the period of circulatory arrest that the patient undergoes during the conduct of the surgical repair whereas others are caused by the specific anatomy of the underlying thoracic aortic pathology.
 - **Circulatory arrest sequelae.** Aortic arch procedures usually have a period of circulatory arrest during the operation, which increases the risk for neurologic complications. Elderly patients with prolonged (>30 min) hypothermic circulatory arrest typically have neurologic dysfunction resulting in agitation and delirium. Although transient, it may necessitate a several-day period of supportive care including mechanical ventilation.
 - Circulatory arrest is also associated with profound coagulopathy. This is especially problematic with long suture lines and friable aortic tissue, hypertension should be avoided. Surgical bleeding should always be suspected with brisk hemorrhage.
 - Complex vascular repairs with long bypass times and circulatory arrest may develop profound vasodilatory shock recalcitrant to vasopressors. The cause is unclear but may be related to bacterial translocation of intestinal flora. Patients should be volume resuscitated and supported with vasopressors and inotropes as needed. With profound vasodilation, intravenous steroids and methylene blue allows reduction of high dose vasopressors.
 - **Spinal cord ischemia.** This occurs during thoracoabdominal aneurysm repair and is exacerbated by postoperative hypoperfusion, particularly when the artery of Adamkiewicz is not reconstituted. Anterior spinal artery syndrome results with impaired lower extremity motor function and, to a lesser degree, impaired sensation. When suspected, a lumbar drain should be placed if not already done intraoperatively. Cerebrospinal fluid (CSF) drainage for pressures 10 mm Hg or higher, and maintaining the mean arterial blood pressure 85 to 100 mm Hg has led to reversal of acute lower extremity neurologic findings. MRI is useful for confirming the diagnosis but should not be delay initiation of treatment.
 - **Malperfusion syndromes.** In patients with aortic dissection, branch orifices become obstructed by the dissected intimal flap or inadequate perfusion by the false lumen causing malperfusion of virtually any limb or end organ, depending on the anatomic extent of the dissection. Patients with ascending aorta involvement (Stanford type A) typically undergo emergency surgery whereas patients with only descending aorta involvement (Stanford type B) are treated initially with medical therapy. After repair of an ascending aortic dissection, patients are frequently left with residual

TABLE 49.3

BENEFITS OF OFF-PUMP CORONARY ARTERY BYPASS GRAFTING DEMONSTRATED IN PROSPECTIVE, RANDOMIZED STUDIES

Myocardial protection
Reduced release of cardiac enzymes
Decreased need for inotropic support
Fewer postoperative arrhythmias
Pulmonary function
Decreased requirement for mechanical ventilation
Renal protection
Improved preservation of glomerular filtration and renal tubular function
Coagulation
Decreased coagulopathy
Decreased transfusion requirement
Inflammation
Reduced release of cytokines
Reduced complement activation
Decreased incidence of postoperative infections
Neurocognitive function
Improved early postoperative neurocognitive function
Resource utilization
Decreased total resource utilization

dissection involving the descending aorta; therefore malperfusion syndromes may develop in both groups. Patients should undergo serial peripheral pulse, neurologic, and abdominal exams; serial arterial blood gases, liver enzymes, and lactate levels are useful when visceral malperfusion is

suspected. Angiography and interventional techniques such as fenestration or stenting can frequently be used to diagnose and treat malperfusion during the same procedure. Laparotomy may be occasionally required for visceral malperfusion that progresses to bowel infarction.

CHAPTER 50 ■ MANAGEMENT OF THE PEDIATRIC CARDIAC SURGICAL PATIENT

The successful collaboration of numerous disciplines including pediatric cardiac surgery, anesthesia, cardiology, and intensive care over the past several decades have led to an increase in the complexity of cardiac lesions repaired, with a simultaneous reduction in surgical mortality. This chapter focuses on the key principles for successful management of the pediatric cardiac surgical patient, including assessment of the preoperative status and operative course, postoperative stabilization, subsequent evaluation of the repair, and support of myocardial function.

CARDIAC INTENSIVE CARE: A SPECIALIZED ENVIRONMENT

- The pediatric cardiac intensive care unit (CICU) must be equipped with bedside monitors able to display vital signs and transduce several pressures simultaneously as many patients have several intracardiac catheters for postoperative hemodynamic monitoring. Storing at least 24 hours of hemodynamic data and alarms is often important for reconstructing critical events and trending a patient's recovery or deterioration over time.
- Ventilators capable of supporting patients of all sizes (from premature neonates through adults) should be readily available. Specialized ventilators such as the oscillator should be also available for patients with coexisting lung disease. There should be several ventilators capable of delivering inhaled nitric oxide, essential in treatment of pulmonary hypertension (PH), as multiple patients commonly receive this therapy simultaneously.
- Bedside blood gas analysis testing devices are the norm at many institutions. If unavailable, a laboratory turnaround time of <15 to 30 minutes is necessary.
- A portable electrocardiogram (ECG) machine and defibrillator are essential devices for bedside diagnosis, cardioversion, and emergency defibrillations. Most contemporary battery-operated temporary pacemakers can deliver rapid atrial pacing to terminate tachyarrhythmia including re-entrant supraventricular tachycardia and atrial flutter.
- Echocardiography allows for rapid assessment of residual lesions or tamponade. A mediastinal cart or tray for emer-

gent bedside sternotomy is required and also facilitates emergency cannulation for extracorporeal membrane oxygenation (ECMO).

POSTOPERATIVE ASSESSMENT AND STABILIZATION

Transition from the Operating Room

- Patients are the most vulnerable to decompensation during the first several hours after cardiopulmonary bypass (CPB). The medical decision making and patient management should be provided by the anesthesia and surgical team until a complete exchange of information occurs.
- Key operative events are details of the repair, length of CPB including any special techniques used such as deep hypothermic circulatory arrest or low-flow regional perfusion; abnormal rhythms; or significant bleeding after CPB.
- Key anesthesia events are airway issues such as difficulty with bag-mask ventilation or tracheal intubation; type of anesthesia given, including cumulative dose of narcotics and benzodiazepines; current vasoactive and inotropic support; and blood and colloid products administered.
- If the sternum is left open, it is important to know whether this is for excessive bleeding, poor myocardial function, or difficulty with ventilation, as each has different implication for management strategies in the first postoperative hours.
- The initial assessment of the repair typically includes transesophageal or epicardial echocardiography, intracardiac saturation to assess for residual shunts, and hemodynamic pressure measurements. If a second CPB run is required to correct residual lesions, this can have important effects on myocardial function. The physical exam should focus on clinical cardiac output and evidence for residual lesions.
- Murmurs are expected after some procedures (e.g., aortopulmonary shunt) but abnormal in others (e.g., ventricular septal defect [VSD] repair).
- Cavopulmonary connections such as the bidirectional Glenn or Fontan procedure should have a quiet precordial exam;

murmurs may indicate outflow tract obstruction or atrioventricular valve regurgitation.

- Arterial blood gas interpretation requires understanding of the patient's physiology. With two-ventricle physiology in the absence of significant pulmonary pathology, a high arterial partial pressure of O_2 (PaO_2) is expected on 100% oxygen (O_2). Mild hyperventilation ($PaCO_2$ 30–35 mm Hg) may be indicated in PH to reduce pulmonary vascular resistance (PVR).
- Patients with large left-to-right shunts preoperatively may have significant alveolar–arterial gradients from pulmonary edema.
- After right ventriculotomy, right ventricular (RV) dysfunction and elevated central venous pressures may cause right-to-left shunt through a patent foramen ovale with $PaO_2 < 100$ mm Hg regardless of the fraction of inspired oxygen (FiO_2).
- PaO_2 35 to 45 mm Hg is targeted in single-ventricle patients to prevent pulmonary overcirculation and systemic undercirculation. Pulmonary overcirculation may be treated with hypoventilation ($PaCO_2$ 45–50 mm Hg) to increase PVR.
- Metabolic acidosis should raise concern for low cardiac output syndrome requiring judicious intravascular volume supplementation, increased inotropic support, and maximization of oxygen-carrying capacity. If the cause is unclear or initial measures fail to improve cardiac output, urgent bedside echocardiography should be performed to evaluate the repair and myocardial function and look for possible tamponade.
- Higher initial ICU lactate (9.4 vs. 5.6 mmol/L) and levels that continue to rise >0.75 mmol/L/hour are associated with poorer outcome (death or use of ECMO).
- Prothrombin time (PT), partial thromboplastin time (PTT), fibrinogen, and platelet count should be normal and aggressively corrected for bleeding. Protamine can be given for a prolonged PTT, but if all coagulation parameters are corrected excessive bleeding persists, an antifibrinolytic such as tranexamic acid or ϵ -aminocaproic acid may be considered. Aprotinin is currently not available until further studies are done. Activated factor VIIa has been used for refractory bleeding in post-CPB ECMO. Pronounced bleeding despite aggressive pharmacologic and blood product transfusion may be surgical, and brisk bleeding that stops abruptly with a concurrent rise in intracardiac pressures is likely tamponade; both require chest exploration.
- A chest radiograph performed minutes after arrival will verify tracheal tube, nasogastric tube, pacing wire, and intracardiac catheter placement; assess cardiac size and rule out a significant pneumothorax or hemothorax. A right or common atrial catheter enters the right atrial (RA) appendage and is directed inferiorly. A left atrial (LA) catheter usually enters a right pulmonary vein taking a horizontal course, alternatively it enters the LA appendage and courses inferiorly. A pulmonary artery (PA) catheter enters the right ventricular outflow tract and is directed superiorly into the main PA. An RV catheter tip sits in the body of the RV.
- A 12- or 15-lead ECG should be performed to assess rhythm and atrioventricular (AV) conduction. Lack of AV synchrony can contribute to a low cardiac output state; temporary pacing for AV nodal block or an ectopic junctional rhythm may be needed. The QRS complex should be assessed for new

abnormalities including bundle branch block. Complete right bundle branch block is common after VSD closure but not usually of hemodynamic significance. Assess the ST segment for signs of ischemia, especially after procedures that include coronary artery reimplantation.

- After the initial assessment and stabilization, a plan is made for weaning inotropes, ventilatory support, analgesia, and sedation over the subsequent hours to days.
- Older children with short CPB support times, stable hemodynamics, and minimal chest bleeding (e.g., conduit revisions, subaortic membrane resections, septal defect closures) can be extubated when they awaken from anesthesia.
- Neonates and younger infants often undergo more complex repairs and will need more gradual weaning of support over 24 to 48 hours. Those undergoing complex neonatal single-ventricle palliation often require several days of stabilization and diuresis before their sternums can be closed.

Hemodynamic Monitoring

- Intracardiac catheters are invaluable and have a low risk of complications.
- Transthoracic RA catheters are also known as common atrial catheters in single-ventricle patients, as common atrium is either created or congenitally present.
- Transthoracic LA catheters are typically used in young infants with complex two-ventricle or a mitral valve repair to assess LV and mitral valve function and intravascular volume.
- Transthoracic PA catheters are placed for selected repairs including truncus arteriosus and tetralogy of Fallot (TOF). With intraoperative transesophageal echocardiography, these catheters are less common and reserved for procedures where the incidence of postoperative PH is high, such as repair of obstructed total anomalous pulmonary venous return.
- Transthoracic RV catheters are more common; entering through the RA appendage the tip crosses the tricuspid valve to assess RV and PA pressures after complex PA reconstructions.
- In contrast to adults, children rarely have flow-directed PA (Swan-Ganz) catheters placed due to both small patient size and the need for unobstructed access for intracardiac repairs.
- Mean RA pressure ranges from 0 to 8 mm Hg; mean LA pressure is typically 1 to 2 mm Hg higher; abnormal pressures have multiple causes (Tables 50.1 and 50.2). Postoperative pressures are higher owing to CPB effects on the myocardium and the volume of fluid received but should not exceed 15 mm Hg.
- The onset is important as gradually increasing pressures often indicate a clinical problem such as low cardiac output or tamponade physiology is evolving. A sudden change without changes in rhythm or other vital signs may indicate a technical problem with the catheter or transducer.
- The morphology of the atrial tracing is also helpful. Large A waves, referred to as *canon A waves*, result from loss of AV synchrony when the atrium contracts against a closed AV valve as in AV block or junctional rhythm. Large V waves occur during ventricular contraction with an incompetent AV valve.

TABLE 50.1**CAUSES OF ELEVATED OR REDUCED RIGHT ATRIAL PRESSURE****Elevated**

Volume overload
 Right ventricular dysfunction
 Systolic dysfunction
 Diastolic dysfunction or noncompliance
 Tricuspid stenosis
 Tricuspid regurgitation
 Tamponade
 Loss of atrioventricular synchrony from heart block, junctional rhythm
 Tachyarrhythmia
 Catheter or transducer malposition or malfunction

Reduced

Volume depletion
 Inadequate preload
 Bleeding
 Catheter or transducer malposition or malfunction

- Low atrial filling pressures in the setting of low arterial blood pressure or cardiac output should be treated with volume expansion. Typically, 5 to 10 mL/kg of colloid or crystalloid is the initial dose to restore preload.
- Causes of abnormal PA or RV pressures are listed in Table 50.3. Normal mean PA pressures are 10 to 20 mm Hg; considerable postoperative variation is possible but should not exceed 25 to 30 mm Hg. Elevated pulmonary pressures are not well tolerated for long periods of time; quickly correct hypocarbia and acidosis, which increase PVR. Inhaled nitric oxide is useful for PH and low cardiac output. The RV systolic pressure, often expressed as a percentage, should be <30% to 50% of the systemic systolic pressure.
- Causes of abnormal RA, LA, and PA saturations are listed in Table 50.4. Accurate interpretation relies on precise knowl-

edge of the catheter tip location and the patient's physiology. RA and PA saturation data are a useful assessment of the patient's cardiac output and oxygen extraction.

- Normal superior vena cava (SVC), RA, and PA saturations with two-ventricle physiology and no intracardiac shunt are approximately 70% to 80%; true mixed venous saturation is in the PA. Elevation after atrial or ventricular septal defect repair indicates a residual left-to-right shunt. An absolute PA saturation of >80% while receiving an $\text{FiO}_2 < 0.4$ is predictive of a residual intracardiac shunt of >1.5:1.
- With normal cardiac output and fully saturated systemic arterial blood, the arteriovenous O_2 saturation difference will be 25% to 30%. RA saturation is commonly around 60% after CPB with adequate oxygen delivery and perfusion.
- Lower RA saturations are expected in single-ventricle physiology from intracardiac right-to-left shunting and systemic O_2 desaturation. As long as the arteriovenous saturation difference is $\leq 30\%$, the cardiac output should be normal.
- Typically, LA and PA catheters are removed within the first 48 hours while still intubated and with chest tubes in place to monitor for bleeding. Although significant bleeding is rare, catheters are removed with blood available at the bedside. RA catheters may remain in place up to 2 weeks but as soon as clinically indicated.

Postoperative Rhythm and Pacing

- Sinus **bradycardia**, normal in children during sleep and with high vagal tone, is generally well tolerated in the absence of long sinus pauses. Hypothermic patients with core temperatures of 32°C to 34°C will remain bradycardic until their temperature rises. At risk are those undergoing atrial baffles such

TABLE 50.4

CAUSES OF ABNORMAL RIGHT ATRIAL, LEFT ATRIAL, AND PULMONARY ARTERY SATURATION

Location	Elevated	Reduced
Right atrium	Left-to-right atrial shunt Anomalous pulmonary venous return Increased venous oxygen content Decreased oxygen extraction Catheter tip position (near inferior vena cava)	Low cardiac output (increased O ₂ extraction) Increased oxygen consumption (fever, high catecholamines) Decreased arterial saturation with normal O ₂ extraction Catheter tip position (near coronary sinus) Anemia
Left atrium	Normal is fully saturated	Right-to-left atrial shunt Decreased pulmonary vein saturation (lung disease, arteriovenous malformation)
Pulmonary artery	Left-to-right cardiac shunt Catheter tip wedged (left atrial sample)	Low cardiac output (increased O ₂ extraction) Increased oxygen consumption (fever, high catecholamines) Decreased arterial saturation with normal O ₂ extraction Anemia

as a lateral tunnel-type Fontan for a single-ventricle defect or atrial switch procedures for transposition of the great arteries. Sinus venosus and primum atrial septal defect repairs also commonly have slower sinus rates. Extremely bradycardic patients can be treated with pacing with temporary epicardial wires.

- Conduction system injury occurs with surgery near the AV node such as VSD repair, AV canal repair, resection of subaortic muscle, and TOF repair. Usually this manifests as bundle branch block, and more significant block, such as complete heart block, is rare. The majority resolve without need for permanent pacemaker placement.
- Common tachycardias include supraventricular, junctional, and ectopic tachycardias. High catecholamine states, intracardiac catheters and suture lines, and electrolyte abnormalities all contribute to the appearance of postoperative tachyarrhythmias in previously asymptomatic patients. Most tachyarrhythmias will improve with time.
 - The onset of tachycardia may provide useful information regarding its etiology. A sudden onset with sustained heart rate and minimal variability is likely to be re-entrant, whereas a gradual increase in heart rate with some beat-to-beat variability is likely to be automatic.
- Temporary epicardial atrial wires can be used to obtain intracardiac atrial electrograms to examine the relationship of the P waves to the QRS complex (Fig. 50.1). Atrial wires can also terminate re-entrant rhythms by overdrive pacing. The indication for treatment is a hemodynamic change causing low cardiac output or blood pressure. A summary of common antiarrhythmics used after congenital heart surgery is provided in Table 50.5.
- For re-entrant and ectopic supraventricular tachycardias, β -blockers are first-line therapy and well tolerated. Digoxin is considered with apparent accessory pathways that are not pre-excited or for rate control in rapid atrial rhythms. Second-line agents include procainamide and amiodarone. Amiodarone is used with caution, given the high incidence of serious side effects including circulatory collapse and proarrhythmia. Refractory cases may be treated with the class III agent sotalol or class IC agents flecainide or propafenone. The length of treatment, at least 1 to 3 months, will vary with the nature of the tachycardia.
- Junctional ectopic tachycardia is a narrow complex rhythm occurring in the first 24 to 48 hours and is almost always self-limited. Most common after VSD closure in TOF and AV canal repairs, the typical ECG finding is AV dissociation (Fig. 50.2) with a more rapid ventricular rate (typically >180 bpm), but there can be retrograde P waves with a 1:1 relationship. Lack of AV synchrony can cause elevated atrial pressures and low cardiac output with hypotension. Atrial overpacing (if <180 bpm) can restore AV synchrony and improve hemodynamics. Reduce catecholamine states by weaning vasoactive infusions; providing sedation, analgesia, and possibly paralysis; and avoiding hyperthermia with active cooling. The best pharmacologic therapy is procainamide in combination with cooling. Amiodarone should be used with caution. Once normal sinus rhythm is restored, a gradual rewarming and removal of deep sedation and/or paralysis can occur. Pharmacologic support should then be weaned over 24 to 48 hours.

FIGURE 50.1. The use of an atrial electrocardiogram to diagnose ectopic atrial tachycardia. The surface electrocardiogram (*lower tracing*) reveals an irregular, narrow complex rhythm. Atrial depolarizations (P waves) are not easily discernible. The unipolar atrial electrocardiogram (*upper tracing*) reveals a rapid ectopic atrial tachycardia with many blocked atrial premature beats. Atrial depolarization is denoted by “A” and ventricular depolarization is denoted by “V.”

TABLE 50.5

COMMON ANTIARRHYTHMIC AGENTS USED AFTER CONGENITAL HEART SURGERY

Drug name	Class/mechanism/indications	Dosing	Considerations/side effects
Adenosine	Blocks AV node; termination of re-entrant SVT	0.1–0.2 mg/kg rapid IV push (max 6 mg)	Sinus arrest (have pacing available); hypotension; bronchospasm
Procainamide	IA, prolongs atrial refractory period; atrial tachycardia (re-entrant SVT, atrial fib/flutter)	5–15 mg/kg IV load (30 min) 20–80 μ g/kg/min IV infusion	Myocardial depressant; vasodilator; monitor levels; lupus syndrome with long-term use
Esmolol	II, β -blocker; re-entrant SVT, ectopic atrial tachycardia, ventricular tachycardia	0.1–0.5 mg/kg IV load 50–250 μ g/kg/min IV infusion	Myocardial depressant; bradycardia; hypotension; bronchospasm
Amiodarone	III, prolongs atrial and ventricular refractory periods; atrial, junctional, ventricular tachycardia	5 mg/kg IV load (60 min) 5–15 μ g/kg/min IV infusion 5–10 mg/kg/day PO	Potent vasodilator and myocardial depressant; proarrhythmic (torsades); hepatic, thyroid, and pulmonary toxicity
Lidocaine	IB, prolongs ventricular refractory period; prevents ventricular ectopy, tachycardia, and fibrillation	1 mg/kg slow IV push 20–50 μ g/kg/min IV infusion	Monitor levels; seizures at toxic levels
Verapamil	IV, Ca channel blocker, prolongs AV node refractory period; re-entrant SVT	0.1 mg/kg/dose slow IV push 3–4 mg/kg/day PO divided q8h	Myocardial depressant; avoid in infants; do not use concurrently with β -blockers
Digoxin	Prolongs AV node refractory period; atrial tachycardia except WPW syndrome	20–60 μ g/kg IV/PO digitalizing 4–10 μ g/kg IV/PO divided q12h	Multiple medication interactions; AV block and proarrhythmic at toxic levels
Propranolol	II, β -blocker; oral treatment atrial tachycardia	2–4 mg/kg/day PO divided q6–8h	Hypotension; hypoglycemia; bronchospasm
Sotalol	III, β -blocker, prolongs atrial and ventricular refractory period; oral treatment, atrial and ventricular tachycardia	80–200 mg/m ² /day PO divided q8–12h	Myocardial depressant
Flecainide, Propafenone	IC, prolongs atrial and ventricular refractory period; oral treatment of atrial tachycardia	Flec: 2–6 mg/kg/day divided q8h Prop: 150–300 mg/m ² /day	Myocardial depressant; proarrhythmic; monitor QRS prolongation

AV, atrioventricular; SVT, supraventricular tachycardia; WPW, Wolf-Parkinson-White; Flec, flecainide; Prop, propafenone.

FIGURE 50.2. The use of an atrial electrocardiogram to diagnose junctional ectopic tachycardia. The surface electrocardiogram (*upper tracing*) reveals a regular, narrow complex rhythm with possible atrioventricular (AV) dissociation. The unipolar atrial electrocardiogram (*lower tracing*) demonstrates AV dissociation with a ventricular rate that is more rapid than the atrial rate. This is junctional ectopic tachycardia. Atrial depolarization is denoted by “A” and ventricular (or junctional) depolarization is denoted by “V.”

- Ventricular ectopy can occur, especially with electrolyte abnormalities. Monomorphic premature ventricular beats or ventricular bigeminy or trigeminy is usually benign and self-limited. Sustained ventricular tachycardia that is rapid and polymorphic is dangerous and concerning for myocardial ischemia. Treatment with lidocaine and cardioversion should be attempted, but an urgent evaluation of myocardial function and perfusion must be pursued or a cardiac arrest may be imminent.

Respiratory and Ventilatory Management

- Ventilatory support and weaning should be individualized to the physiology and hemodynamic status of each patient using a set of guiding principles. Frequent reassessment and ventilatory adjustments should be expected.
- **Positive pressure ventilation** has effects on preload. Increasing tidal volumes and positive end-expiratory pressure increase intrathoracic pressure, limiting systemic venous return and increasing afterload to the RV.

- With limited RV function, elevated mean airway pressures may result in high right-sided filling pressure, poor RV function, hepatomegaly, ascites, and pleural effusions. With fluid overload and impaired gas exchange, increasing ventilatory support is tempting but may worsen the clinical status. Cavopulmonary connections and passive pulmonary blood flow are also compromised with positive pressure ventilation.
- A strategy of a larger tidal volume (15 mL/kg) with a lower ventilatory rate may minimize afterload and give the RV an opportunity to eject or the PA additional filling time during a longer expiratory phase. Encourage spontaneous breathing with less mandatory ventilator breaths or extubation if possible.
- Positive pressure has the opposite effect on the LV: The increased intrathoracic pressure decreases transmural pressure across the myocardium to reduce LV afterload. Patients with LV dysfunction have increased pulmonary edema and decreased lung compliance; positive pressure ventilation helps decrease work of breathing and oxygen consumption. A judicious amount of positive end-expiratory pressure at 3 to 5 cm H₂O maintains lung volumes at functional residual capacity to minimize PVR from atelectasis.
- The **mode of ventilation** used depends on the experience of the CICU team, pressure and volume ventilation are equally acceptable. Novel techniques such as high-frequency oscillatory ventilation and airway pressure release ventilation are used successfully with primary lung disease but have limited use after congenital heart surgery due to higher mean airway pressures.
- Prior to extubation, the patient should be awake, not tachypneic for age, hemostatic, and evaluated for significant residual cardiac lesions and the adequacy of myocardial function. Support is weaned to no or few mandatory breaths (4–6 per minute) and an FiO₂ of ≤ 0.4 ; spontaneous tidal volumes should be 6 to 8 mL/kg.
- Problems encountered after extubation include atelectasis, stridor, and diaphragm paresis or paralysis. Chest physiotherapy and occasionally bronchoscopy may be employed to re-expand atelectatic segments of lung. Stridor, usually self-limited, can be treated with nebulized racemic epinephrine and steroids.
- Persistent stridor or a weak cry can be a manifestation of recurrent laryngeal nerve injury with vocal cord paresis or paralysis; formal assessment of swallowing function to prevent recurrent aspiration may be required.
- In phrenic nerve injury, an elevated hemidiaphragm with ipsilateral lung collapse is seen on the postextubation chest radiograph. Decreased (paretic) or paradoxical (paralyzed) movement of the diaphragm on fluoroscopy confirms the diagnosis; the injury usually recovers with time. Ultrasound is less reliable in distinguishing a paretic from a paralyzed diaphragm. Older children often tolerate the injury; neonates and infants may require a hemidiaphragm plication.
- **Noninvasive forms of respiratory support** are being used more commonly. Continuous positive airway pressure and bilevel positive airway pressure delivered with nasal or full-face masks provide positive pressure without a tracheal tube. Utilities include avoiding reintubation for increased work of breathing and providing postextubation systemic afterload reduction.

Sedation, Analgesia, and Neurologic Monitoring

- The strategy should be tailored to the age and anatomy of the patient, type of repair and operative course, and anticipated postoperative course.
- High-dose **narcotics** alleviate the stress response associated with cardiac surgery and CPB; fentanyl (up to 25 μ g/kg) can be administered to neonates with minimal hemodynamic effect. Patients with marginal hemodynamics and complex repairs or palliations are initially deeply sedated with continuous fentanyl infusions and usually paralyzed to minimize the stress response and oxygen consumption.
- Of the common **muscle relaxants**, rocuronium has the shortest onset, making it useful for intubation, whereas vecuronium is employed for continuous paralysis. Pancuronium is the longest-acting agent and is cleared by the kidneys. Cisatracurium undergoes Hofmann degradation (i.e., independent of renal and hepatic function); it may be the best choice in multisystem organ failure. The significant side effects of succinylcholine, including severe bradycardia, have limited its routine use.
- Hemodynamically stable patients who require a longer ventilatory course for diuresis or pulmonary recovery benefit from continuous infusions of a narcotic and benzodiazepine though tolerance may develop after 5 to 7 days and require transition to methadone and lorazepam, longer-acting oral agents, for a weaning taper after extubation.
 - Morphine is the most common narcotic used, but fentanyl (shorter-acting) and hydromorphone are alternatives. Bolus dosing of fentanyl may result in an idiosyncratic chest wall rigidity reaction requiring rapid muscle relaxation.
 - Midazolam is the most common benzodiazepine, having sedative and amnestic properties. Lorazepam and diazepam are administered in bolus doses rather than infusions.
- After extubation, transition to oral agents, including acetaminophen, ibuprofen, and oxycodone. Older patients can benefit from narcotic-based patient-controlled analgesia. Short courses of the nonsteroidal anti-inflammatory drug ketorolac (eight doses or less) can be used with normal coagulation and renal function.
- Propofol, a popular sedating agent in adult ICUs, has a rapid onset of action and clearance. It has no analgesic properties, however, and is a potent vasodilator and negative inotrope, limiting use with decreased myocardial function. There are reports of myocardial failure and acidosis in children, so propofol is restricted to short-term use in older patients with two-ventricle physiology and normal myocardial function who are anticipated to extubate within 6 to 12 hours.
- Dexmedetomidine, an α_2 agonist, is given as a continuous infusion to decrease narcotic and benzodiazepine requirements. It does not depress respiration, and patients do not develop tolerance. Some patients develop bradycardia, which resolves when the infusion is discontinued. A relative contraindication may be high-grade AV nodal block or concurrent medications that slow conduction at the AV node such as digoxin.
- For procedural anesthesia in the CICU, ketamine is an excellent agent. It is a dissociative anesthetic with rapid onset, excellent analgesia, and minimal effects on respiratory drive at lower doses, although airway secretions can be increased.

Heart rate and blood pressure are preserved through central stimulation and diminished postganglionic reuptake. A benzodiazepine is given concurrently for hallucinations in older children. Etomidate causes minimal cardiovascular depression and is ideal intubation in a hemodynamically compromised patient. Chloral hydrate is a hypnotic agent that can be safely given by mouth or per rectum for nonpainful procedures such as echocardiography.

- Neurologic monitoring is evolving as the incidence of abnormalities after CPB is likely to be higher than reported. Postoperative electroencephalographic seizures occur in up to 11% to 20% of neonates and may be related to the duration of deep hypothermic circulatory arrest. Periventricular leukomalacia (as a marker of brain injury) is found on brain magnetic resonance imaging in >50% of neonates after congenital heart surgery. Most appear to resolve over time, but the long-term implications on cognition and development are still being determined.
- Near-infrared spectroscopy to monitor transcutaneous cerebral oxygen saturation may help identify periods of vulnerability to central nervous system injury. The measured saturation is a combination of mixed venous (85%) and arterial (15%), normally 70% in acyanotic lesions. A decrease of 20% from baseline is associated with increased seizures and coma, and prolonged cerebral desaturation <45% is associated with an increased incidence of periventricular leukomalacia.

Fluids and Nutrition

- Post-CPB inflammation significantly increases total body water and edema with diffuse capillary leak; ultrafiltration and steroids are given during the operation to minimize this. Fluid management and diuretic therapy in the first 24 to 48 hours after cardiac surgery have a significant impact on the patient's hemodynamic status and recovery.
- During the first 24 hours, many patients are oliguric despite adequate atrial filling pressures. Longer CPB, increased complexity of the repair, and preoperative renal dysfunction contribute to the duration of oliguria. Restrict fluids to one-half calculated maintenance for at least 24 hours if oliguria does not improve. Preload should be maintained using intermittent boluses, 5 to 10 mL/kg, of crystalloid or colloid solutions. Anecdotally, neonates benefit from volume expansion with 5% albumin over crystalloid.
- Electrolytes should be normalized; replace potassium cautiously with oliguria to avoid hyperkalemia. Maintain high normal ionized calcium levels (1.2–1.3 mmol/L) with bolus dosing (10 mg/kg CaCl or 100 mg/kg Ca gluconate) or a continuous infusion especially in myocardial dysfunction, neonates, and patients with 22q11.2 deletions (DiGeorge syndrome) with hypoparathyroidism. Magnesium should be repleted to avoid developing ventricular dysrhythmias.
- **Diuretics** are introduced after 12 to 24 hours as bolus doses or a continuous infusion. Use earlier with large left-to-right shunts and pulmonary edema to clear excess lung water and wean from the ventilator, but delay after 24 hours in hemodynamically unstable patients with frequent preload repletion. Furosemide is administered as 1 to 2 mg/kg IV doses every 6 to 12 hours; a continuous infusion (1 mg/kg load, 0.1 to 0.3 mg/kg/h) is useful in hemodynamically fragile or significant fluid overload patients. If output remains inadequate, chlorothiazide (5 to 10 mg/kg dose IV every 6 to 12 hours) or metolazone (0.1 to 0.4 mg/kg enterally once daily) are common second agents added. Newer agents include fenoldopam (Table 50.6), a selective dopamine receptor agonist, and nesiritide (Table 50.7), a natriuretic peptide.
- Hypochloremic metabolic alkalosis and hypokalemia and hyponatremia are common when receiving furosemide and/or chlorothiazide.
- Chloride can be repleted with arginine chloride, potassium chloride, or sodium chloride (only if hyponatremic from sodium loss and not congestive heart failure).
- Neonates with shunted single-ventricle physiology can develop a compensatory respiratory acidosis; metabolic alkalosis, and hypochloremia should be normalized prior to extubation.
- Significant **renal dysfunction** beyond 72 hours is uncommon. Consider renal replacement therapy when function continues to worsen despite maximizing cardiac output. Often a peritoneal dialysis catheter placed to gravity drainage can improve fluid balance without dialysis. Indications for dialysis include life-threatening electrolyte abnormalities including hyperkalemia, persistent metabolic acidosis, severe fluid overload impairing ventilation or sternal closure (if open), and rising blood urea nitrogen levels >100 mg/dL. If required, dialysis can be accomplished with peritoneal exchanges or continuous venovenous hemofiltration. Conventional hemodialysis is usually not well tolerated with myocardial dysfunction. Significant ongoing renal dysfunction can have a poor prognosis with >50% mortality.
- Adequate **nutrition** is required for adequate wound healing and recovery but is often compromised for several days due to hemodynamic instability and fluid restrictions. Use of promotility agents, metoclopramide, and postpyloric feeding tubes can enable enteral feeding. Enteral feedings should be restarted as soon as feasible; however, an absolute contraindication is necrotizing enterocolitis. Relative contraindications are the presence of an umbilical artery catheter, high-dose vasoconstrictive agents, and paralysis.
- Neonates with left-sided obstructive lesions, aortopulmonary shunts, and cyanotic lesions are at increased risk for necrotizing enterocolitis. Enteral feedings in these patients should advance slowly with close observation for feeding intolerance such as emesis and abdominal distention.
- If enteral feedings are not feasible, use total parenteral nutrition to avoid a catabolic state. A histamine-2 antagonist should be routinely prescribed for protection against gastric mucosal bleeding from stress and nasogastric tubes until full-volume enteral feeds are re-established.

Infection Issues

- In the first 24 hours, fever is common, does not represent infection, and should be treated to minimize oxygen consumption. All patients receive at least three doses of a second-generation cephalosporin IV as prophylaxis. Treatment is extended in high-risk patients such as those with an open sternum, with immune deficiency, or receiving mechanical circulatory support.
- Fevers that persist or arise after the first 24 hours should be evaluated with a physical exam focused on the sternal

TABLE 50.6

SUMMARY OF CATECHOLAMINES AND DOPAMINERGIC AGENTS

Name	IV dose range	Peripheral vascular effect			Cardiac effect		Comment
		Alpha	Beta ₂	Dopa	Beta ₁	Beta ₂	
Dopamine	2–4 µg/kg/min	0	0	2+	0	0	Increasing doses produce increasing alpha effect; splanchnic vasodilator
	4–10 µg/kg/min	0	2+	2+	1–2+	1+	
	10–20 µg/kg/min	2–4+	0	0	1–2+	2+	
Epinephrine	0.01–0.05 µg/kg/min	1+	1–2+	0	2–3+	2+	Increasing doses produce increasing alpha effect
	0.1–0.5 µg/kg/min	4+	0	0	4+	3+	
Dobutamine	2–10 µg/kg/min	1+	2+	0	3–4+	1–2+	Dose-dependent effect similar to dopamine; increasing doses associated with tachycardia and dysrhythmias
Isoproterenol	0.1–0.5 µg/kg/min	0	4+	0	4+	4+	Potent inotrope and chronotrope; vasodilator; increasing doses produce tachycardia and increased oxygen consumption
Norepinephrine	0.01–0.1 µg/kg/min	4+	1+	0	2+	1+	Moderate inotrope; increases systemic vascular resistance
Phenylephrine	0.01–0.5 µg/kg/min	4+	0	0	0	0	Increases systemic vascular resistance; no inotropy
Fenoldopam	0.05–1 µg/kg/min	0	0	yes	0	0	Dopaminergic receptor agonist; little chronotropic or inotropic effect; may increase renal blood flow

IV, intravenous.

TABLE 50.7

SUMMARY OF NONCATECHOLAMINE VASOACTIVE AGENTS

Name	IV dose range	Peripheral vascular effect	Cardiac effect	Comment
Calcium		Vasoconstrictor	Inotropic effect; depends on iCa level	Slows sinus node and AV node conduction
Chloride	10–20 mg/kg			
Gluconate	50–100 mg/kg			
Milrinone	50 µg/kg load 0.25–1 µg/kg/min	Systemic and pulmonary vasodilator	Diastolic relaxation, decreases afterload	Minimal tachycardia
Amrinone	1–3 mg/kg load 5–20 µg/kg/min	Systemic and pulmonary vasodilator	Diastolic relaxation, decreases afterload	Minimal tachycardia, lowers platelet count, longer half-life than milrinone
Nitroprusside	0.5–5 µg/kg/min	NO donor, relaxes smooth muscle, dilates pulmonary and systemic vessels	Decreases afterload	Reflex tachycardia
Nitroglycerin	0.5–10 µg/kg/min	NO donor, venodilator, more preload effect than nitroprusside	Decreases preload and afterload, may decrease myocardial wall stress	Minimal tachycardia, sometimes used as a coronary vasodilator
Vasopressin	0.0003–0.003 U/kg/min	Potent vasoconstrictor	Weak inotrope	Used to increase systemic blood pressure
Tri-iodothyronine	0.05–0.1 µg/kg/hour	Vasodilation	Inotrope	Tachycardia
Nesiritide	0.01–0.03 µg/kg/min	Natriuresis	Diastolic relaxation	Hyponatremia
Digoxin	6–10 µg/kg/day	Increases systemic vascular resistance	Inotrope	Slows sinus node and AV node conduction

IV, intravenous; iCa, ionized calcium; NO, nitric oxide; AV, atrioventricular.

incision, blood cultures obtained from indwelling intravascular catheters, and a urine culture. If tracheal secretions are copious and/or discolored, suggesting a respiratory source, an aspirate is obtained for Gram stain and culture. Chronically ventilated patients are often colonized; a qualitative change in secretions or increase in white blood cells on Gram stain may indicate infection.

- If the clinical suspicion for infection is high, IV antibacterial coverage should be broadened while awaiting culture results. Nosocomial infections are a significant cause of morbidity in the ICU; maintain sterile technique while inserting or manipulating catheters and remove them as soon as feasible.
- Mediastinitis is a serious postoperative infection, commonly *Staphylococcus aureus* affecting 2% of patients. Risk factors include prolonged open sternum and need for multiple chest re-explorations. Prompt antibiotic treatment with debridement and use of muscle flaps has decreased morbidity and mortality.

Low Cardiac Output Syndrome

- Low cardiac output syndrome (LCOS) is common after congenital heart surgery with CPB, especially in neonates and young infants. Many factors are thought to contribute to decreased cardiac output, including myocardial ischemia from aortic cross-clamping and associated reperfusion injury, inflammation from CPB, ventriculotomies, and the existence of hemodynamically significant residual lesions. There is an expected decrease in cardiac output that occurs over the first 6 to 12 hours after CPB with a nadir of <2 L/minute/m² in the youngest patients. With appropriate recognition, the significant morbidities and occasional mortality related to LCOS can be prevented. Milrinone combined with dopamine is currently the combination therapy most commonly used to prevent and treat LCOS.

Recognition of Low Cardiac Output

- There are several clinical symptoms and signs of LCOS that should be immediately recognized (Table 50.8). Hypotension and metabolic acidosis are late findings; they require immediate attention, or a cardiac arrest may be imminent. Auscultation for pathologic murmurs caused by residual obstructions, shunts, or valvar regurgitation is important. Hepatomegaly and ascites may indicate right heart failure, especially with right ventriculotomies.
- Echocardiogram can assess ventricular systolic function and rule out tamponade. Large residual shunts, severe valvular regurgitation, outflow tract obstructions, and venous baffle obstructions are generally poorly tolerated. If the patient has an open sternum or if chest dressings obstruct transthoracic echocardiographic windows, a transesophageal echocardiogram should be performed.
- Occasionally, the etiology of LCOS is not obvious by echocardiography or needs additional clarification before considering reoperation. Cardiac catheterization is safe, even with ECMO, and diagnoses important lesions addressed with interventional catheter procedures or reoperation in a majority of patients.

TABLE 50.8

SIGNS OF LOW CARDIAC OUTPUT SYNDROME

Physical exam/signs

Tachycardia
Hypotension
Narrowed pulse pressure/diminished pulses
Cool extremities
Central hyperthermia
Diminished heart sounds
Hepatomegaly
Pleural effusion and ascites
Oliguria
Elevated central venous pressure/left atrial pressure

Laboratory

Anion gap acidosis
Elevated lactate
Low mixed venous saturation
Indices of abnormal end organ function
Cardiomegaly on chest radiograph

Treatment

- Concurrent with ruling out correctable residual lesions, immediate therapy should be initiated. The goals of therapy are to maximize oxygen delivery and minimize oxygen consumption. Transfuse red blood cells in anemia to increase oxygen-carrying capacity. Optimize cardiac output by repleting intravascular volume and utilizing pharmacologic agents to increase inotropy and decrease afterload (see Tables 50.6 and 50.7). Neuromuscular blockade, deep sedation or anesthesia, and active cooling are used to minimize oxygen consumption.
- Continual reassessment of the response to therapy by physical exam focused on perfusion, and monitored parameters such as urine output and acidosis are required.

Pharmacologic Therapy

- Catecholamines (see Table 50.6) have been the first-choice pharmacologic agents for increasing cardiac output. Almost all patients receive dopamine immediately after CPB to stimulate coronary β receptors and increase contractility (initial dose 3 to 7 $\mu\text{g/kg/min}$); higher doses (>10 $\mu\text{g/kg/min}$) stimulate α receptors causing peripheral vasoconstriction. Low to moderate doses of epinephrine (0.02–0.1 $\mu\text{g/kg/min}$) increase contractility and cause mild peripheral vasoconstriction. Dobutamine acts primarily on coronary β receptors and is most often used in chronic congestive heart failure (e.g., dilated cardiomyopathy); high doses are associated with arrhythmias and tachycardia. Isoproterenol stimulates β receptors and is both an inotrope and chronotrope. It increases oxygen consumption and peripheral vasodilation and is not commonly used in LCOS. Norepinephrine and phenylephrine (pure α agonist) are predominantly α -receptor agonists; their use is limited to patients with profound hypotension.
- Arginine vasopressin, a noncatecholamine vasoconstrictor, promotes vascular smooth-muscle constriction without causing tachycardia. Its role in cardiogenic shock is unclear.
- Patients requiring continued high doses of these potent vasoconstricting agents to support systemic blood pressure should be considered for mechanical circulatory support.

- Relatively noncompliant neonatal myocardium may be more susceptible to catecholamine-driven increases in tachycardia, afterload, and oxygen consumption.
- Afterload reduction is increasingly recognized as the principal form of pharmacologic support for the myocardium after CPB. The type III phosphodiesterase inhibitors enhance myocyte contractility, peripheral vasodilation, and diastolic relaxation. Milrinone is tolerated well by postoperative neonates, and it promotes increased cardiac output, lower atrial pressures, and decreased pulmonary and systemic vascular resistance; it also has a shorter half-life and fewer antiplatelet effects than amrinone. A large, multicenter trial of milrinone after congenital heart surgery found prophylactic milrinone at 0.75 $\mu\text{g/kg/minute}$ had a relative risk reduction of 55% for LCOS compared to placebo. The vasodilators nitroprusside and nitroglycerine, nitric oxide donors, can decrease afterload and improve cardiac output, but they have no direct inotropic effects on the heart.
- Other agents include thyroid hormone, B-type natriuretic peptide, and glucocorticoids. All patients develop low thyroid hormone levels approximately 24 hours after CPB; this typically recovers by 5 to 7 days. Replacing tri-iodothyronine may increase cardiac output, blood pressure, and time to negative fluid balance and extubation. Infusions of nesiritide, a synthetic form of BNP, in adults with heart failure decreases atrial pressures and systemic vascular resistance and improves cardiac output, but pediatric findings are less convincing. Hydrocortisone decreases the inotrope requirements in neonates and infants receiving high-dose catecholamines ($>0.15 \mu\text{g/kg/min}$ epinephrine) after congenital heart surgery, possibly due to a relative adrenal insufficiency after CPB.

Extracorporeal Membrane Oxygenation

- The principal mode of mechanical circulatory support in the postoperative pediatric cardiac patient is venoarterial (cardiac) ECMO, ideally before the development of severe end organ dysfunction or cardiac arrest. The overall goal is to provide myocardial rest; indications are listed in Table 50.9. Cannulation can be initiated via an open sternum with direct

atrial and aortic cannulation when the patient fails to wean from CPB or suffers a postoperative cardiac arrest. Alternatively, the neck or groin vessels can be accessed if there is more time for cannulation.

- The expected course of myocardial recovery after CPB is 3 to 5 days. If unable to wean from ECMO after this time and there are no residual cardiac lesions to be corrected, the possibility of cardiac transplantation should be explored. Most patients cannot be supported with ECMO for longer than 2 to 4 weeks owing to complications. Smaller ventricular assist devices are becoming available to bridge infants and young children to transplantation. Poor outcomes are seen in those who fail to wean from CPB, those with cavopulmonary connections, and adult congenital patients. The results of cardiac ECMO for all indications through July 2006 as reported to the international registry of the Extracorporeal Life Support Organization were 60% survival through decannulation and 42% survival to discharge.

SUPPORT OF THE MYOCARDIUM AFTER CARDIAC TRANSPLANTATION

- Myocardial function of the donated heart will depend on the circumstances leading to donor status, the level of vasoactive support preharvest, and the ischemic time. Recipient factors include preoperative PVR, end organ function, and the overall condition of the patient.
- The transplanted heart is denervated and tends to be bradycardic in the immediate postoperative period; pacing wires should be placed. Alternatively, isoproterenol can be used as a chronotrope, but it increases oxygen consumption and can cause arrhythmias and systemic hypotension at higher doses.
- All cardiac transplant patients should have both right and left atrial pressures monitored to differentiate right heart failure (RHF) caused by elevated PVR from biventricular failure due to graft ischemia or acute rejection. RHF is an important cause of morbidity and mortality after cardiac transplantation and should be treated aggressively.

Pulmonary Hypertension and Right Heart Failure

- Primary RHF and PH leading to secondary RHF are significant causes of postoperative morbidity. Primary RHF should be anticipated after right ventriculotomies for RV outflow tract reconstruction or conduit placement where the hypertrophied noncompliant RV may develop both systolic and diastolic dysfunction. Those at risk for PH and secondary RHF include patients with pulmonary arterial or venous obstruction, heart transplant recipients with elevated PVR from preoperative LA hypertension, and patients with preoperative PH from large left-to-right shunts.
- Patients expected to have a reactive pulmonary vascular bed should have a transthoracic PA or RV catheter placed intraoperatively. In the absence of direct PA pressure measurement, signs of PH include elevated right-sided filling pressures with normal or low left-sided filling pressures and tachycardia. Right-to-left shunts can become more cyanotic. As the right heart fails, physical exam will reveal poor perfusion, hepatomegaly, and possibly a loud tricuspid regurgitation murmur.

TABLE 50.9

INDICATIONS FOR VENOARTERIAL EXTRACORPOREAL MEMBRANE OXYGENATION

Low cardiac output

Cardiomyopathy with progressive dysfunction
Myocarditis
Failure to wean from cardiopulmonary bypass
Sudden cardiac arrest

Cyanosis

Marked intracardiac shunting with inadequate oxygenation
Acute obstruction to pulmonary flow (shunt thrombosis)
Pulmonary hemorrhage from pulmonary venous hypertension
Respiratory failure

Arrhythmia

Refractory primary arrhythmias
Postoperative arrhythmia

Support during interventional procedures

Intervention that creates life-threatening physiology

- In a pulmonary hypertensive crisis, signs of poor left heart filling including systemic hypotension and bradycardia occur. In the immediate postoperative period, evaluate for residual anatomic problems; residual pulmonary venous obstruction, PA stenosis, or significant left-to-right shunts can cause PH unresponsive to medical therapies.
- If PH is anticipated, patients may benefit from leaving the foramen ovale patent or even creating a new atrial level communication to allow the RV decompression. With the right-to-left shunt, systemic cardiac output will be preserved at the expense of mild cyanosis, which is usually well tolerated and transient.
- The post-CPB inflammatory response, PA endothelial dysfunction, and alveolar hypoxia from edema and atelectasis all contribute to PH but should be time-limited processes. The strategies for medical treatments are outlined in Table 50.10.
- Inhaled nitric oxide (iNO) is a selective pulmonary vasodilator without significant systemic hemodynamic effects usually delivered via a tracheal tube but can also be delivered via a face mask or nasal cannula. A reduction in PA pressure is usually seen at doses of up to 40 parts per million; higher doses may increase toxicity (from methemoglobinemia) without any additional benefit. With PH caused by severe LV dysfunction, pulmonary vasodilation can increase pulmonary blood flow and LA pressures, which may volume-overload the LV, causing further dysfunction.
- The most responsive patients appear to be those who have relief of pulmonary venous obstruction such as with repair of obstructed total anomalous pulmonary venous return or congenital mitral stenosis.
- It is an ideal agent to prevent RV failure in a transplanted heart due to elevated PVR.
- Once PA pressures have normalized and diuresis is achieved, iNO can be slowly weaned off. Rapid iNO weaning (e.g., dose lowered at intervals <4 to 6 hours), especially below doses of 5 parts per million, can result in “rebound” PH. If unable to wean off iNO, transition to sildenafil.
- Intravenous vasodilators are not selective for the pulmonary vasculature, but some agents still have a role in treating PH and RV dysfunction. Milrinone is used to afterload reduce

the RV and provide inotropic support and diastolic relaxation. Prostaglandin derivatives such as prostacyclin, delivered either nebulized or as an IV infusion, can be beneficial but are limited by systemic vasodilatory effects.

- Nonspecific vasodilators such as nitroprusside, tolazoline, and isoproterenol should be used infrequently for treatment of PH. Oral therapies for adults with chronic primary PH, including calcium channel blockers and endothelin receptor blockers, have not been adequately studied in children in the postoperative setting, but may have a future role.

SINGLE-VENTRICLE PHYSIOLOGY

- There are many variations of single-ventricle anatomy, but the defects can be broadly divided into those with obstruction to pulmonary blood flow (tricuspid or pulmonary atresia) or obstruction to systemic blood flow. Most will need a palliative operation; either an aortopulmonary shunt when pulmonary flow is obstructed or a stage I (Norwood) operation with aortic arch reconstruction and an aortopulmonary shunt or RV-PA conduit when systemic flow is obstructed. Occasionally, a patient will have two well-developed unobstructed outflow tracts and require a PA band shortly after birth as first-stage palliation.
- Most neonates with single-ventricle anatomy require prostaglandin E₁ to maintain adequate pulmonary or systemic blood flow via the ductus arteriosus. The single ventricle's output occurs in parallel rather than in series; output to the systemic and pulmonary circulations is dependent on the vascular resistance of each. The single ventricle's workload is the sum of the outputs to these two circulations so that the single ventricle does the work of two ventricles. During the postnatal transition, PVR falls rapidly, so these patients often develop excessive pulmonary blood flow and compromised systemic flow within a few days of birth. This is commonly referred to as pulmonary overcirculation.

Shunted Single-ventricle Physiology

- Irrespective of the operation, the principles of balancing the parallel circulations are the same. An acceptable balance of pulmonary-to-systemic blood flow can be defined as sufficient pulmonary blood flow to provide adequate systemic oxygenation without pulmonary overcirculation. An RV-PA conduit is less likely to create overcirculation compared to an aortopulmonary shunt, as pulmonary blood flow occurs only in systole but can still occur.
- Assuming normal pulmonary venous saturations of 100% and normal oxygen extraction with a mixed venous saturation of 60%, a systemic and PA saturation of 80% would result in a pulmonary blood flow (Q_p)-to-systemic blood flow (Q_s) ratio of 1:1 and correlate with a PaO₂ of 40 mm Hg. Typically, the Q_p:Q_s ratio is higher than this, and as it progresses toward 2:1, the single ventricle becomes volume-overloaded; ratio >2:1 may be associated with low systemic output, hypotension, and acidosis.
- The ability to monitor Q_p:Q_s accurately at the bedside is limited. Arterial saturations and mixed venous saturations can be measured, but pulmonary venous saturations are assumed. The degree of postoperative lung disease is highly variable, assuming that pulmonary venous saturations are normal can

TABLE 50.10

TREATMENT OF POSTOPERATIVE PULMONARY HYPERTENSION

Encourage/administer

Investigate for residual shunts, obstructions to pulmonary blood flow
 Supplemental oxygen
 Mild alkalosis (pH 7.45–7.5)
 Mild hyperventilation (pH 7.45–7.5)
 Sedation and analgesia, consider paralysis
 Inotropic support of right ventricle
 Intravenous vasodilators
 Inhaled nitric oxide

Avoid

Metabolic acidosis (pH <7.30)
 Hypoventilation or respiratory acidosis
 Agitation and pain
 Alveolar hypoxia
 Atelectasis or alveolar overdistention
 Polycythemia

erroneously underestimate pulmonary blood flow and the degree of overcirculation in patients with low systemic oxygen saturations. Patients with complete cardiac mixing, high systemic saturations (>90%) and high arterial PaO₂ (>50 mm Hg) with low blood pressure and metabolic acidosis should be treated for pulmonary overcirculation.

- Strategies to treat pulmonary overcirculation focus on increasing PVR and decreasing pulmonary blood flow. Transfusing the patient to a hematocrit of 45% to 50% will increase blood viscosity and PVR. Minimizing inspired oxygen to a room air level and/or lower (e.g., FiO₂ of 17%–19%) with the addition of nitrogen also increases PVR. Allowing the PaCO₂ to rise (e.g., to 45–50 mm Hg with a pH <7.34) with hypoventilation or by the addition of carbon dioxide to the ventilator circuit has a similar effect but may increase oxygen delivery to the brain as measured by increased mixed venous saturations in the SVC and decreased arteriovenous saturation difference.
- High SVR should be avoided, as it increases pulmonary blood flow and the afterload on the single ventricle. High upper-extremity blood pressures and oxygen saturations should raise the suspicion of residual coarctation of the aorta in single-ventricle patients and aortic arch obstruction. Large-dose catecholamines should be avoided, and afterload reduction with milrinone should be optimized.
- If a patient remains in a low cardiac output state despite ventilatory and pharmacologic strategies to limit pulmonary blood flow, surgical options such as narrowing the pulmonary conduit or aortopulmonary shunt with clips should be considered.
- Excessive cyanosis is less common after patients are palliated with an aortopulmonary shunt, but it does occur. Possible etiologies include lung disease, elevated PVR, obstruction to pulmonary blood flow, and low mixed-venous saturation from increased oxygen consumption or low cardiac output.
- When a shunt-dependent postoperative patient suddenly develops oxygen desaturation and bradycardia, it should raise the suspicion of acute shunt thrombosis. These patients need emergent cannulation for ECMO and shunt revision. Many patients with shunted single-ventricle physiology have labile hemodynamics for the first several postoperative hours to days. Delayed sternal closure is an accepted strategy that provides rapid access for additional procedures such as clipping of the shunt and emergent ECMO cannulation.

Cavopulmonary Connections

- The transition to a SVC-PA connection, which is called a bidirectional Glenn (BDG) shunt, is typically performed when the patient is 3 to 6 months old. The BDG is the first of a two-stage conversion to a total cavopulmonary circulation with separation of pulmonary and systemic blood flow (Fontan circulation) to reduce volume load and work for the single ventricle. Systemic hypertension and irritability are common after the BDG; this may be secondary to intracranial hypertension from elevated SVC pressures. Mild hypertension preserves cerebral blood flow during the transition to passive pulmonary blood flow through the BDG. Systemic hyperten-

sion associated with bleeding or marked hypertension (>120 mm Hg systolic blood pressure) should be treated.

- Cyanosis associated with elevated SVC pressure occasionally occurs after BDG. If there is a low transpulmonary gradient with elevated atrial pressures, ventricular function should be optimized with inotropes. If the atrial pressures are low and the transpulmonary gradient is >10 mm Hg, this suggests either anatomic obstruction to pulmonary blood flow or elevated PVR.
- The role of carbon dioxide and its effects on PVR and pulmonary blood flow are complex in BDG patients. Modest hypoventilation with elevated carbon dioxide increases arterial PaO₂, presumably by increasing pulmonary blood flow via greater cerebral blood flow from cerebral autoregulation. The vasodilatory role of carbon dioxide in the brain predominates over any increase in PVR from hypoventilation and lower blood pH. The data for use of nitric oxide in these patients are mixed.
- Positive pressure ventilation and increased intrathoracic pressures may play a role in limiting passive pulmonary blood flow, so early extubation is advocated. An SVC pressure >20 mm Hg that is unresponsive to medical therapies is concerning for the successful transition to BDG physiology. Postoperative cardiac catheterization to assess for reversible causes and consideration of possible takedown of the BDG should be pursued.
- The final stage is the completion of the cavopulmonary connection with a Fontan operation performed with either a lateral tunnel baffle through the common atrium or an extracardiac conduit, usually when the patient is 2 to 3 years old and weighs 10 to 15 kg. Postoperative concerns are usually focused on PVR and cardiac output, with an ideal Fontan baffle pressure at 10 to 15 mm Hg and a transpulmonary gradient of <10 mm Hg.
- A Fontan baffle pressure >20 mm Hg is worrisome. Elevated Fontan baffle and atrial pressures indicate low cardiac output or tamponade physiology. An elevated Fontan baffle pressure with a low atrial pressure indicates either high PVR or obstruction in the Fontan pathway; these patients should be promptly investigated and treated.
- Low Fontan baffle and atrial pressures indicate inadequate intravascular volume status. The passive pulmonary blood flow of the Fontan circulation is preload dependent, so hypovolemia will quickly lead to low cardiac output and hypotension.
- Patients undergoing Fontan operations often have sinus node dysfunction with junctional rhythm. AV synchrony is preserved with mechanical pacing to maximize cardiac output.
- Surgical fenestration allows right-to-left shunt to decompress the Fontan baffle and causes mild oxygen desaturation but preserves cardiac output by increasing preload to the ventricle. The Fontan circulation is highly sensitive to elevations in PVR, so acidosis, alveolar hypoxia, and atelectasis should be avoided. As the patient diureses and is extubated from positive pressure ventilation, PVR decreases, and the arterial oxygen saturation improves as less blood is shunted right to left. The fenestration may be electively closed with an occluder device during cardiac catheterization at a later time with good intermediate functional outcomes.

CHAPTER 51 ■ VASCULAR SURGERY IN THE INTENSIVE CARE UNIT

- Patients requiring open vascular or endovascular procedures are elderly and have comorbidities that complicate their overall care. The perioperative care of the vascular surgery patient requires meticulous attention to detail and knowledge about the possible pitfalls these patients can encounter to achieve acceptable perioperative outcomes. A key element is the recognition of vascular pathology as a systemic disease and not just a focal anatomic problem regardless of the procedure.
- **Atherosclerosis** affects the blood vessels of all circulatory beds: cardiac, peripheral, and cerebral. Patients with leg ischemia are at significantly higher risk over the general population for having myocardial infarctions and/or cerebrovascular accidents. The average patient with claudication has an estimated mortality rate of 50% over 5 years, predominantly from cardiovascular causes. Evidence suggests increased inflammation in vascular patients. These patients have elevated levels of C-reactive protein, interleukin-6 (IL-6), and soluble intercellular adhesion molecule-1. Elevated C-reactive protein is a predictor of cardiovascular events among patients with peripheral artery disease.
- **Tobacco use** exceeds 50% and often approaches 90% in patients with peripheral artery disease. Patients with vascular occlusive disease have a high incidence of **chronic obstructive pulmonary disease, occult cardiac disease, diabetes, and renal insufficiency**. The adverse pulmonary sequelae of vascular procedures are frequently related to the ravages of smoking. Endovascular therapy, despite decreased durability, may be appropriate for patients based on their condition and ability to tolerate general anesthesia. Similarly, spinal or epidural anesthesia, rather than general anesthesia, may be more appropriate.
- **Coronary artery disease** is present in up to 93% of patients undergoing the most common vascular procedures (abdominal aortic aneurysm [AAA] repair, carotid endarterectomy, peripheral bypass). Additionally, most vascular surgery procedures for occlusive or aneurysmal disease are considered “high-risk.” Much attention has been given to preoperative risk stratification and how to minimize the risk of perioperative cardiac events in the vascular surgery patient.
 - The American Heart Association/American College of Cardiology goals should be targeted, including a blood pressure <140/90 mm Hg, serum low-density lipoprotein <100 mg/dL, and hemoglobin A_{1C} <7%.
 - To achieve these goals, patients should be on an aspirin, a β -blocker dosed judiciously to a target heart rate of 70 to 75, an angiotensin-converting enzyme inhibitor, or other antihypertensive therapy.
 - The electrocardiogram should be monitored continuously for any changes suggestive of ischemia.
- Coronary revascularization (percutaneous or open) before elective major vascular surgery has not been shown to decrease the overall mortality.
- A preoperative cardiology consultation may be useful to help determine existing cardiac function.
- There is increasing evidence that all patients with vascular disease, regardless of cholesterol levels, benefit from **statin therapy** due to its anti-inflammatory, immunomodulatory, and anticoagulant effects.
- Perioperative continuation of statin therapy is recommended due to a rebound effect and a possible increase in cardiovascular complications with abrupt discontinuation.
- Cardiac dysrhythmias are often caused by ischemia, electrolyte disturbances, or fluid shifts in the postoperative period. Patients should be monitored closely for such events.
- **Renal insufficiency**, as determined by creatinine clearance, may be present in vascular patients without prior known elevated serum creatinine. Perioperative mortality after most vascular procedures is increased in patients with renal failure. Nephrotoxic effects of the IV contrast commonly used in revascularization procedures make postoperative renal dysfunction a constant threat. Strict monitoring of fluid balance, maintenance of serum electrolytes, appropriate dosing of nephrotoxic medications, adequate hydration, and resumption of chronic diuretics may minimize the chance of postoperative renal dysfunction.
- **Diabetes mellitus** is present in the majority of vascular patients. This group is at higher risk for postoperative vascular and nonvascular complication. Patients with diabetes have a higher rate of postoperative amputations after peripheral bypass surgery for tissue loss and a higher rate of wound infections. Additionally, patients with diabetes can manifest angina as nausea, diaphoresis, or “indigestion.” Euglycemia should be maintained, utilizing a constant IV infusion of insulin if necessary.
- **Hypercoagulability** is present in a subset of patients with vascular disease. Suspicion for a hypercoagulable state should be raised with patients with seemingly advanced atherosclerotic disease at a younger age. A careful history can assist with determining these patients, but when identified, they should be started on appropriate anticoagulation. A hematology consultation should be obtained but may be of somewhat limited value in the setting of the acute thrombotic event.

VASCULAR CARE IN THE INTENSIVE CARE UNIT

- The routine assessment of the vascular intensive care unit (ICU) patient includes not only all the usual cardiovascular,

pulmonary, and metabolic parameters but frequent and detailed physical exams. Objective assessment of distal perfusion should be performed regularly, even hourly, in the immediate postoperative period. This assessment includes looking at the extremity for cutaneous signs of malperfusion, assessing motor function, and palpating the major muscle groups for tenseness, which may signify compartment syndrome in patients who are too sedated to relate the classic “pain with passive motion.” All incisions should be inspected for signs of early wound complications such as infection, separation, or hematoma.

- **Extremity perfusion** should be assessed by checking for palpable pulses; if none is found, Doppler signals must be auscultated to assess the perfusion.
 - Normal Doppler signals are described as *triphasic*.
 - Doppler signals distal to an obstruction may be characterized as *biphasic* or *monophasic* with the latter suggesting significantly diminished blood flow.
 - Extremity perfusion is assessed prior to leaving the operating room (OR). The quality and location of each Doppler signal or palpable pulse should be communicated and recorded as a reference.
 - A worsening exam or inability to detect the signal may potentially constitute an emergent trip back to the operating room to restore perfusion.
 - Bedside ankle-brachial index measurements is an objective marker of extremity perfusion. Any change of more than 0.15 is significant and should be reported, independent of any other clinical event.
- **Compartment pressure** monitoring devices are advocated by some centers. We perform fasciotomies emergently if compartment syndrome is even suspected. Fasciotomies can be performed in the ICU setting using Bovie electrocautery and sterile scissors.
 - The two-incision technique—a medial infrageniculate incision releasing the deep and posterior compartments—and a lateral incision release the anterior and lateral compartments.
 - The underlying muscle should bulge when released, thereby confirming the diagnosis.
 - The wound should be left open and treated with routine dressing changes with subsequent closure in several days to weeks when the swelling abates.
 - Metabolic sequelae of compartment syndrome may consist of cellular lysis with release of potassium and myoglobin that may cause systemic hyperkalemia and acute renal failure.
 - We routinely check urine myoglobin and administer aggressive IV fluids to ensure brisk urine output of at least 100 mL/hour. Electrolytes are checked frequently, and continuous telemetric cardiac monitoring is employed.
- **All vascular surgery wounds** should be examined daily for signs of infection. Groin wounds can be problematic, with wound complications in up to 44%. Most wound breakdowns can be treated with local wound therapy at the bedside. However, wound breakdown with exposure of the underlying vascular graft or anastomosis is a serious vascular wound complication due to the devastating potential for anastomotic disruption. In this situation, patients should be scheduled for the OR for exploration and attempted reclosure of the wound, preferably with autogenous tissue such as a sartorius or rectus flap. Additionally, it is imperative that all health care per-

sonnel treating the patient be aware of exposed vasculature. A “blowout precaution” protocol may be instituted wherein patients are kept at bedrest and blood is typed and crossed. Any bleeding from the wound is a potential emergency. Immediate pressure should be placed on the wound, the patient stabilized, and the operating team notified. Direct pressure on the wound should be maintained until the patient is intubated and anesthetized, the surgeon scrubbed in, and the operative field prepped (even if this includes the team member’s gloved hand being prepped into the field).

- **Meticulous skin care** is mandatory for the vascular patient. Even modest duration of pressure on the heel by the bed mattress can lead to skin breakdown and turn a successful revascularization into an amputation. As the vast majority of vascular patients have compromised distal perfusion, heels may be elevated off the bed by placing pillows under the leg to distribute leg weight over a larger surface area. There is no substitute for frequent inspection of all pressure-sensitive areas, and this should be part of the physician’s and nurse’s practice.
- **Pharmacologic prophylaxis** against thromboembolic events is the routine. All vascular patients in an ICU have a propensity for developing venous thromboembolic events as dictated by Virchow’s triad. Venous stasis is inevitable in the postsurgical patient due to relative immobility. Endothelial injury occurs during the course of the surgical procedure. Many patients require systemic anticoagulation after vascular surgical procedures such as with distal bypasses when there is compromised outflow or less than ideal conduit. The need for systemic anticoagulation must be balanced with the risk of bleeding complications, and usually we hold off full anticoagulation until postoperative day 2 or 3. Patients are monitored for any decline in platelet counts, and if seen, a heparin antibody panel is sent. If the clinical suspicion is high, we stop all heparin and switch to anticoagulation with other agents.
- **Stress gastritis** is a constant threat in the vascular ICU patient. Consideration of either histamine-receptor blockers or proton pump inhibitors, irrespective of any clinically detected gastrointestinal hemorrhage, is suggested.
- **Ventilator-associated pneumonia** has been well documented to increase in-hospital mortality, length of stay, and overall cost of hospitalization. We employ routine suctioning, aggressive bronchoscopy to control secretions, and head elevation for all our intubated patients. Once extubated, activity is encouraged, and adequate pain control is important for patients with an abdominal or a thoracic incision.
- **Acute limb ischemia** in the ICU setting can have disastrous consequences. The pathologic differential includes embolic events (usually from cardiac or aortic sources) or *in situ* thrombosis of preexisting atherosclerotic lesions.
 - If identified acutely, there may be a role for intra-arterial thrombolysis, although this modality is limited due to excessive bleeding risk in the postsurgical patient.
 - When an ischemic extremity is identified, patients should immediately be fully anticoagulated.
 - More aggressive intervention, either catheter-based therapy or open surgical thrombectomy, should be entertained.
 - If the acute arterial occlusion is associated with motor or sensory deficits, an emergent exploration is indicated.
 - On rare occasions, patients present with acute lower-extremity paralysis secondary to acute infrarenal aortic occlusion. Absence of femoral pulses is a clue to the

vascular nature of the paralysis. These patients typically require emergent procedures, and despite operative success, the perioperative mortality rate exceeds 50%.

- **Common ICU causes of arterial occlusion** include sequelae of invasive monitoring, usually intra-arterial lines.
 - Brachial artery cannulations for cardiac catheterizations have an overall complication rate as high as 36%.
 - Arterial lines can impair distal perfusion. In this situation, the first step is to remove the catheter and to observe for restoration of perfusion.
 - The collateral blood supply and distal perfusion should also be assessed, and a motor and sensory assessment of the affected limb should be performed.
 - Choices of therapy include observation, systemic anticoagulation, local thrombolysis, and operative thrombectomy with the potential for bypass.
- **Invasive arterial and venous monitoring** is a challenge in the vascular ICU patient.
 - Lower-extremity IV and arterial lines are contraindicated in patients with peripheral arterial occlusive disease.
 - Patients with dialysis-access fistulae should have that extremity kept free of IVs, central venous catheters, invasive arterial lines, and noninvasive blood pressure cuffs.
 - If a patient is likely to require future permanent vascular access, duplex ultrasonography should be used to identify a potential arm. Invasive lines in this arm should be avoided.
- **Various bleeding complications** can occur in the postoperative vascular wound. These can range from simple “skin edge” bleeding to frank exsanguination.
 - Skin edge bleeding may be a nuisance and may be treated with manual compression, application of silver nitrate, or a simple suture.
 - Hematomas are monitored closely. Recurrent blood transfusion requirements, overlying skin or wound compromise, deleterious mass effects, and hemodynamic instability are all indications for operative evacuation of the hematoma.
 - Patients who have had percutaneous interventions (usually through the groin at the common femoral artery) should also be monitored for hematomas.
 - Attempted femoral artery punctures that are aimed more cephalad may in fact be external iliac artery punctures. Compression may be ineffective due to the retroperitoneal location of the arteriotomy. A progressive hematoma in such a location more often requires surgical repair (open or endovascular).

SPECIFIC CONDITIONS

Aneurysmal Disease

The natural history of aneurysms of the aorta is to expand and rupture. An unstable condition develops as expansion of the aortic diameter leads to further aortic wall thinning and, by the Law of Laplace, increased wall tension. Increased wall tension promotes further aortic dilatation, and the vicious cycle continues until the aortic wall ruptures.

Infrarenal Abdominal Aortic Aneurysm

- Approximately 90% of the extracranial aneurysms involve the infrarenal aorta.
- Most aneurysms are asymptomatic and are discovered during radiographic workup of other problems.
- Symptomatic aneurysms frequently present with back or abdominal pain. These symptoms may herald impending rupture and thus require urgent repair.
- Operative repair is recommended when the aortic aneurysm diameter reaches 5.5 cm in asymptomatic males.
- Preoperative preparation includes a single dose of preoperative antibiotics for all patients and arterial lines, central lines, and Foley catheters for most patients.

Endovascular Repair

- Depending on patient anatomy and institutional expertise, abdominal aortic aneurysm repair can be performed via an endovascular approach. This approach is appealing in terms of reduced physiologic insult to the patient. These patients rarely require admission to the ICU but are monitored for hematomas and lower-extremity pulses. The devices used to deploy endovascular stents can be as large as No. 26 French, and these are introduced through femoral or external iliac arteries. There is a possibility of local arterial damage or dislodging of plaque that may embolize distally.

Open Repair

- Open aneurysm repair, conversely, requires surgical ICU monitoring postoperatively. The overall perioperative mortality is approximately 5%. Bleeding is the main concern due to the aorta-to-graft anastomosis. Perfusion of the lower extremities is an additional concern due to arterial occlusion during the procedure. Lower-extremity ischemic events after open abdominal aortic aneurysm repairs occur in 2% to 5% of patients. Any inability to detect a Doppler signal or palpate a pulse when there previously was one is a potential surgical emergency.
- **Postoperative complications**
 - **Prolonged postoperative ileus** may occur in up to 11% of patients. A retroperitoneal approach may be shorten the duration of postoperative ileus.
 - Nonischemic diarrhea may occur in 7.1% of patients.
 - **Colonic ischemia** has an estimated prevalence of 0.6%. It typically presents as bloody stools 3 to 5 days postoperatively but may occur as early as the first 24 hours after surgery. Additional signs of colonic ischemia are fever, abdominal pain, thrombocytopenia, unexplained leukocytosis, or lactic acidosis.
 - Any suspicion of colonic ischemia should prompt endoscopic evaluation, with the caveat that endoscopy cannot evaluate for transmural ischemia.
 - In the appropriate clinical setting, mucosal ischemia may justify operative exploration with possibly colon resection and end colostomy.
 - Broad-spectrum antibiotics to include gram-negative and anaerobic coverage are used.
 - Patients with colonic ischemia require intensive invasive ICU monitoring, as they often progress to multisystem organ failure.
 - **Pancreatitis and cholecystitis** may also complicate aneurysm surgical repair.
 - Pancreatitis is self-limited and likely related to direct surgical trauma during aortic exposure.
 - Cholecystitis may be ischemia-related or may be a variant of acalculous cholecystitis seen in ICU patients. Treatment

options range from percutaneous cholecystostomy to surgical cholecystectomy.

- **Postoperative renal dysfunction** can be as high as 5.4% after open infrarenal aortic surgery, but dialysis requirement is much less at 0.6%. The exact etiology of the renal dysfunction after infrarenal clamping is largely speculative but may involve migration of atheroemboli leading to acute tubular necrosis.
- Renal dysfunction is lower in patients with infrarenal versus suprarenal aortic cross-clamping.
- In the early postoperative period, oliguria is most frequently due to intravascular depletion and not intrinsic renal dysfunction.
- Patients with baseline renal insufficiency or those who do not respond appropriately to IV fluid challenges should be investigated for acute tubular necrosis or other intrinsic cause of oliguria.
- **Thrombocytopenia** may occur in the absence of other causes (e.g., colon ischemia). Although an inciting event or agent is not always identifiable, there are several likely etiologies. Unless there is evidence of ongoing bleeding, mild thrombocytopenia is usually well tolerated.
- Perioperative cardiac events occur in 15% for any perioperative cardiac event is observed in patients with AAAs. Patients with AAAs may have coronary artery disease and are at risk for postoperative myocardial infarctions (5.2%), heart failure (8.9%), and dysrhythmia requiring treatment (10.5%). Unless contraindicated, patients undergoing open aneurysm repair should be on a medical regimen consisting of a β -blocker with a target heart rate of 70 to 75, a statin (independent of serum cholesterol levels), and some form of antiplatelet therapy, usually aspirin.

Ruptured Aortic Aneurysms

- Operative mortality rate of ruptured AAA is near 50% versus <5% in elective cases. With ruptured AAA, there are impressive fluid shifts that transpire during such an emergent operation, independent of overt blood loss. These fluid shifts, associated with the hypotension and the physiologic strain of an emergent procedure, contribute to a tenuous postoperative course. The incidence of colonic ischemia is significantly higher after ruptured aneurysm repair compared to elective open aneurysmorrhaphy, and some authors recommend empiric and routine endoscopic evaluation of the colonic mucosa.

Juxtarenal or Suprarenal Aortic Aneurysms

- Aneurysms that extend to the level of the renal arteries or involve the paravisceral aorta are technically more challenging.
- Postoperative complications escalate dramatically due to renal and possibly mesenteric ischemia-reperfusion.
- Depending on the length of intraoperative ischemia, there is a resultant release of pro- and anti-inflammatory cytokines that drives a systemic inflammatory reaction resulting in multisystem organ failure.
- There is considerable third spacing of fluid in the first 24 hours. Attempts to improve mortality and morbidity by a hybrid approach involving multiple visceral bypasses and endovascular repair of the aneurysm have met with mixed results.
- Adequate pain control is key in these patients.

Infected Aortic Graft

- One of the more dreaded complications of aortic surgery is infection of the prosthesis. Graft infection is a serious problem and should be investigated and treated aggressively.
- Early postoperative graft infection is rare. The majority occur months to years later, with unexplained fevers.
- Infection may also present as gastrointestinal bleeding (a manifestation of an aortoenteric fistula) or a draining sinus in the groin.
- The causative organism is usually *Staphylococcus*.
- Computed tomography (CT) scan shows fluid around an aortic graft.
- Broad-spectrum antibiotics, IV resuscitation, and close hemodynamic monitoring should be undertaken. Patients should be medically optimized and prepared for a staged procedure. The initial step is usually an extra-anatomic bypass with subsequent laparotomy and excision of the aortic graft. In good operative candidates, a single-stage aortic replacement using autogenous tissue (syndactylized bilateral femoral veins) or cadaveric vessels can be performed. Patients are routinely sent to the ICU as some may become floridly septic after manipulation of the infected retroperitoneum.

Arterial Occlusive Disease

Aortoiliac Occlusive Disease

- The most durable surgical solution for aortoiliac occlusive disease is an aortobifemoral bypass.
- Peripheral pulses are regularly monitored. Any deviation from the immediate postoperative pulses is a potential emergency as it may represent a graft thrombosis.
- Distal embolization involves ischemia of the toes (trash foot). Management is expectant, and most often this resolves with minimal or no permanent tissue loss.
- Patients < 55 years of age are believed to have better long-term vascular durability for infrarenal aortic reconstruction with autogenous tissue rather than Dacron grafts.
- Redo aortic surgery is fraught with intraoperative and postoperative complications. Extra-anatomic bypasses may be performed, usually axillobifemoral.
- As endovascular technology evolves, many iliac lesions are treated with angioplasty and possible stent placement.

Infrainguinal Bypasses

- The incisions that are made are significant, and may not only be located on the extremity being reperfused but may be on either leg or either arm as a site of vein harvest.
- The patency of infrainguinal bypass grafts using autogenous tissue is superior to that using prosthetic tissue.
- The main sources of morbidity from these procedures are arterial occlusion, bleeding, and wound complications.
- The mortality from peripheral bypasses is estimated to be between 2% and 8%.
- Mortality is primarily cardiac. Aggressive cardiac medical management, judicious use of antiplatelet therapy, and careful fluid status monitoring are essential.
- Bypass is associated with a reperfusion syndrome. The reperfused extremity should be monitored for compartment

syndrome, and electrolytes and urine myoglobin should be monitored.

Carotid Endarterectomy

- Carotid endarterectomy decreases the chance of a future cerebrovascular accident in certain patients with carotid stenosis. The key outcome variable is perioperative stroke related to disruption of cerebral blood flow or embolic event from clamping an atherosclerotic vessel.
- Aspirin should be continued in the recovery phase. Full anticoagulation is seldom indicated unless carotid occlusion has occurred.
- A new neurologic deficit may manifest itself upon awakening or occur in the early postoperative period. This should be investigated with imaging or a return to the OR.
- Large postoperative fluctuations in blood pressures occur due to carotid bulb baroreceptor “stretch.” Blood pressure should be targeted to the “normal range” of 120 to 140 mm Hg.
- Wound hematoma is of concern as a moderate hematoma can cause carotid compression and resultant bradycardia or airway compression. The operating team should be alerted if hematoma is suspected.
- Several cranial nerves are intimately associated within the field of dissection. Thus, a detailed head and neck exam is mandatory at regular intervals.
- Particular attention should be paid to assessing the function of the marginal mandibular nerve and the hypoglossal nerve.
- Headache and seizure activity may be manifestations of cerebral reperfusion syndrome. This is rarely seen in the immediate postoperative period but may cause readmission for blood pressure control in the weeks after carotid endarterectomy.
- Patients with these symptoms should receive a CT scan due to the incidence of intracranial bleeding that accompanies these symptoms.

Mesenteric Revascularization

- Mesenteric ischemia, whether acute or chronic, can have lethal consequences. The restoration of intestinal perfusion sets in motion a cascade of inflammatory cytokines that frequently progress to the systemic inflammatory response syndrome, multisystem organ failure, and even death.
- After restoration of blood flow, patients typically have a period of hemodynamic stability for 24 to 48 hours after the procedure.
- After 48 hours, some patients show signs of unrelenting systemic inflammation with a continuation of fluid third spacing and progressive thrombocytopenia.
- Efforts to predict which patient will progress to clinical deterioration have been unsuccessful.
- Like any other revascularization bypass, the patency of the mesenteric graft should be assessed objectively. Duplex ultrasound is noninvasive and is highly sensitive.
- Despite all the usual supportive measures, the average postoperative length of stay is more than 3 weeks.

Aortic Dissections

- Dissections start as an intimal flap, and blood escapes the true lumen and channels down the aorta, shearing apart the layers of the wall.
- Dissections of the ascending aorta (Stanford type A) are cardiac surgical emergencies, as potential retrograde dissection can cause coronary malperfusion or cardiac tamponade.

- Dissections of the descending aorta (Stanford type B) are usually treated medically with aggressive blood pressure control.
- Four indications for operative intervention are branch vessel malperfusion (usually celiac, superior mesenteric, renal, or iliac), inability to control hypertension, persistent pain related to the dissection, or aneurysmal degeneration.
- Dissections can be repaired via open techniques or endovascularly.
- Postoperative blood pressure control is paramount.

Hemodialysis

- Although the annual mortality of patients on hemodialysis approaches 25%, many patients in the ICU are on chronic hemodialysis with functional fistulae.
- The extremity with the fistula should be preserved from invasive and noninvasive monitoring devices, and all IVs and central lines should be placed away from that extremity if possible.
- If a fistula is present, the extremity distal to it is at risk of ischemic events and should be monitored closely.
- Tunneled catheters should not be used as an IV line except in dire circumstances. Limiting their use to their intended purpose will decrease the chance of infection.
- It is routine practice to “lock” the catheter with concentrated heparin to decrease mechanical catheter complications. Flushing this heparin “lock” will systemically anticoagulate the patient.

Vascular Trauma

The care of the trauma patient with vascular injuries shares many of the same principles as care of other vascular surgery patients with the exception that this cohort frequently, but not always, lacks the systemic comorbidities of the typical atherosclerotic vascular patient.

- Most extremity vascular injuries are associated with orthopedic fractures and dislocations (e.g. posterior knee dislocation and popliteal artery injury).
- Extremity pulses should be assessed in the secondary survey as part of the Advanced Trauma Life Support evaluation and clearly documented.
- The same assessment is merited in any patient recovering from an orthopedic procedure.
- Any change in pulse exam or hard sign of vascular injury mandates radiographic evaluation, usually with an arteriogram or, alternatively, with a CT angiogram.

Penetrating extremity trauma associated with hard signs of vascular injury (decreased distal perfusion, active arterial hemorrhage, or a rapidly expanding hematoma) should be evaluated immediately after lifesaving measures are undertaken.

- Operative exploration with visual inspection of the vessel should be performed.
- If injured, it is either repaired or blood flow is rerouted around the “blast field.”
- Venous injuries are ligated unless easily repaired.
- Revascularization of an extremity malperfused for >6 hours increases the likelihood of a reperfusion syndrome and/or compartment syndrome.

- Fasciotomy is prudent if there is any question of reperfusion injury.
- Severe musculoskeletal damage beyond that which is salvageable can be treated with simple ligation and amputation.
- Trauma to an artery and adjacent vein can cause an arteriovenous fistula. This can present months after the inciting trauma with unexplained extremity swelling, distal ischemic symptoms, heart failure, or an audible bruit over an extremity.

Aortic trauma is increasing, possibly due to the increased use of CT scans in trauma management. With the resolution of the current scanners, we are seeing a number of intimal injuries and short segments of dissection that previously were not detected.

- In the absence of hemodynamic compromise, most intimal injuries or short dissections of the in the infrarenal aorta and iliac vessels can be observed.
- In the abdomen, any central periaortic hematoma should be operatively evaluated.
- Initial care thoracic aortic injuries of is directed toward treating the urgent life-threatening injuries and controlling blood pressure with β -blockers.
- Thoracic aortic injuries are increasingly treated with endovascular devices. Though open surgical repair is still a viable option, in most series the morbidity is clearly greater.

Penetrating neck trauma can involve the carotid artery, which can be exposed readily in certain locations (zone 2).

- In the stable patient with a zone 2 injury, perform the global assessment of the patient, including abdominal sonography and IV resuscitation, and then take the patient to the OR for exploration.
- For more proximal or distal injuries (zones 3 and 1), angiography (standard contrast angiography or CT angiography) plays a vital role in both diagnosing and planning either open or endovascular treatment.

Blunt cerebrovascular injury injuries are relatively rare (<1% of blunt trauma patients), and controversy remains about the best way to diagnose and treat these patients. The Eastern Association for the Surgery of Trauma guidelines recommend screening, preferably with angiography, for blunt trauma patients who present with the following:

- Cervical spine fractures
- LeFort II or III fractures
- Petrous bone fracture
- Fracture through the foramen transversum
- Glasgow coma scale <8 or diffuse axonal injury

Additionally, any patient with an unexplained neurologic deficit should prompt further investigation.

The general consensus is that these lesions should be treated with either full anticoagulation or an antiplatelet agent that should continue for 3 to 6 months. Occasionally, pseudoaneurysms are seen, and endovascular repair seems to be the evolving treatment modality for this lesion. Morbidity from this lesion remains high as many patients present with a deficit.

CHAPTER 52 ■ CNS VASCULAR DISEASE

IMMEDIATE CONCERNS

Stress Points

- Strokes may be ischemic, resulting from the occlusion of small or large arteries, or hemorrhagic, resulting from the rupture of a conducting artery or an intraparenchymal arteriole.
- An abrupt focal lateralizing neurologic deficit attributable to a cerebrovascular distribution is the hallmark of ischemic stroke.
- A depressed level of consciousness is rarely the presenting symptom of ischemic stroke and much more commonly occurs in the setting of a hemorrhagic event.
- Patients with acute ischemic stroke may be candidates for thrombolytic therapy, but the therapeutic window is extremely narrow, so timely diagnosis and evaluation are of the utmost importance.

Essential Diagnostic Tests and Procedures

- A computed tomography (CT) scan of the brain is critical for the initial evaluation and management of the stroke patient.

Additionally, when available, CT angiography and perfusion studies may aid in diagnosis and management.

- Magnetic resonance imaging (MRI) is more sensitive than CT, but it is usually less available urgently, and patients must remain still for a much longer period of time.
- Vascular ultrasound allows rapid bedside assessment of abnormal flow within the major intracranial and extracranial arteries and can provide valuable immediate information about the vascular physiology to supplement the anatomic information provided by the CT scan.
- A transthoracic or transesophageal echocardiogram may identify potential cardiac sources of cerebral emboli.
- An electrocardiogram followed by continuous cardiac telemetry monitoring is often necessary to identify arrhythmias associated with stroke.
- A lumbar puncture may be necessary to rule out subarachnoid hemorrhage (SAH) in patients in whom the diagnosis is strongly suspected, but CT is unrevealing.

Initial Therapy

- Thrombolytics are the mainstay of treatment of acute ischemic stroke in eligible patients.

- Careful attention to blood pressure may reduce complications such as hemorrhage.
- Supportive care, with special attention paid to prevention of aspiration pneumonia and deep-vein thromboses, is essential to reduce mortality associated with stroke.
- Rapid initiations of secondary preventive therapies are effective in reducing risk for recurrent stroke.
- Certain patients, such as those with large ischemic or hemorrhagic strokes, will require monitoring of intracranial pressure and, potentially, decompressive surgery.

DIFFERENTIAL DIAGNOSIS

Stroke Symptoms

- Most patients who suddenly develop a lateralized focal neurologic problem have, in fact, had a stroke (Table 52.1).
- When the presentation differs from this definition, further investigation and supportive evidence should be sought before establishing the diagnosis.
- Many stroke symptoms may occur alone, unaccompanied by other evidence of neurologic damage, that are not an expression of vascular disease.
- Most of the errors in the diagnosis of stroke occur in patients with altered mental status. Beware of attributing such non-focal symptoms to strokes without corroborating historic or diagnostic evidence.

Diseases Most Commonly Mistaken for Stroke

- Epilepsy mimics stroke more often than any other condition (Table 52.2).
- Intracranial hemorrhage, encephalitis, or other structural brain lesions, such as tumors, may produce focal deficits identical to ischemic stroke.
- Drug intoxication, alcohol, or metabolic abnormalities constitute the next largest group of mistaken diagnoses in patients suffering confusion and neurologic deficits.
- Extreme electrolyte or serum glucose derangements can produce temporary focal deficits.
- Migraine may produce several transient neurologic symptoms that may be misinterpreted as stroke.
- Occasionally, peripheral nerve lesions, such as Bell palsy, may appear suddenly and mimic an ischemic stroke.

TABLE 52.1

SYMPTOMS SELDOM RESULTING FROM CEREBROVASCULAR DISEASE

Vertigo alone	Confusion
Dysarthria alone	Memory loss
Dysphagia alone	Delirium
Diplopia alone	Coma
Headache	Syncope
Tremor	Incontinence
Tonic-clonic motor activity	Tinnitus

TABLE 52.2

CONDITIONS MOST FREQUENTLY MISTAKEN FOR STROKE

Seizures	Peripheral neuropathy and Bell palsy
Metabolic encephalopathy	Multiple sclerosis
Cerebral tumor	Hypoglycemia
Subdural hematoma	Encephalitis
Cerebral abscess	Migraine
Vertigo, Ménière disease	Psychogenic illness

Ischemic Stroke

Pathogenesis

- Ischemic stroke occurs when the supply of blood to brain tissue is acutely interrupted.
- Autoregulation of the cerebral vasculature adjusts vascular resistance to maintain normal blood flow in the setting of blood pressure changes.
- Once these vessels are maximally dilated, further drops in systemic pressure will reduce cerebral blood flow.
- Normal cerebral blood flow in the cortical mantle is about 50 mL/100 g tissue per minute. When cerebral blood flow drops below 20 mL/100 g tissue per minute, synaptic failure occurs, and patients become symptomatic.
- When cerebral blood flow drops below 10 mL/100 g tissue per minute, metabolic failure and irreversible cell death occur.
- A potentially salvageable area of brain tissue is referred to as the *penumbra*. This occurs in regions with diminished flow that will survive longer but not indefinitely. The purpose of acute stroke therapies is to salvage the penumbra.
- The causes of disruptions of arterial flow can be separated into three major categories based on cause: (a) large-vessel atherothrombotic disease, (b) small-vessel (lacunar) infarction, and (c) cardiogenic embolism.

Large-vessel Atherothrombosis

- Large-vessel atherothrombosis encompasses approximately 15% of all strokes; of these, two-thirds are of extracranial internal carotid artery (ICA) origin, and one-third are due to intracranial atheromatous disease.
- Atheromatous vascular plaques may fragment, exposing an ulcerated surface that is highly thrombogenic and leading to local occlusion or creation of emboli material.
- Atherosclerotic lesions tend to occur at bifurcations or sharp turns in the vessel where flow turbulence is increased. The prototypic example of this is carotid stenosis at the origin of the ICA.
- Intracranially, common sites include the distal vertebral artery, the midbasilar artery, the siphon of the ICA, and the proximal middle cerebral artery (MCA).

Lacunar Strokes

- Lacunar strokes represent approximately one-fourth of all such events. The primary risk factor for lacunar infarction is hypertension.
- These strokes are caused by occlusion of a single perforating arteriole, typically to those that supply deep brain structures like the thalamus, pons, or basal ganglia.

- The result is a small infarction ($<1\text{ cm}^3$) that undergoes liquefaction necrosis.

Cardiogenic Embolism

- Embolism causes ~60% of all ischemic strokes, of which only one-third have a definitively known clinical source.
- Cerebral emboli may be composed of atherosclerotic plaque material, clotted blood or, in rare cases, air or fat.
- Emboli tend to follow the straightest path formed by the most blood. Therefore, most emboli will affect distal branches of the MCA.
- Cerebral emboli may originate from atheromatous disease of the carotid arteries or the aortic arch or from material in the heart.
- Atrial fibrillation is the most common cardiac cause, but others include valvular heart disease, intracardiac thrombus, atrial myxoma, dilated cardiomyopathy, patent foramen ovale, especially when accompanied by an atrial septal defect, and endocarditis.
- Air emboli are usually iatrogenic and result when a large amount of air enters the venous circulation and bypasses the lungs through a patent foramen ovale, thereby entering the arterial circulation.
- Fat emboli are generally the result of long-bone fractures in severe trauma.
- The definitive source should be identified as it can alter the management of secondary stroke prevention.

Arterial Dissections

- Arterial dissections are the most common cause of stroke in young patients (<50 years old) who are unlikely to have typical risk factors.
- Arterial dissections may arise spontaneously or follow a traumatic head or neck injury.
- These lesions typically arise at the petrous portion of the ICA or at cervical level 1 to 2 in the vertebral artery.
- Dissection may also lead to subarachnoid hemorrhage when a pseudoaneurysm forms after the artery passes intradurally.

CLINICAL EVALUATION

History

- The history, when available, is the key instrument in diagnosing neurologic disease. If the patient is unable to provide a reliable history, historic details should be sought from witnesses, family, emergency medical services (EMS) records, or any available sources.
- The key historic element in ischemic cerebrovascular disease is *sudden* onset of symptoms, which are typically maximal at onset.
- Additional history should be focused on obtaining the exact time of symptom onset, as current acute stroke treatment protocols depend on this for inclusion.
- If the onset was not witnessed, the time when last known to be normal is used.
- Aside from time of onset, factors that may place the patient at increased risk for bleeding must be sought. Tables 52.3, 52.4, and 52.5 list common inclusion and exclusion criteria for intravenous (IV)-tPA (tissue plasminogen activator).

TABLE 52.3

INCLUSION CRITERIA FOR tPA USE

1. Symptoms consistent with acute ischemic stroke, with a clearly defined onset of <3 hours before rt-PA will be given. (If the onset was not witnessed, the ictus is measured from the time the patient was last seen to be at baseline.)
2. A significant neurologic deficit is expected to result in long-term disability.
3. A noncontrast CT with no evidence of hemorrhage or well-established infarction.

tPA, tissue plasminogen factor; CT, computed tomography. From Adams HP Jr, Del Zoppo G, Albert MJ, et al. Guidelines for the early management of adults with ischemic stroke: a guideline from the American Heart Association/American Stroke Association Stroke Council, Clinical Cardiology Council, Cardiovascular Radiology and Intervention Council, and the Atherosclerotic Peripheral Vascular Disease and Quality of Care Outcomes in Research Interdisciplinary Working Groups: the American Academy of Neurology affirms the value of this guideline as an educational tool for neurologists. *Stroke*. 2007;38(5):1655–1711, with permission.

- Once a decision regarding acute treatment has been made, attention can be directed to identifying conditions that may have caused the patient's stroke.

Neurologic Examination

- The neurologic examination will allow the clinician to quickly determine which brain areas are dysfunctional and further narrow the differential diagnosis.
- The first step in localization of vascular lesions is determining whether the signs and symptoms arise from the anterior circulation or the posterior circulation.
- The two symptoms that most accurately reflect carotid (anterior) circulation disease are aphasia and monocular blindness.
- The areas responsible for language reside in the dominant (nearly always left) hemispheric cortex, within the territory of the MCA; a stroke causing aphasia must, therefore, involve this circulation.
- Similarly, the blood supply of the eye arises largely from the ophthalmic artery, a direct branch from the carotid artery.

TABLE 52.4

ABSOLUTE CONTRAINDICATIONS TO tPA USE

1. Mild or rapidly improving deficits
2. Hemorrhage on CT, well-established acute infarct on CT, or any other CT diagnosis that contraindicates treatment, including abscess or tumor (excluding small meningiomas)
3. A known CNS vascular malformation or tumor
4. Bacterial endocarditis

tPA, tissue plasminogen factor; CT, computed tomography; CNS, central nervous system. From Adams HP Jr, Del Zoppo G, Albert MJ, et al. Guidelines for the early management of adults with ischemic stroke: a guideline from the American Heart Association/American Stroke Association Stroke Council, Clinical Cardiology Council, Cardiovascular Radiology and Intervention Council, and the Atherosclerotic Peripheral Vascular Disease and Quality of Care Outcomes in Research Interdisciplinary Working Groups: the American Academy of Neurology affirms the value of this guideline as an educational tool for neurologists. *Stroke*. 2007;38(5):1655–1711, with permission.

TABLE 52.5**RELATIVE CONTRAINDICATIONS TO tPA USE**

1. Significant trauma within the past 3 months (including CPR with chest compressions within the past 10 days)
2. Ischemic stroke within 3 months
3. History of intracranial hemorrhage, or symptoms suggestive of subarachnoid hemorrhage
4. Major surgery within the past 14 days
5. Minor surgery within past 19 days, including liver and kidney biopsy, thoracentesis, and lumbar puncture
6. Arterial puncture at a noncompressible site within past 14 days
7. Pregnancy (and ≤ 10 days postpartum)
8. Gastrointestinal, urologic, or respiratory hemorrhage within past 21 days
9. Known bleeding diathesis (includes renal and hepatic insufficiency)
10. Peritoneal dialysis or hemodialysis
11. PTT > 40 s, PT > 15 (INR > 1.7), platelet count $< 100,000$
12. Seizure at onset of stroke (This relative contraindication is intended to prevent treatment of patients with a deficit due to postictal Todd paralysis or with seizure due to some other CNS lesion that precludes thrombolytic therapy. If rapid diagnosis of vascular occlusion can be made, treatment may be given.)
13. Glucose < 50 or > 400 mg/dL (This relative contraindication is intended to prevent treatment of patients with focal deficits due to hypoglycemia or hyperglycemia. If the deficit persists after correction of the serum glucose, or if rapid diagnosis of vascular occlusion can be made, treatment may be given.)
14. Systolic BP > 180 mm Hg or diastolic BP > 110 mm Hg, despite basic measures to lower it acutely
15. Consideration should be given to the increased risk of hemorrhage in patients with severe deficits (NIHSS > 20), age > 75 , or early edema with mass effect on CT.

tPA, tissue plasminogen factor; CPR, cardiopulmonary resuscitation; PTT, partial thromboplastin time; PT, prothrombin time; INR, international normalized ratio; CNS, central nervous system; BP, blood pressure; NIHSS, National Institutes of Health Stroke Scale; CT, computed tomography.

- Posterior circulation syndromes that result from strokes are usually more complex than those in the cerebral hemispheres.
- Strokes involving the brainstem often manifest with cranial nerve dysfunction (dysarthria, dysphagia, diplopia).
- Crossed signs, with motor or sensory deficits affecting one side of the face and the opposite side of the body, may occur as major decussations in these pathways and occur in the pons and medulla.
- The unique vascular anatomy of the basilar artery may lead to bilateral neurologic deficits.
- Classic lacunar syndromes include pure motor hemiparesis, pure hemisensory symptoms, dysarthria-clumsy hand syndrome, and ataxia-hemiparesis (pontine infarct).

Vascular System Examination

- The neurologic examination complements the history, but physical examination of the vascular system itself is usually surprisingly unrewarding.

- The presence of carotid bruits is of low sensitivity and specificity for predicting vascular disease. Many bruits reflect benign conditions.
- Clinical decisions should be based on definitive assessment of blood vessels using ultrasound or angiography.
- Examination of the heart should focus on detecting thrombogenic diseases, including myocardial infarction, congestive heart failure, arrhythmias, prosthetic valves, and bacterial endocarditis.

Laboratory Studies: General

- Laboratory studies may narrow the differential diagnosis and reveal relevant comorbid conditions.
- Studies that need to be obtained immediately to determine a patient's candidacy for thrombolytic therapy include an electrolyte battery, glucose, platelet count, cardiac enzymes, human chorionic gonadotropin, and coagulation parameters.
- Severe hyponatremia, hypernatremia, or glucose disturbances can cause neurologic dysfunction that may mimic stroke.
- Coagulation parameters and a platelet count will identify patients who may be at greater risk for bleeding.
- A fasting lipid profile should be obtained for potential vascular risk factor modification.
- In patients older than 50 years, an erythrocyte sedimentation rate and C-reactive protein are essential if giant-cell arteritis is suspected.
- In patients for whom an unusual cause of stroke is suspected (young patients or minimal vascular risk factors), investigation of prothrombotic states may be performed.
- Toxicology screening should be performed on hospital admission, with attention directed to amphetamines, phencyclidine, ephedrine, and cocaine.

Imaging Studies

- **Computed tomography**
 - A noncontrasted CT scan of the brain is the standard initial evaluation for stroke.
 - CT is very sensitive to the presence of hemorrhage and is the only radiologic test necessary to determine eligibility for IV-tPA.
 - CT is not sensitive for detection of an acute cerebral infarction, and the lack of abnormality within the first 24 hours should be expected.
 - The view of the posterior fossa is also quite limited, and any changes (with the exception of hemorrhage) seen within the brainstem or cerebellum should be confirmed with MRI.
 - When available, CT angiography (CTA) and perfusion studies can be obtained with very little additional time and provide valuable additional information regarding the patency of blood vessels and blood flow to individual large-vessel territories.
 - The angiographic results from CTA are closest to the traditional gold standard exam: digital subtraction catheter angiography.
 - When examining the carotid arteries, the results from CTA are often sufficient to differentiate a high-grade stenosis (60%–99%) that is treatable from complete occlusion that is not.

- **Magnetic resonance imaging**

- MRI is far more sensitive for acute infarction than CT. Diffusion MRI sequences can detect ischemia within minutes of onset.
- MRI is of special value in brainstem and posterior circulation strokes, as the images are not obscured by bony artifacts as with CT.
- Multiple MRI sequences allow for much more specific differentiation between ischemic brain and other structural abnormalities. In addition, MRI can display flow-related enhancement of the vasculature, resulting in a magnetic resonance angiogram (MRA).
- MRA tends to slightly overestimate the degree of stenosis, and thus is not usually sufficient to differentiate high-grade stenosis from occlusion.
- Disadvantages of MRI and MRA include reduced availability and substantially longer scanning times, which place some limitations on their use.

- **Digital subtraction catheter angiography**

- Digital subtraction catheter angiography is no longer used as a routine screening test as the quality of noninvasive imaging techniques has improved.
- Indications now include precisely delimiting critical vascular stenoses and examination of arterial dissections, arteriovenous malformations, and aneurysms.

- **Carotid ultrasound**

- Carotid ultrasound provides a rapid noninvasive assessment of carotid artery disease, based on abnormalities of either flow (Doppler) or morphology (B-mode).
- Ultrasound, however, suffers from the same limitation as MRA in differentiating high-grade stenosis and occlusion.
- Lesions of the more distal internal carotid artery may also be difficult to visualize in some patients.

- **Transcranial Doppler**

- Transcranial Doppler allows rapid bedside assessment of abnormal flow within the distal ICA and major intracranial arteries.
- The 2-MHz ultrasonic signal can penetrate various bony “windows” in most patients, and its gated character allows identification of arteries by “depth” of the reflected signal.
- Transcranial Doppler can examine proximal portions of all major branches of the circle of Willis but is insensitive for pathology beyond the A1, M1, or P1 segments.
- Newer applications include detection of microemboli and online monitoring of arterial flow during invasive procedures, such as carotid endarterectomy.
- Disadvantages include major dependency on operator skill and the prevalence of acoustically inadequate bony windows.

- **Transthoracic echocardiography (TTE) and transesophageal echocardiography**

- TTE is essential to evaluate cardiac function.
- Physicians must attend not only to a visualized thrombus but to other pathologic states associated with systemic embolization, including left ventricular wall motion abnormalities, chamber dilatation, valvular disease, ejection fraction, and septal defects.
- TTE can be routinely performed and is a superior study for the detection of ventricular apex pathology, left ventricle thrombus, and views of prosthetic valves.
- TEE provides much greater resolution and is more sensitive for pathology of the left atrial appendage, intra-atrial

septum, atrial aspect of mitral-tricuspid valves, and the ascending aorta.

- TEE is an invasive procedure that requires sedation but can be performed safely on most patients.

MANAGEMENT

Acute Therapy

- The immediate goal is to determine whether the patient is a candidate for thrombolytic therapy; thus attention should be focused on obtaining the relevant history and performing a neurologic examination.
- Patients with acute stroke are often markedly hypertensive, and one should be cautious in aggressively treating elevated blood pressure before a more complete assessment of the patient has been completed.
- Blood pressure goals are determined by type of stroke, cause, and the presence of comorbid conditions, such as coronary artery disease (CAD).
- All patients should be evaluated with the National Institutes of Health Stroke Scale, which can help to exclude a patient from potentially harmful therapy on the basis of the stroke being too small or too severe.
- **Thrombolytic therapy**
 - Currently, thrombolytic treatment with tPA in eligible stroke patients is the standard of care.
 - Multiple trials indicate that patients treated with tPA within 3 hours of onset were $\geq 30\%$ more likely to have minimal or no disability at 3 months compared with placebo.
 - To optimize the risk-benefit ratio, strict inclusion criteria (see Table 52.3) for the administration of thrombolytic therapy in acute stroke patients are followed.
 - Absolute exclusion criteria have been established as well (see Table 52.4).
 - Additionally, there is a long list of *relative* contraindications to thrombolytic therapy (see Table 52.5).
 - Most patients who experience intracerebral hemorrhage (ICH) after tPA therapy have severe baseline insults and were already destined for a poor outcome; thus, the hemorrhage does little to alter the final outcome.
 - The dose of tPA is 0.9 mg/kg, with a maximum dose of 90 mg; 10% is given as a bolus over 1 minute, and the remaining 90% is infused over 60 minutes.
 - All invasive procedures, including placement of nasogastric tubes, urinary bladder catheters, central venous lines, arterial lines, intramuscular injections, and rectal temperature probes, must be avoided for 24 hours.
 - After treatment, patients should be monitored in an intensive care unit for more than 24 hours. Vital signs and neurologic exams should be checked frequently.
 - Blood pressure should be strictly controlled for 24 hours, keeping the systolic blood pressure <180 mm Hg and the diastolic blood pressure <105 mm Hg.
 - The benefit of therapeutic hypothermia is yet to be confirmed, but euthermia is clearly associated with better outcome.
- **STAT head CT**
 - A STAT head CT should be performed for any worsening neurologic status.
 - Should an intracerebral hemorrhage develop after thrombolysis, several steps must be taken emergently.

- Neurosurgery should be contacted for possible hematoma evacuation, and anticoagulation should be reversed.
- **Intra-arterial approach for thrombolytic therapy**
 - The use of thrombolytic interventions outside of the 3-hour time window is controversial.
 - Trials that have extended the therapeutic window beyond 3 hours for IV therapy have failed to show convincing benefit as the risk of hemorrhage rapidly increases with time.
 - According to the American Stroke Association guidelines, intra-arterial thrombolysis is an option for treatment of selected patients who have major stroke of <6 hours' duration due to occlusion of the MCA and who are not otherwise candidates for IV-tPA.
 - The availability of intra-arterial thrombolysis should not preclude the administration of IV-tPA in otherwise eligible patients.
 - Treatment requires immediate access to cerebral angiography and qualified interventionalists.
 - Recommendations for blood pressure control after tPA use are presented in Table 52.6.
 - Management of post-tPA hemorrhage is presented in Table 52.7.

Supportive Care

- Early initiation of physical, occupational, and speech therapy services hastens functional recovery from stroke.

TABLE 52.6

BLOOD PRESSURE CONTROL AFTER tPA

1. Management of blood pressure during and after treatment with tPA or other acute reperfusion intervention:
 - a. Monitor blood pressure every 15 min during treatment and then for another 2 h, then every 30 min for 6 h, and then every hour for 16 h;
 - b. For systolic 180–230 mm Hg or diastolic 105–120 mm Hg:
 - i. Labetalol 10 mg IV over 1 to 2 min, may repeat every 10 to 20 min, maximum dose of 300 mg; or
 - ii. Labetalol 10 mg IV followed by an infusion at 2 to 8 mg/min
 - c. For systolic >230 mm Hg or diastolic 121 to 140 mm Hg:
 - i. Labetalol 10 mg IV over 1 to 2 min, may repeat every 10 to 20 min, maximum dose of 300 mg; or
 - ii. Labetalol 10 mg IV followed by an infusion at 2 to 8 mg/min; or
 - iii. Nicardipine infusion, 5 mg/h, titrate up to desired effect by increasing by 2.5 mg/h every 5 min to maximum of 15 mg/h
 - iv. If blood pressure not controlled, consider sodium nitroprusside.

tPA, tissue plasminogen factor.

From Adams HP Jr, Del Zoppo G, Albert MJ, et al. Guidelines for the early management of adults with ischemic stroke: a guideline from the American Heart Association/American Stroke Association Stroke Council, Clinical Cardiology Council, Cardiovascular Radiology and Intervention Council, and the Atherosclerotic Peripheral Vascular Disease and Quality of Care Outcomes in Research Interdisciplinary Working Groups: the American Academy of Neurology affirms the value of this guideline as an educational tool for neurologists. *Stroke*. 2007;38(5):1655–1711, with permission.

TABLE 52.7

MANAGEMENT OF POST-tPA HEMORRHAGE

1. Blood should be sent STAT for CBC, PT, PTT, platelets, fibrinogen and D-dimer (this should be repeated every 2 h until bleeding is controlled).
2. Give 2 U of fresh frozen plasma every 6 h for 24 h after the thrombolytic agent was given.
3. Give cryoprecipitate (20 U); if the fibrinogen level is <200 mg/dL at 1 h, repeat the cryoprecipitate dose.
4. Give 4 U of platelets.
5. Give protamine sulfate (1 mg/100 U heparin given in the last 3 h);
 - a. A test dose of 10 mg slow IV push over 10 min should be given while observing for anaphylaxis;
 - b. Then the remaining dose by slow IV push, up to a maximum dose of 50 mg.
6. Institute frequent neurologic checks, as well as management of increased ICP, as needed.
7. Aminocaproic acid (Amicar) can be given as a last resort, in a dose of 5 g in 250 mL normal saline IV over 1 h.

CBC, complete blood count; PT, prothrombin time; PTT, partial thromboplastin time; IV, intravenous; ICP, intracranial pressure. From Adams HP Jr, Del Zoppo G, Albert MJ, et al. Guidelines for the early management of adults with ischemic stroke: a guideline from the American Heart Association/American Stroke Association Stroke Council, Clinical Cardiology Council, Cardiovascular Radiology and Intervention Council, and the Atherosclerotic Peripheral Vascular Disease and Quality of Care Outcomes in Research Interdisciplinary Working Groups: the American Academy of Neurology affirms the value of this guideline as an educational tool for neurologists. *Stroke*. 2007;38(5):1655–1711, with permission.

- Dysphagia is common after stroke. All patients should be screened for dysphagia before being allowed to take anything by mouth, as aspiration pneumonia is a substantial contributor to mortality after stroke.
- Early mobilization not only prevents deep vein thromboses but speeds rehabilitation.
- Deep vein thrombosis prophylaxis with low-molecular-weight heparin is safe and more effective than unfractionated heparin in stroke patients.
- For most stroke patients with acute hypertension, aggressively lowering the blood pressure may cause more harm than benefit.
- The general practice is to refrain from intervening until the pressure exceeds an arbitrary limit of 220 mm Hg systolic or 120 mm Hg diastolic. In patients having received thrombolytics, the tolerable limit is lower (<180 mm Hg systolic or <105 mm Hg diastolic).
- Control of hyperglycemia is recommended as persistent hyperglycemia (blood glucose level >200 mg/dL) during the first 24 hours after stroke is associated with poor neurologic outcomes.
- Although most patients eventually improve after a stroke, early clinical deterioration is not uncommon. Neurologic causes of clinical deterioration include progressive or recurrent stroke, hemorrhagic transformation of the infarct, and local cerebral edema.
- Cerebral edema is the most common cause of deterioration and may cause fatal herniation in large MCA infarctions, especially in the young, women, and in patients with involvement of additional vascular territories.

- Corticosteroids do not appear helpful and hyperglycemia associated with their use may worsen clinical outcome.
- Decompressive surgery, including hemicraniectomy and durotomy with temporal lobe resection, for treatment of brain edema after stroke is controversial.

INTRACEREBRAL HEMORRHAGE

Pathogenesis

- Primary ICH involves bleeding, usually of arterial origin, into normally perfused brain and thus must be distinguished from hemorrhagic transformation of an initially ischemic stroke.
- The expanding hematoma causes direct injury to local brain tissue and dysfunction in surrounding regions.
- In younger patients, hypertension is by far the more common cause and, as such, ICH tends to occur in the same brain areas where other hypertensive pathologies occur.
- In contrast, lobar ICHs occur more commonly in the elderly population and are often associated with cerebral amyloid angiopathy in the absence of hypertension.
- ICH may also occur in the setting of trauma, use of illicit drugs or over-the-counter medications, excessive alcohol consumption, an underlying vascular abnormality, brain tumor, or a bleeding diathesis.

Clinical Evaluation

- Rapid diagnosis of ICH is essential, as progression during the first several hours is the norm.
- The hallmark is sudden-onset focal neurologic deficit, which progresses over minutes to hours. Headache, increased blood pressure, and impaired level of consciousness are common features that complete the presentation.
- History gathering should be directed at elucidating the presence of risk factors as outlined earlier. Other considerations include the use of antithrombotic medications (e.g., aspirin or warfarin) or hematologic disorders that predispose to bleeding.
- The patient's coagulation parameters should be checked immediately and corrected if abnormal.
- Once stabilized, the patient should undergo a noncontrast head CT immediately to verify brain hemorrhage. CT angiography may also be helpful in detecting aneurysms, arteriovenous malformations, underlying tumors, or abscesses.
- MRI will also provide information about the hemorrhage but is time-consuming and potentially dangerous for an unstable patient.
- Catheter angiography should be considered in a young patient with an ICH with no history of hypertension, as an occult arteriovenous malformation or aneurysm may be responsible.
- Cardiac arrhythmias represent another potentially catastrophic secondary complication of ICH, especially those that occur in the right hemisphere insular region. Dysfunction of this area has a propensity for causing abnormal cardiac electrical activity and "cerebrogenic sudden death."
- Patients with such lesions must have close cardiac monitoring in the intensive care unit during their first several days after hemorrhage.

Management

- The mainstays of medical treatment of acute ICH are correction of any coagulopathy and avoidance of hypertension.
- Beyond the first few hours after onset, aggressive lowering of blood pressure may be potentially harmful (Table 52.8). When necessary, certain pharmacologic agents may be used (Table 52.9). Attention must be focused on maintaining the cerebral perfusion pressure >70 mm Hg to avoid secondary ischemia.
- Seizures—occasionally nonconvulsive—occur commonly after ICH. Prophylactic anticonvulsant medications may be considered for patients. If seizures are confirmed, they should be treated aggressively.
- Treatment of increased ICP should initially focus on more conservative noninvasive measures.
- An implanted ICP monitor should be considered for those patients with large hematomas to guide whether to place an intraventricular drain or perform a surgical evacuation.
- In general, patients with a Glasgow Coma Score of 4 or more have a uniformly poor outcome, regardless of whether surgery is performed, and thus these patients should be treated medically.
- Patients with cerebellar hemorrhages >3 cm in diameter should be considered for emergency decompression, especially if there are signs of brainstem compression, hydrocephalus, or neurologic deterioration.
- Patients who deteriorate despite maximal medical therapy may benefit from surgical decompression, but results from clinical trials have been mixed.

TABLE 52.8

SUGGESTED RECOMMENDED GUIDELINES FOR TREATING ELEVATED BLOOD PRESSURE IN SPONTANEOUS ICH

1. If SBP is >200 mm Hg or MAP is >150 mm Hg, then consider aggressive reduction of blood pressure with continuous intravenous infusion, with frequent blood pressure monitoring every 5 min.
2. If SBP is >180 mm Hg or MAP is >130 mm Hg and there is evidence of or suspicion of elevated ICP, then consider monitoring ICP and reducing blood pressure using intermittent or continuous intravenous medications to keep cerebral perfusion pressure >60 to 80 mm Hg.
3. If SBP is >180 mm Hg or MAP is >130 mm Hg and there is not evidence of or suspicion of elevated ICP, then consider a modest reduction of blood pressure (e.g., MAP of 110 mm Hg or target blood pressure of 160/90 mm Hg) using intermittent or continuous intravenous medications to control blood pressure, and clinically re-examine the patient every 15 min.

ICH, intracerebral hemorrhage; SBP, systolic blood pressure; MAP, mean arterial pressure; ICP, intracranial pressure.
From Broderick J, Connolly S, Feldmann E, et al. Guidelines for the management of spontaneous intracerebral hemorrhage in adults: 2007 update: a guideline from the American Heart Association/American Stroke Association Stroke Council, High Blood Pressure Research Council, and the Quality of Care and Outcomes in Research Interdisciplinary Working Group. *Circulation*. 2007;116(16):e391–413, with permission.

TABLE 52.9**INTRAVENOUS MEDICATIONS THAT MAY BE CONSIDERED FOR CONTROL OF ELEVATED BLOOD PRESSURE IN PATIENTS WITH ICH**

Drug	Intravenous bolus dose	Continuous infusion rate
Labetalol	5–20 mg every 15 min	2 mg/min (maximum 300 mg/d)
Nicardipine	NA	5–15 mg/h
Esmolol	250 $\mu\text{g/kg}$ IVP loading dose	25–300 $\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$
Enalapril	1.25–5 mg IVP every 6 h ^a	NA
Hydralazine	5–20 mg IVP every 30 min	1.5–5 $\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$
Nipride	NA	0.1–10 $\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$
Nitroglycerin	NA	20–400 $\mu\text{g/min}$

ICH, intracerebral hemorrhage; NA, not applicable; IVP, intravenous push.

^aBecause of the risk of precipitous blood pressure decrease, the first test dose of enalapril should be 0.625 mg.

From Broderick J, Connolly S, Feldmann E, et al. Guidelines for the management of spontaneous intracerebral hemorrhage in adults: 2007 update: a guideline from the American Heart Association/American Stroke Association Stroke Council, High Blood Pressure Research Council, and the Quality of Care and Outcomes in Research Interdisciplinary Working Group. *Circulation*. 2007;116(16):e391–413, with permission.

- Patients with lobar hemorrhages secondary to amyloid angiopathy have exceptionally friable cortical blood vessels and are poor surgical candidates.
- ICH causes approximately 10% of first-time strokes. The 30-day mortality rate is high at 35% to 50%, with half of the deaths occurring within the first 2 days.
- Outcome in ICH is dependent on several factors, including the location and size of the hemorrhage, the presence of intraventricular blood or hydrocephalus, the age of the patient, the Glasgow Coma Scale on presentation, and the cause of the hemorrhage.

SUBARACHNOID HEMORRHAGE

- SAH is a relatively uncommon but often devastating type of stroke.
- Incidence is estimated at 30,000 patients per year in the United States, with a mortality that exceeds 50%.
- Whereas head trauma is the most frequent cause of subarachnoid hemorrhage, aneurysmal rupture results in the greatest morbidity and mortality.
- Most commonly, patients perceive a sudden severe headache with rapid impairment of consciousness.
- Focal neurologic symptoms such as hemiparesis, sensory loss, or diplopia may occur if loculation of subarachnoid blood or intraparenchymal extension of the hemorrhage develops.
- The most important features of the neurologic examination are the assessment of level of consciousness, cranial nerve function, and motor function.

Diagnosis

- Diagnosis of SAH is based on neuroimaging or cerebrospinal fluid (CSF) analysis.
- Brain CT scan is a very sensitive indicator of the presence of subarachnoid blood.
- Brain parenchyma itself most commonly displays no acute abnormalities.

- Erythrocyte concentration in CSF below approximately 30,000 cells/ μL may not result in the diagnostic increased density within CSF on CT scans.
- In approximately 10% of patients, diagnosis requires CSF analysis through lumbar puncture.
- In addition to elevated erythrocyte count, CSF xanthochromia and elevation of CSF D-dimer can often be detected in true subarachnoid hemorrhage.
- The latter two findings may help distinguish bloody CSF from a “traumatic tap,” as these serve as markers of the breakdown of thrombosis or blood products.
- Serial cell counts should always be obtained, however, whenever SAH is suspected.
- Cell counts in SAH should be roughly equivalent in all tubes, whereas a declining count is usual in traumatic punctures.
- Lumbar puncture should be avoided in any patient with a depressed level of consciousness until CT scan excludes a focal mass (such as intraparenchymal or subdural hemorrhage).
- If bacterial meningitis is a concern, blood cultures should be obtained and antibiotics started while awaiting results of the CT scan.

Management

- Patients with acute SAH are at high risk for a multitude of complications (Table 52.10) that usually mandate admission to an intensive care facility.
- All patients should be placed on strict bed rest, with appropriate precautions for deep venous thrombosis and aspiration.
- Patients with progressive lethargy may require intubation for airway protection and mechanical ventilation.
- Until the aneurysm has been ablated, blood pressure should be kept in the normotensive range, and isotonic intravenous fluids should be used to maintain normovolemia.
- All patients should be started on nimodipine at 60 mg every 4 hours (duration 21 days), either orally or through a nasogastric tube, for prevention of vasospasm.
- The practice of prophylactic anticonvulsants has recently come into question, as recent data suggest that patients who

TABLE 52.10

COMPLICATIONS OF SUBARACHNOID HEMORRHAGE

Complication	Clinical features	Diagnostic tests	Therapy
Increased ICP	Decreased alertness, worsened headache, herniation syndrome	ICP monitor	Mannitol, steroids, hyperventilation
Hydrocephalus	Decreased alertness, worsened headache, herniation syndrome	CT scan	Ventriculostomy drainage or shunt
Vasospasm	Delayed focal neurologic deficit	TCD, angiography	Nimodipine, hypervolemia, hypertension, angioplasty
Rebleed	Worsened neurologic condition, especially level of consciousness	CT scan, lumbar puncture	Ablation of aneurysm
Seizure	Sudden behavioral change or uncontrolled motor activity	EEG	Anticonvulsants
Hyponatremia	Confusion, seizure	Serum electrolytes	Isotonic fluids to achieve euolemia or hypervolemia
Infection	Confusion, lethargy	Panculture, chest radiograph, urinalysis	Appropriate antibiotic

ICP, intracranial pressure; CT, computed tomography; TCD, transcranial Doppler; EEG, electroencephalogram.

were on prophylactic anticonvulsants had significantly more in-hospital complications and worse clinical outcomes.

- Electrocardiogram changes and elevations in cardiac enzymes, troponin, and CK-MB are commonly seen in SAH patients and may represent the phenomenon of stunned myocardium, in which case management should be aimed at optimizing left ventricular function to support cardiovascular and cerebrovascular perfusion.
- Serum electrolytes are closely monitored, as hyponatremia may be seen in more than 30% of patients after SAH; however, hypernatremia can occur as well and is significantly associated with clinical outcome.
- Serum glucose levels should also be closely monitored, as hyperglycemia has been significantly associated with mortality and poor functional outcome in SAH patients.
- Because fever in SAH patients has been associated with mortality and poor clinical outcome and has even been linked to vasospasm, patients should be kept normothermic.
- Platelet levels should be monitored, as a relatively significant incidence of heparin-induced thrombocytopenia has been reported in SAH patients.

Complications

- In those patients surviving the initial hemorrhage, *the leading factor associated with mortality is rebleeding from the aneurysm*. A second bleed from an aneurysm is associated with a 74% mortality rate.
- Untreated aneurysms rebleed at a rate of 4% on day 1, then 1% to 2% a day for the next 4 weeks. Thus, early treatment to secure a ruptured aneurysm is critical.
- Aneurysmal clipping is best performed either early (0 to 3 days) or late (11 to 14 days). Outcome is worse when performed at 7 to 10 days after the onset of SAH.
- Early treatment of the ruptured aneurysm also allows aggressive management of vasospasm, manipulations that would increase the risk of rebleeding from an unsecured aneurysm.
- After rebleeding, vasospasm is the next leading cause of mortality and morbidity from an SAH.

- The exact cause of arterial vasospasm after SAH is unknown, but its incidence does appear to be correlated with the density of blood products seen on CT scan.
- Severe vasospasm may result in cerebral infarction within the vascular distribution of the involved artery.
- The risk for vasospasm begins about 3 days after the bleed and may persist for 3 weeks.
- Transcranial Doppler is a sensitive indicator of the presence and degree of vasospasm within proximal arteries, although it may not detect vasospasm restricted to smaller peripheral vessels.
- The calcium channel blockers nimodipine and nicardipine can reduce the incidence of vasospasm and associated cerebral infarction.
- Studies with statin therapy (HMG Co-A inhibitors) have demonstrated promising results with reduced rates of vasospasm and better clinical outcomes.

Management after Aneurysm Ablation

- Triple-H therapy—hypertension, hypervolemia, hemodilution—is the first-line therapy against vasospasm.
- Once vasospasm occurs, IV fluids should be pushed to the tolerance of the patient (<400 mL/h).
- As congestive heart failure is a potential complication, central pressure monitoring—at a minimum—should be used in patients at risk; optimal central venous pressure is 8 to 12 mm Hg.
- Other modalities of monitoring, from pulse-waveform variability to placement of a pulmonary artery catheter may be necessary to properly care for these patients.
- If hypervolemic therapy is not adequate to control vasospasm, hypertension can be initiated by cessation of antihypertensives or use of vasopressors (e.g., phenylephrine, 0.1–5 µg/kg/min, or vasopressin, 0.01–0.04 U/min), targeting mean arterial pressures of 120 to 140 mm Hg (systolic blood pressure 180–200 mm Hg).
- Triple-H therapy does not increase the risk of rupture of other, incidentally found, aneurysms in patients with multiple aneurysms.

- Acute hydrocephalus occurs in approximately 20% of survivors of SAH.
- The likelihood of hydrocephalus increases with worsening grade of hemorrhage.
- Ventriculostomy drainage is recommended for patients with acute hydrocephalus and decreased level of consciousness; improvement can be expected in >50% of patients.

CHAPTER 53 ■ UROLOGIC SURGERY AND TRAUMA

IMMEDIATE CONCERNS

- Primary emergency considerations in urology from the critical care perspective include hemorrhagic, obstructive, infectious, and ischemic processes, in addition to a wide variety of general postoperative difficulties that may warrant emergent intervention. Oncologic emergencies also arise in urology and may require urgent critical care management.
- **Gross hematuria** may require immediate critical care intervention depending on the magnitude of the hematuria and details of the individual case.
 - Gross hematuria may have a defined cause (e.g., known radiation cystitis, recurrent benign prostatic hypertrophy [BPH]-related bleeding) or may be a new sign.
 - Immediate urologic intervention is necessary if the patient has clot retention, is bleeding severely, has significant pain, is infected, has coagulopathy, or has underlying medical factors that increase risk of further complications.
 - Vital signs, physical examination, and basic laboratory studies including complete blood count (CBC), coagulation functions, electrolyte and renal function testing, urinalysis, and culture will often lead to a diagnosis and determine the need for immediate intervention.
 - In the setting of gross hematuria and a distended bladder, a catheter must be inserted. The catheter should be irrigated using 60 to 120 mL of normal saline.
 - A three-way catheter for continuous bladder irrigation (CBI) in the setting of continuing bleeding may be used to keep the catheter patent in this situation, but this decision is best made along with urologic consultation.
 - Risks of CBI include bladder rupture if the outflow lumen becomes occluded without recognition and the inflow of irrigant continues.
 - Early cystoscopy can provide diagnosis and definitive intervention.
 - Other hemorrhagic urologic problems requiring immediate critical care intervention include renal or perirenal bleeding (e.g., spontaneous hematoma or renal tumor) or scrotal hematoma.

Urosepsis

- Sepsis of the urinary tract or urogenital origin may present in a most precipitous and potentially life-threatening manner, or may be indolent.

- The combination of infection and obstruction of the urinary tract is a surgical emergency requiring immediate action.
- Septic shock may unfold rapidly in such situations with a significant mortality rate, even in the otherwise healthy host.
- Other infectious states requiring urgent critical care intervention include renal or perirenal abscess, scrotal abscess, acute epididymo-orchitis, and Fournier gangrene.

Obstruction of the Urinary Tract and Urinary Retention

- May require critical care intervention independent of the presence or absence of hematuria or infection.
- Upper or lower tract obstruction can result in acute or chronic renal failure, mandating prompt drainage to control metabolic instability.
- Acute urinary retention with bladder distention must be promptly relieved by introduction of a catheter into the bladder, preferably by a transurethral route, or alternatively by a suprapubic route if the urethra is impassable.

Ischemic States

- The quintessential example is that of testicular torsion. The other condition of critical care relevance is the ischemic kidney.
- Delayed diagnosis of torsion is a common cause of unnecessary testicular loss. After 8 hours, the likelihood of testicular salvage decreases significantly.
- A high index of suspicion is necessary when addressing “the acute scrotum,” with accurate history and physical examination forming the core of this assessment.
- When clinical suspicion of acute testicular torsion is high, surgical exploration should not be delayed to obtain confirmatory imaging that is not readily and rapidly available.
- The differential diagnosis of the acute scrotum includes incarcerated or strangulated inguinal hernia for which urgent surgical management is also critical.
- The kidney begins to undergo irreversible loss of function following approximately 30 minutes of warm ischemia time; thus, rapid action is necessary.

Oncologic Emergencies

- Often involve hemorrhagic, obstructive, and infectious problems. Other emergencies include neurologic compromise and pain management issues.
- Prostate cancer may metastasize preferentially to the skeletal system and may cause sudden neurologic compromise from spinal cord compression.
- Manifestations include sensory loss, paralysis, and loss of urinary, bowel, and sexual function; when observed, immediate neurosurgical consultation should be obtained.
- Antiandrogen therapy may be of great value when prostate cancer patients present with complications such as neurologic or urinary obstructive compromise. Intramuscular luteinizing hormone–releasing hormone agonists may be started immediately.
- An antiandrogen drug such as bicalutamide should be commenced simultaneously or prior to the luteinizing hormone–releasing hormone analog to prevent transient worsening from the androgen flare.

POSTOPERATIVE MANAGEMENT

- Both major and minor urologic surgery may present critical care issues that require rapid and accurate assessment and intervention. Currently, many urologic procedures that have traditionally been performed through open surgical approaches are now commonly being approached by laparoscopic, robotic, and other minimally invasive techniques, which bring with them their own set of postoperative challenges.

Upper Abdominal Surgery

- **Patient position and selection of incision** are relevant to the postoperative management to anticipate the types of problems that may arise postoperatively.
 - In flank surgery, it is not uncommon to encounter a “down-lung” syndrome, with postoperative atelectasis involving the lung positioned downward against the operating table.
 - Occasionally lobar or complete lung atelectasis may be noted and may require bronchoscopic intervention.
 - Excellent pulmonary toilet is critical following upper abdominal and flank urologic surgery and ideally should be initiated preoperatively.
 - Postoperative pain from flank surgery can be a major problem and can require expert pain management intervention, continuous epidural analgesic strategies, subcutaneous pain pumps, and patient-controlled intravenous analgesics.
 - Appropriate pain control is also key to minimizing pulmonary complications by aiding respiratory and coughing efforts.
- **Early postoperative hypoadrenal state** should be considered after surgery involving removal or manipulation of the adrenal gland.
 - The critical care specialist should know if the adrenal was removed along with a nephrectomy procedure and whether there is any reason to suspect hypofunction or absence of the contralateral gland.

- **Acute renal insufficiency** may occur following any major surgery, and is of particular concern following renal surgery.
 - Partial nephrectomies may be performed using warm or cold ischemia techniques.
 - When the latter approach is used, vascular control of the kidney is obtained and the patient’s kidney is packed in saline slush. The excisional procedure is completed in a setting of local hypothermia.
 - Some degree of postoperative acute tubular necrosis may still occur despite the cold ischemia technique.
 - The clinical relevance of the acute tubular necrosis depends largely on the state of the contralateral kidney, and standard management principles for acute renal insufficiency are applicable.
- **Postoperative bleeding** may be manifested by hemodynamic changes, acute anemia, physical findings such as palpable flank hematoma or ecchymosis, or radiologic findings of blood in the renal fossa, chest (after a transthoracic procedure) or peritoneal cavity (after a transperitoneal procedure).
 - Following a partial nephrectomy, significant postoperative bleeding most commonly arises from arterial branch vessels within the renal parenchyma at the resection site.
 - If significant bleeding occurs following renal surgery, expectant management with transfusion, correction of any coagulopathy, angiographic embolization, CT scanning to assess the specific anatomic site of bleeding and judge the size of the hematoma, and/or a return to the operating room for re-exploration are options to be considered.
 - The choice between these measures is individualized based on the severity of the bleeding, patient condition and physiologic reserve, and access to imaging, interventional radiologic and surgical resources.
 - If there is evidence that major early postoperative bleeding occurs that may be due to an uncontrolled renal pedicle, rapid surgical re-exploration is the best approach.
 - If bleeding occurs subacutely and renal parenchymal bleeding is suspected, interventional radiology is usually favored.
 - The patient should be maintained in a fluid-resuscitated state when a renal bleeding issue is evolving, with the hemoglobin at a level that would allow the patient to tolerate continued blood loss without catastrophic decompensation.
- **Urinary extravasation** following upper urinary tract surgery may be manifested by increased drainage from suction drains for which creatinine determination confirms the fluid’s identity as urine.
 - Urologic input should be sought as to whether the region is well drained, whether the leak is expected, and whether intervention versus observation is indicated.

Pelvic Surgery

- Critical care issues typically relate to standard postoperative abdominal surgical concerns such as pain, bleeding, and ileus.
- Procedures requiring postoperative critical care include exenterative procedures for malignancies (radical prostatectomy or cystectomy), simple open prostatectomy for benign prostatic hyperplasia, and reconstructive pelvic surgeries for incontinence.

- Management of tubes and drains and recognizing when urinary extravasation arises in the postoperative period is important.
- Bleeding following major urologic pelvic surgery may result in Foley catheter occlusion with clot. The acceptable degree of hematuria and management of catheter drainage failure should be established with the urologist.
- The possibility of anastomotic leakage or a missed injury to the ureter exists in the radical prostatectomy patient. If suspected, the fluid should be sent for creatinine level to determine if a urine leak is present.
- Radical cystectomy is the procedure carrying the greatest deep vein thrombosis risk of the urologic operations, as an extensive pelvic lymphadenectomy is also typically included.
- Many urologic oncologists will start low-molecular-weight heparin regimens 24 hours after surgery if there are no bleeding issues.

Endoscopic Upper and Lower Urinary Tract Surgery

- The above category includes diagnostic cystoscopy (rigid, flexible), cystoscopic surgery (bladder biopsy, transurethral resection of prostate or bladder tumor [TURP, TURBT]), ureteroscopy, and percutaneous renal access surgery (percutaneous nephrostolithotripsy).
- Postprocedure infection can occur after lower tract endoscopy, but the risk is small if the urine is sterile preprocedure. Prophylactic oral antibiotics are often administered for all endourologic procedures to minimize the infection risk.
- Cystoscopic surgery using glycine or sterile water can result in significant hyponatremia if major absorption occurs.
- As hyponatremia develops, the patient may develop altered mental status, bradycardia, hypertension, and respiratory compromise. If under general endotracheal anesthesia, foamy material may be noted in the breathing circuit.
- Severe hyponatremia may cause cerebral edema and grand mal seizures, and may be life threatening.
- Diuretics with normal saline or hypertonic saline administered intravenously may be indicated. The more abrupt the development of the hyponatremia and the lower the serum sodium, the more dramatic the clinical manifestations are.
- Minimal intraperitoneal resectoscopic injuries may be manageable with catheter drainage alone. If problems arise (abdominal distention, persistent extravasation) with this nonoperative approach, laparoscopic or open surgical repair should be performed.
- Bleeding may be a problem following either TURP or TURBT. Often three-way catheter CBI is employed following these procedures.
- For TURP procedures, catheter traction may help control bleeding from within the prostatic fossa, whereas for TURBT procedures, catheter traction is of no value. Only the urologist should implement or adjust the traction system.
- If a catheter needs to be changed in the early postoperative period following a TURP or TURBT, this should be done by the operating urologist's team or on their specific order.
- Laser energy to ablate, vaporize, or coagulate tissue endoscopically for TURP and TURBT usually result in less bleeding than the traditional approaches. Complications usually relate to obstruction following catheter removal or to iatrogenic injury from misdirected laser energy.
- **Upper tract endoscopy** (ureteroscopy, percutaneous nephroscopy) has progressed greatly in the last two decades, with the current instrumentation allowing complex upper tract procedures to be performed with low morbidity.
 - Problems that the critical care provider may encounter usually relate to ureteral perforation, gross hematuria with stent occlusion, or obstructive problems from stone fragments.
 - Percutaneous nephrostolithotomy or nephrolithotomy may be accompanied by problems related to having surgery in the prone position, a high access traversing or affecting the chest, and postoperative bleeding.
 - If entry into the upper pole calyx is needed for stone access, a supracostal puncture may be required (above the 12th rib). The risk exists to traverse the chest cavity resulting in pneumothorax or hydrothorax, which may require tube thoracostomy postoperatively.
 - Significant bleeding can occur intraoperatively, perioperatively, or days or weeks postoperatively at the time of nephrostomy removal. Occasionally angiographic embolization may be necessary for major renal bleeding.
 - When removing a nephrostomy tube following percutaneous nephrostolithotomy or nephrolithotomy, a tamponade catheter should be immediately available to place into the tract and inflate if dangerous bleeding ensues following tube removal.
 - Extracorporeal shock wave lithotripsy involves the noninvasive fragmentation of renal or ureteral calculi with a shock wave generator system under fluoroscopic or ultrasound guidance. Following extracorporeal shock wave lithotripsy, colic can occur due to passage of fragments. Whether manageable expectantly or requiring stent insertion depends on the stone burden, the amount of debris created, the size of residual fragments, the degree of symptoms, and whether there are signs of infection and septic shock.
- **Laparoscopy** in urologic surgery has come into its own in recent years and has become a major element of our approach to a wide range of surgical tasks that previously were performed solely through major open approaches.
 - In many centers, the open radical retropubic prostatectomy has been nearly replaced by the robotic-assisted laparoscopic prostatectomy.
 - Potential issues include postoperative ileus, CO₂ retention, venous CO₂ embolism, postoperative bleeding, unrecognized intraoperative iatrogenic injury, and trocar and port-site complications.
 - Two potential major sites of postoperative bleeding in laparoscopic renal surgery are the renal pedicle and the renal parenchyma.
 - Bleeding can occur immediately postoperatively or in a more delayed fashion. When precipitous and life threatening, a quick return to the operating room with either laparoscopic or open re-exploration may be the most appropriate course.
 - If the patient's condition and rate of bleeding allows for further evaluation, postoperative CT scanning to determine if there is a renal or perirenal hematoma may be relevant prior to a surgical effort.
 - If bleeding occurs from the cut surface of the kidney following either open or laparoscopic partial nephrectomy, angiography with subselective embolization is often the preferred approach.

- **Drains** left within the abdomen following laparoscopic procedures are often placed intraperitoneally, as opposed to the case in extraperitoneal flank surgery, where the drain is often not within the peritoneal cavity. As such, intraperitoneal drains may drain retained irrigant or peritoneal fluid in copious amounts following surgery.
- If there is uncertainty as to the significance of increased drain output, fluid may be sent for chemical analysis (creatinine to determine if fluid is urine, amylase to rule out pancreatic fluid leak).
- Leakage of urine following laparoscopic urologic surgery may not require immediate intervention if the leak is well drained. If action is needed, postoperative ureteral stent insertion (along with a urethral Foley catheter or in some cases nephrostomy insertion) will often allow the collecting system to heal without sequelae.
- **Unrecognized bowel injury** must be appreciated during and after laparoscopic urologic surgery, especially if electrocautery is extensively utilized.
- The presentation of such complications may be subtle, with low-grade fever; minimal diffuse tenderness, which may be consistent with the expected postsurgical state, or delayed return of bowel function or persistent anorexia.
- A high degree of suspicion is important when patients fail to thrive following laparoscopic surgery. Postoperative CT scanning may demonstrate a fluid collection in an unexpected location or inflammatory changes in or near the intestine that is unanticipated.
- **Genital surgery** issues that may arise in the critical care setting may relate to penile, sphincter, and testicular prosthetic implants, neurologic stimulator implants, or complications of the wide range of other genital procedures urologists perform.
- Dressings on the genitalia should be inspected for bleeding or excessive tightness, which can cause vascular compromise, especially if applied circumferentially around the penis.
- Any major local complaint by a patient following genital surgery should be referred to the urologic surgeon for input.
- Other genital surgery procedures can be complicated by bleeding or infection. If marked swelling occurs following genital surgery, the urologist should be immediately made aware.

UROLOGIC TRAUMA

- The urologist's experience in elective urologic surgery; endoscopic, radiologic, and open surgical intervention; reconstructive approaches; and management of complications may be very helpful to the trauma and critical care teams when faced with the multiply injured patient or with solitary urologic organ trauma. When no urologist is available, the critical care provider must have a working knowledge of the approach to the most common and important types of urologic trauma.

Iatrogenic Injury Management

- A generously sized Foley catheter should be used (No. 20 French or larger) to allow drainage of bloody efflux and allow efficient irrigation when needed.
- If the bladder wall surrounding the injury is markedly abnormal (fibrotic, friable, irradiated), a two-layer closure may not be feasible and a one-layer, interrupted closure with heavy suture may be performed.
- If there is involvement of the trigone, ureteral orifices, or intramural ureters, the situation is more complex, and ureteral stent insertion or ureteral reimplantation may be needed.
- Prophylactic insertion of externalized ureteral catheters prior to complex pelvic or retroperitoneal surgery may be helpful in avoiding surgical injury to the ureter.
- For iatrogenic ureteral injuries, the repair approach depends on the level of injury, whether there is loss of ureteral length, the condition of the ureter and surrounding tissue, and the comfort of the surgeon.
- Traditionally, if the ureter is transected caudal to the crossing of the internal iliac artery, a reimplant rather than a primary anastomosis should be performed.
- Reimplantation can be performed with or without a psoas hitch depending on ureteral length and bladder status.
- For injuries in the mid- or upper ureter, primary, spatulated anastomosis performed over an indwelling stent is the preferred solution.
- If primary repair is not possible, the options include ligation followed by nephrostomy insertion and planned delayed reconstruction, transureteroureterostomy, renal autotransplantation, or ileal ureteral replacement.

Penetrating and Blunt Trauma to the Genitourinary System

General Evaluation

- Diagnosis of urinary tract injury is typically based on history and mechanism of injury, physical examination, laboratory assessment, and the findings on imaging studies. Any patient with a history of gross hematuria following trauma should be imaged, unless of course he or she is unstable and/or must be taken directly to surgery.
- Current literature supports obtaining imaging studies for patients with microscopic hematuria and hypotension at any time following trauma, as well as those patients with significant deceleration mechanisms of injury and other injury factors that portend a high risk of urinary tract injury such as lower posterior rib fracture, transverse spinal process fracture, or pelvic or femur fracture.
- The contrast-enhanced CT scan of the abdomen and pelvis has become the standard study of choice for assessment of hematuria, for staging of injuries in the trauma setting, and for the evaluation of renal or ureteral injuries.
- The "shock room intravenous pyelogram" has fallen out of favor and provides much less information than the CT scan.
- Bladder injuries may be suspected based on the presence of gross hematuria following pelvic trauma with confirmation by either standard radiographic or CT cystography. Adequate bladder filling must be accomplished to demonstrate extravasation and minimize false-negative studies.
- When urethral injury is suspected (following pelvic fracture or perineal or genital trauma), especially when blood is

exiting from the urethra or present at the urethral meatus, retrograde urethrography should be performed prior to any attempt at urethral catheterization.

- For genital trauma, scrotal ultrasonography may be of great value in diagnosing testicular rupture from blunt forces; in penetrating genital trauma, surgical exploration is usually necessary and one can usually forego imaging studies.
- **Urethral injuries** should be suspected in cases of pelvic fracture, particularly with severe pubic diastasis and vertical shear injuries. A urethrogram that demonstrates contrast extravasation is diagnostic.
 - The standard approach remains suprapubic tube insertion. Suprapubic cystostomy insertion may be accomplished using trocar-based percutaneous systems if the bladder is adequately distended. If not, an open surgical approach in the operating room is preferable.
 - Blunt trauma to the perineum with complete urethral rupture is also best handled with suprapubic diversion.
 - Penetrating injuries to the urethra can also be managed in a delayed fashion with suprapubic diversion, or, if the injury is readily apparent, direct suture repair with fine absorbable suture may be attempted in the stable patient.
 - All such injuries can be managed in a delayed fashion as long as proximal urinary diversion is achieved acutely.
- **Extraperitoneal bladder injuries** from blunt trauma are diagnosed on cystography, and can usually be managed with catheter drainage alone.
 - Adequate-bore catheters (No. 20 French or larger) are preferable to evacuate grossly bloody efflux. If there is failure of catheter management, surgical repair may be necessary.
 - Surgical repair to such an injury is approached through a high midline cystotomy to avoid entering into a fresh retroperitoneal hematoma, which may produce problematic bleeding.
 - Other cases of extraperitoneal bladder injury that benefit from surgical repair include those that involve communication with a vaginal or rectal injury.
 - A suprapubic tube, in addition to the urethral Foley catheter, may be left indwelling in cases in which the repair is tenuous or prolonged tube drainage is anticipated.
 - In the uncomplicated case, a contrast cystogram at approximately 10 to 14 days after injury and prior to catheter removal ensures complete healing before stressing the bladder.
- For **intraperitoneal bladder injuries**, direct suture repair is required. These injuries invariably occur in the bladder dome, and result from sudden compression of the full bladder.
- **Ureteral injury** is usually noted upon abdominal exploration in the penetrating trauma setting, or may be noted on preoperative CT scanning.
 - It is necessary to obtain a delayed excretory phase on the CT such that the excreted contrast column has transited the entire ureter, or the risk of missing a ureteral injury is significant.
 - For gunshot wounds to the middle and upper ureter, limited debridement to viable ureter, careful extra-adventitial mobilization, and spatulated suture anastomosis is appropriate.
 - For distal ureteral injuries, reimplantation into the bladder ("ureteroneocystostomy") is a more dependable approach.
 - Ureteral injuries from blunt trauma are rare. Exceptions would include the pediatric population, where ureteropelvic

avulsion injuries or renal pelvic lacerations may occur following blunt injuries.

- When major injury occurs to the urinary tract following seemingly trivial trauma, one should be suspicious of the presence of previously existent underlying pathology of the urinary tract such as neoplasm or ureteropelvic junction obstruction.
- **Renal injuries** are typically staged by contrast-enhanced CT using the American Association for the Surgery of Trauma Organ Injury Scaling system.
 - Renal injuries are managed according to a multifactorial decision process that considers grade and whether they are due to blunt or penetrating forces, and is based on patient clinical status and hemodynamic stability.
 - For **blunt renal injury**, grade I, II, and III injuries are routinely managed nonoperatively.
 - Grade IV injuries require a selective approach, largely influenced by hemodynamic parameters and degree of progressive blood loss, and often warrant monitoring to address whether continued bleeding or urinoma formation occurs.
 - The majority of such injuries in most series do not require early exploration. Observation of extravasation from the collecting system is not, in itself, a strong indication for surgical exploration. If there is extensive medial extravasation on CT, retrograde pyelography may be indicated to exclude a major injury to the renal pelvis or proximal ureter.
 - Grade V injuries from blunt trauma routinely require surgical exploration and often nephrectomy, and most reported results of attempts to manage true grade V injuries nonoperatively have not resulted in good outcomes.
 - Renal pedicle injuries, which are considered in both the grade IV and V groups, require careful consideration to select appropriate management. When the kidney suffers a pedicle stretch injury from deceleration trauma, resulting in arterial intimal disruption, the artery can thrombose, resulting in renal devascularization.
 - If the vessels are thrombosed but not avulsed or lacerated, the decision of whether to operate to revascularize the kidney depends on how much time has elapsed, which predicts renal salvage, as well as the patient's other injuries and ability to tolerate a laparotomy. After 30 minutes of warm ischemia, irreversible renal damage begins; by 3 hours, the kidney is not retrievable.
 - If there is a pedicle avulsion injury, surgery is mandatory to prevent delayed catastrophic bleeding.
 - For **penetrating renal trauma**, the standard approach is operative exploration and repair; departure from this approach is appropriate when complete staging information is available that predicts a favorable outcome for a specific injury with a nonoperative approach, the patient is hemodynamically stable, and careful monitoring for failure of nonoperative management can be carried out. Criteria and a plan for changing to an operative strategy should exist.
 - When comparing the approach to blunt versus penetrating trauma, one must consider the high likelihood of there being associated injuries in penetrating trauma.
 - Proactive angiography may be considered when weighing the safety of a nonoperative approach to the penetrating renal injury in selected cases, and admission to the ICU is essential to monitor for renewed bleeding.
- **Genital injuries** require specialized care and should be handled by practitioners experienced in genital surgery. As a

general principle, a very conservative approach to genital debridement should be maintained, with tissues of questionable viability reassessed in a delayed fashion.

- Nearly all penetrating genital injuries should be surgically explored acutely, assuming the patient is sufficiently stable to undergo a reconstructive effort.
- Penetrating penile injuries are repaired surgically by closing lacerations in the corpus cavernosum, urethral repair, and skin and soft tissue reconstruction. Penetrating testicular injuries can usually be repaired by closing the tunica albuginea of the testis after debriding nonviable testicular parenchyma.
- Blunt fracture of the penis, which results from forcible flexing of the penile shaft during erection (often due to trauma during intercourse), should be explored and repaired acutely, upon presentation, to achieve the most favorable cosmetic and functional outcome.
- For blunt scrotal injury, it is often useful to assess the patient with scrotal ultrasonography to determine if testicular rupture is present. Ultrasound is quite accurate for detecting testicular rupture: loss of capsular continuity or marked heterogeneity of testicular parenchyma is predictive of rupture. Testicular salvage is enhanced by early exploration and repair.

Damage Control Strategies for the Management of Urologic Injury in the Unstable Patient

- Many urologic injuries are quite amenable to initial management by applying damage control strategies. With the exception of severe renal or bladder bleeding cases, urinary tract injuries do not directly result in early mortality. When, in the surgeon's judgment, the patient would not tolerate the magnitude of reconstructive effort needed to deal definitively with a urologic injury at initial laparotomy (due to pattern of injury, hypothermia, acidosis, coagulopathy, or other parameters that mandate a damage control approach), certain temporary solutions may be very desirable.
- Renal injuries that are incompletely staged or unstaged may be approached with delayed assessment and exploration, as long as a determination is made that early, exsanguinating bleeding from the injury is unlikely.
- In the absence of significant bleeding from the renal fossa into the peritoneal cavity, a large midline hematoma, or an expanding or pulsatile renal hematoma, one can elect to leave the perinephric hematoma undisturbed and either obtain postoperative imaging during the resuscitation phase following initial laparotomy or explore during a second-look procedure.
- If the kidney is already surgically exposed, hemostasis for major bleeding from parenchyma or branch renal vessels can be rapidly obtained.
- If a major reconstructive effort is still needed in the unstable patient, packing the kidney and returning for reconstructive interventions later is also an option.
- Ureteral injuries may be initially managed with externalized stenting, ligation, or simple local drainage.
- A similar approach can be utilized for extensive bladder injuries: the ureteral orifices can be catheterized, the

catheters externalized, and the pelvis packed, leaving bladder reconstruction to be performed at a more suitable time, following appropriate resuscitation.

- Urethral and genital injuries are also amenable to damage control approaches, generally involving tube urinary diversion, placement of moistened dressings, and tissue preservation until definitive reconstruction following appropriate resuscitation.

URINARY DIVERSION MANAGEMENT FROM THE CRITICAL CARE PERSPECTIVE

- Beyond the considerations regarding tube diversion or drainage, some patients under the critical care team's care may have undergone, either acutely or remotely, a surgical urinary diversion procedure. Problems include urinary outflow obstruction, intra-abdominal urinary extravasation, infectious complications, and problems with the intestinal anastomosis.
- One can divide urinary diversion procedures into conduits and reservoirs. Conduits are simple surgical reconstructions that allow urine to exit to the outside and do not involve an internal urinary reservoir.
- An **ileal conduit** is one of the most commonly encountered urinary diversions. In this procedure, a segment of distal ileum is isolated from the fecal stream, followed by a small bowel anastomosis to re-establish intestinal continuity. One end of the isolated segment is closed, and the other end is brought to the skin of the abdominal wall as a stoma. The ureters are sutured into the conduit intra-abdominally to route the urinary stream externally.
- **Other conduits** employed in urologic surgery may utilize other bowel segments, including jejunum and descending or transverse colon, especially when there has been extensive pelvic irradiation that has damaged the ileum and lower small intestine.
- **Reservoirs (neobladders)** involve the use of larger segments of intestine to fashion a neobladder internally, along with some form of urinary efflux mechanism, often designed to create a continent diversion that the patient can catheterize (and not wear a urinary collection appliance) or that is sutured to the native urethra (in the male or female) to allow restoration of voiding (an "orthotopic neobladder").
- Reservoir urinary diversions can develop certain other potentially serious problems including "pouchitis," pouch rupture, and formation of pouch calculi.
- The issue of pouch rupture deserves specific mention as this must be promptly recognized. Any patient with signs of abdominal infection or sepsis who has a neobladder should raise the suspicion of pouch rupture. This entity can also be seen in patients who have had an augmentation cystoplasty, in which a segment of bowel is added to the native bladder to increase capacity or deal with severe and intransigent overactive bladder symptoms.
- Such patients should have urgent urologic assessment, which may involve contrast imaging studies (CT or "pouchography") to rule out urinary leakage intra-abdominally. Broad-spectrum antibiotics should be instituted early in

such cases, as the urine is often colonized and intra-abdominal infection may be developing.

- Many such cases can be managed with tube drainage of the neobladder alone, though in some cases surgical exploration and repair, and/or evacuation of infectious fluid from the abdominal cavity are necessary.
- Depending on the type of urinary diversion and the specific segment of the gastrointestinal tract used for the reconstruction, these patients may be at risk for dehydration, and specific electrolyte and metabolic disturbances.
- Jejunal conduits may result in hyponatremic, hypochloremic metabolic acidosis; this process may be clinically manifested by nausea, vomiting, anorexia, and muscular weakness.
- When ileum and colon are utilized for the urinary diversion, hyperchloremic metabolic acidosis may be seen. Clinically this may produce weakness, anorexia, vomiting, or Kussmaul breathing, and may progress to coma.
- When gastric segments are utilized for urinary diversion, dehydration and hyponatremic metabolic alkalosis may occur, requiring replacement of sodium and chloride through intravenous salt administration.
- Abnormal bile salt metabolism following ileal resection, can affect fat digestion and uptake of vitamins A and D.
- Malabsorption and steatorrhea and a propensity to develop cholelithiasis may also be associated with ileal resection.
- Gastric or ileal resection may cause vitamin B₁₂ deficiency, which can lead to megaloblastic anemia and peripheral nerve dysfunction; B₁₂ nutritional supplementation may be indicated.

UROSEPSIS AND COMPLEX UROGENITAL INFECTION IN THE CRITICAL CARE SETTING

Specific Infectious Processes of the Upper and Lower Urinary Tract

- The combination of obstruction and infection of the upper and lower urinary tract requires urgent drainage, antibiotic therapy, and supportive care.
- Initial empiric antibiotic therapy for presumed urosepsis must address the likely offending organisms and must consider the “worst-case scenario” from the bacteriologic standpoint.
- While awaiting culture data, Gram’s stain findings can also be very helpful in selecting initial therapy. Broad-spectrum antibiotics that cover aerobic gram-negative rods and the typical gram-positive cocci that appear as uropathogens are critical.
- If the patient has been recently instrumented, has been recently hospitalized, or has other risk factors for having sepsis due to atypical or resistant pathogens, coverage should be expanded accordingly.
- It may be necessary in certain situations to consider the presence of anaerobic infections of the genitourinary system. Sepsis following transrectal prostate biopsy may introduce the risk of anaerobic infection. Additionally, anaerobic infection of the urinary tract has also been described outside the setting of iatrogenic rectal violation, so this uncommon scenario is worth bearing in mind.
- Staphylococcal infections of the urinary system do also occur, particularly in the elderly or immunocompromised population, or in patients who have iatrogenic manipulation.
- When a gram-positive coccus is noted on stained urine or infectious fluid, vancomycin is an appropriate empiric choice for sepsis of urinary tract origin, as both *Enterococcus* and *Staphylococcus* species are usually covered.
- Fungal organisms should be considered especially in the diabetic patient and in the patient who has had extensive antibiotic therapy. Empiric fluconazole is appropriate.
- In addition to supportive care and antibiotic management, prompt drainage of the urinary tract is critical in certain conditions of urinary infection and urosepsis. Rapid decline in clinical status may ensue if there is a delay in instituting prompt drainage of an infected, obstructed system.
- When either upper or lower tract obstruction is present with urosepsis, prompt imaging of the urinary tract should be obtained (noncontrast CT of the abdomen and pelvis or renal ultrasound, bladder ultrasound to exclude retention).
- One major potential diagnostic pitfall occurs when a patient has complete unilateral upper tract obstruction with a negative urinalysis, as no urine from the obstructed system enters the bladder, and the urinary tract origin of sepsis is therefore not suspected.
- Emphysematous pyelonephritis and cystitis are infections of the kidney and bladder, respectively, which result in gas formation within the tissues.
- The presence of gas in the urinary tract may be due to gas-forming infection, previous instrumentation, or fistula. The clinical situation will usually lead to the correct etiology.
- The most commonly seen organism in such infections is *Escherichia coli*, which may enter into a state of facultative anaerobic metabolism, especially in a diabetic when severe hyperglycemia is present.
- These patients may become severely ill and require aggressive resuscitation and sometimes drainage procedures or occasionally urgent nephrectomy; urologic consultation is essential.
- Emphysematous cystitis reflects the same bacteriologic basis and propensity for the diabetic patient as for the renal counterpart. Bladder catheter drainage and aggressive antibiotic management will usually correct the process.
- Renal and perinephric abscesses are the important causes of urosepsis, and one must have a high index of suspicion in the setting of incomplete resolution of upper tract urinary infection with standard antibiotic regimens, prompting imaging to detect an undrained source of relapsing or persistent infection.
- CT scanning is significantly superior to ultrasound for imaging the perinephric space, and is preferable when an abscess is suspected.
- Small renal parenchymal abscesses not causing a septic picture may resolve with antibiotic treatment alone.
- When multiloculated or when inadequately drained by the percutaneous route, an open surgical drainage procedure may be necessary.
- Acute bacterial prostatitis can present with a septic picture. Common symptoms include dysuria, frequency, urgency, chills and fever, elevated white blood count on CBC, and infected urine.
- If the patient is emptying adequately, antibiotic administration is usually adequate without catheter drainage. If the patient is in acute urinary retention, bladder drainage is

needed; one can proceed either with a gentle attempt at Foley catheter passage per urethra or with percutaneous suprapubic cystostomy placement.

- For patients presenting with acute prostatitis or other complex lower tract infection who do not respond appropriately to antibiotic therapy, or for those with suspicious findings on a digital rectal examination, prostatic abscess should be suspected.
- Transrectal ultrasound or CT scanning of the pelvis will usually confirm the presence of a prostatic abscess when present, and can also guide therapy by revealing whether the abscess cavity may be best drained through a transurethral, transperineal, or transrectal route.

Urologic Involvement in Complex Soft-Tissue Infectious Processes

- Urologic involvement with such entities as perirectal abscess or Fournier gangrene is common. Fournier gangrene may be idiopathic with no identifiable point of origin, or may be due to extension from primary rectal, urinary, intra-abdominal, or retroperitoneal processes. These patients require a combination of aggressive antibiotic therapy, metabolic and fluid resuscitation, and prompt and aggressive surgical debridement and drainage. These infectious processes can progress very rapidly, and delays in bringing the patient to surgery may result in loss of otherwise salvageable tissues and increased mortality.
- Diabetics are at increased risk for this disease. When there is genital, perineal, or groin involvement in such processes, several applicable management principles may be of value.
- Broad-spectrum (“triple antibiotic”) regimens that cover aerobes, anaerobes, and gram-positive and gram-negative organisms should be started, as polymicrobial infection is the norm.
- Aggressive surgical debridement and drainage by close collaboration between the urology and general surgery teams may aid functional and organ preservation, and subsequent reconstructive efforts.
- When an abscess or necrotizing process extends into the region of the perineum or genital soft tissues, incision or debridement of scrotal or penile skin and underlying dartos may be necessary.
- In the scrotum, we try to establish a dissection plan just superficial to the parietal tunica vaginalis and keep this membrane, which surrounds the testes, intact.
- The testes are rarely involved in these soft tissue infections, and preserving the parietal tunica vaginalis directly will aid in subsequent wound management and avoid the pain and desiccation that occurs when the testis is exposed externally.
- If the surgeon must enter the scrotal wall for drainage of a local abscess, it is best to avoid deep incision into the tunica vaginalis compartment to avoid preventable injury to the scrotal contents.
- On the penis, necrotic skin and dartos may be debrided up to the coronal sulcus when necessary, taking care to stay superficial to the Buck fascia (deep fascial layer) of the penis, to avoid injury to the corpora and the dorsal neurovascular bundle.
- Fournier gangrene may occasionally arise from a urethral source (such as a periurethral abscess or perforated stricture or diverticulum). Debridement of urethral tissue should be avoided unless it is grossly necrotic, as a superficial exudate may create the appearance of marginally perfused tissue; such changes can be reassessed on take-back to the operating room.

SECTION IX ■ ORGAN TRANSPLANTATION

CHAPTER 54 ■ CRITICAL CARE AND TRANSPLANTATION: OVERVIEW

- Critical care and clinical organ transplantation have developed in parallel over the past several decades. While organ transplantation has emerged as the treatment of choice for an ever-growing number of patients with end-stage organ failure, the intensive care unit (ICU) has become the venue where much of this care is rendered. The modern intensivist plays an important role in the care of the critically ill patient awaiting transplant, the postoperative management of the transplant recipient, and the identification and management of the potential deceased organ donor.
- The success of organ transplantation can be attributed to a number of factors. These include better patient selection and preoperative preparation, standardization of surgical techniques, advances in immunosuppression and graft surveillance, and improved postoperative care. This success, in part reflective of advances in critical care medicine, poses a great challenge to the skills of the intensivist and the resources of the ICU. The continuing shortage of organs available for transplantation translates into longer waiting times for recipients, during which their condition may further deteriorate. Additionally, organ allocation algorithms—especially heart, lung, liver, and intestine—in the United States emphasize the “sickest first” philosophy, which states that the highest priority for organs should go to those most in danger of imminent death. Finally, the shortage of organs has forced the transplant community to consider the use of organs from less-than-ideal donors. The organs from these marginal or “expanded criteria” donors, though used with caution, must be considered to minimize deaths on the waiting list. The impact on the ICU is clear: More transplants are being performed on critically ill patients with an organ pool that now includes compromised organs.
- A prerequisite to the success of organ transplantation is the availability of suitable organs. Deceased organ donors are, and will continue to be in the foreseeable future, our most important organ source. A crucial consideration of the ICU staff should be the timely recognition of the potential organ donor, both those who are brain-dead and those for whom death is imminent, and the early involvement of organ procurement organization (OPO) personnel to facilitate the process. The assessment of the potential organ donor, a clear understanding of donation after brain death and cardiac death protocols, and donor management are skills of the intensivist that are fundamental to the organ procurement process and the subsequent transplants performed.

INTESTINAL TRANSPLANTATION

- Intestinal transplantation has emerged as an accepted therapy for complicated intestinal failure. Standardization of

surgical techniques, better management of the intestinal failure patient, improvements in immunosuppression, and advances in graft surveillance have led to better patient and graft survival. Survivors are almost always able to be completely tapered from parenteral nutrition.

- The intestine can be transplanted as an isolated organ or as part of a composite graft depending on the needs of the patient. The multivisceral graft includes, en bloc, the stomach, liver, duodenum, pancreas, and small intestine. This graft can be modified to include or exclude the liver, spleen, colon, or a kidney. Each modification has critical care implications, especially when the recipient requires a liver as part of the transplantation.
- The number of intestinal transplants has been increasing, as illustrated in Figure 54.1. Many variables affect outcome and, in recent years, patient and graft survival have been improving. Patient survival from data over the past 15 years are shown in Figure 54.2.

DONOR RECOGNITION AND ASSESSMENT

- Transplantation depends on organ donation. OPOs are charged with the responsibility of deceased organ donor recognition and assessment. Medical professionals are required to cooperate with OPO personnel to ensure that all potential organ and tissue donors are identified and afforded the opportunity to donate. It is recommended that OPO and hospital staff collaborate by establishing criteria as to when it is the earliest appropriate time to consult the OPO.
- The critical care physician's first priority is to provide excellent patient care. Additionally, he or she should recognize, when brain death is imminent or when withdrawal of support measures are considered, that there is an opportunity through organ donation to help other patients. Timing is critical: Approaching a family too early is inappropriate and too late threatens the potential for organ donation.
- To assist in defining the appropriate time to consider OPO involvement, the United Network for Organ Sharing (UNOS) has devised the term *imminent neurologic death*. This term describes the patient with an irreversible brain injury who may fit the general criteria of a potential organ donor but has not been legally declared brain-dead. It is appropriate to notify the OPO when a patient meets this definition and displays an absence of at least three of the following neurologic functions as a result of the brain injury (not pharmacologic sedation or other confounding variables):
 - Pupillary reaction
 - Response to cold calorics

FIGURE 54.1. Number of intestinal transplants by age group and era. TX, transplant; LI, liver; IN, intestine; Peds, pediatric patients. (Source: 2006 Annual Report of the U.S. Organ Procurement and Transplantation Network and the Scientific Registry of Transplant Recipients: Transplant Data 1996–2005. Rockville, MD: Health Resources and Services Administration, Healthcare Systems Bureau, Division of Transplantation. The data and analyses reported in the 2006 Annual Report of the U.S. Organ Procurement and Transplantation Network and the Scientific Registry of Transplant Recipients have been supplied by the United Network for Organ Sharing and Arbor Research under contract with the Department of Health and Human Services. The authors alone are responsible for reporting and interpreting these data; the views expressed herein are those of the authors and not necessarily those of the U.S. government).

- Gag reflex
- Cough reflex
- Corneal reflex
- Doll's eyes reflex
- Response to painful stimuli
- Spontaneous breathing
- In short, when the diagnosis of brain death is being considered and the clinical assessment has begun to confirm that diagnosis, the OPO should be notified.
- There are two important implications of the preceding statement that warrant clarification. First, OPO personnel are permitted access to patients' medical records per an exemption in the Health Insurance Portability and Accountability Act. Second, the critical care provider is not required to notify the patient's family that the OPO has been consulted. If they wish, critical care providers can inform the family and/or introduce the idea of organ donation. It is not recommended that they discuss the process and options in detail. That task should be left to OPO personnel who are specially trained to approach grieving families and are qualified to obtain informed consent for organ and tissue donation.

ORGAN DONATION PROCESS

- There are fundamentally two types of potential donors who can be considered from the critical care population: ventilator-dependent patients who will be withdrawn from life-sustaining measures and patients who are declared clinically brain dead. In the former circumstance, it is possible to offer the option of organ donation after cardiac death, provided certain criteria are met. In the latter, donation may occur in the presence of circulation after the patient has been declared clinically brain dead. This is termed *organ donation after brain death*. As guidelines, the UNOS has published the Critical Pathway for the Organ Donor and the Critical Pathway for Donation after Cardiac Death.

DONOR MANAGEMENT

- In many ways, management of the organ donor resembles that of the critically ill patient, with an important distinction. The goal for the critically ill patient is recovery, prolonging

FIGURE 54.2. Patient survival after intestinal transplant, 1991–2005. (Source: 2006 Annual Report of the U.S. Organ Procurement and Transplantation Network and the Scientific Registry of Transplant Recipients: Transplant Data 1996–2005. Rockville, MD: Health Resources and Services Administration, Healthcare Systems Bureau, Division of Transplantation. The data and analyses reported in the 2006 Annual Report of the U.S. Organ Procurement and Transplantation Network and the Scientific Registry of Transplant Recipients have been supplied by the United Network for Organ Sharing and Arbor Research under contract with the Department of Health and Human Services. The authors alone are responsible for reporting and interpreting these data; the views expressed herein are those of the authors and not necessarily those of the U.S. government).

life, and improving its quality. The goal of donor management is maximization of the number and quality of transplantable organs. Once brain death has been determined, OPO personnel play an instrumental role in donor management. Brain death is associated with grossly impaired body temperature regulation, profound hypernatremia due to diabetes insipidus, impaired blood pressure regulation, coagulopathy, endocrine dysfunction, and electrolyte and acid-base disturbances. Physiologic derangement may have been the manifestation of the inciting injury or insult; this is often worse at the time of cerebral edema, herniation, and brain death.

- Donor maintenance has become more sophisticated in recent years. Each OPO has detailed protocols and care pathways for organ donor optimization. Each has a medical director and/or critical care physician as a consultant or as an active participant in the process. The OPO community under the direction of the Health Resources and Services Administration has developed its “best practices” for donor monitoring and maintenance. Fluids administered and urine output and any other fluid losses are measured. Monitoring routinely includes the use of arterial catheters for blood pressure monitoring, central venous pressure monitoring, and sometimes pulmonary artery catheter placement. Arterial oxygenation is monitored via continuous pulse oximetry.
- Fluid warmers and other warming devices are utilized as needed to maintain normothermia. Mechanical ventilation modalities geared toward maintaining oxygenation and ventilation while minimizing pulmonary injury are utilized. Hemodynamic derangement is addressed with fluids (crystalloid, colloid, and blood products) and the administration of vasopressors, inotropes, or antihypertensives as indicated. A standardized battery of laboratory tests is obtained, and detected abnormalities are corrected, if possible. Acid-base abnormalities are corrected, and hypernatremia and hyperglycemia are treated. Antibiotics, corticosteroids, endocrine replacement, and other medications are given to the donor in accordance with detailed management protocols. Cultures, viral serologies, blood type, and human leukocyte antigen studies are performed to assess donor and recipient compatibility.

ASSESSMENT OF DONOR'S ORGAN FUNCTION

- Coincident with monitoring and correction of physiologic derangement, the donor organs are evaluated for transplantation. A thorough history is obtained and the medical record reviewed. Emphasis is placed on detection of infection, presence or a history of malignancy, and comorbid conditions that can affect organ viability.
- Each organ is considered individually, and specific tests are available to measure function or detect impairment. The heart is evaluated by an assessment of the donor's hemodynamic status, sometimes with the aid of a pulmonary artery catheter, need for vasopressors or inotropic drugs, transthoracic echocardiography and, in selected cases, coronary angiography. Lung assessment includes serial arterial blood gas measurement, chest radiography, and flexible bronchoscopy. The kidneys are evaluated by urine output, serum creatinine measurement and, for some OPOs, a calculation of the glomerular filtration rate. After procurement, a renal cortical biopsy can yield important information regarding organ quality. Some OPOs and TCs preserve kidneys with a pulsatile perfusion machine.
- Some transplant surgeons use the performance parameters of the kidney(s) on the pump as an adjunct measure of quality. There are few specific indicators of pancreas viability and quality. Euglycemia without the need for significant amounts of exogenous insulin is preferable. Elevated serum amylase may raise concern that the gland is not suitable because of pancreatitis.
- The liver is assessed by transaminase and bilirubin measurements. Serum albumin and coagulation studies are measures of liver function. A liver biopsy obtained percutaneously before procurement or in the operating room at the time of organ recovery can be useful for detecting inflammation, necrosis, fibrosis, or steatosis. There are no specific standardized methods for the evaluation of the donor intestine.

CHAPTER 55 ■ HEART TRANSPLANTATION

- The number of patients on the waiting list for a heart and the number of transplantations performed has decreased significantly over the past decade. Over the same time, deaths on the waiting list have declined, and survival results after heart transplantation remain high (Fig. 55.1). These data reflect the improvements in transplantation, better medical management of interventional techniques for patients with heart disease, and the development of more effective mechanical support devices.

PERIOPERATIVE CARE OF HEART TRANSPLANTATION

Hemodynamic Markers of Heart Failure

- Knowing the risk of dying and the prognosis of patients receiving optimal medical therapy is critical to the determination of transplant candidacy and timing. Cardiopulmonary

FIGURE 55.1. Patient survival after heart transplant by diagnosis. (Source: 2006 Annual Report of the U.S. Organ Procurement and Transplantation Network and the Scientific Registry of Transplant Recipients: Transplant Data 1996–2005. Rockville, MD: Health Resources and Services Administration, Healthcare Systems Bureau, Division of Transplantation. The data and analyses reported in the 2006 Annual Report of the U.S. Organ Procurement and Transplantation Network and the Scientific Registry of Transplant Recipients have been supplied by the United Network for Organ Sharing and Arbor Research under contract with the Department of Health and Human Services. The authors alone are responsible for reporting and interpreting these data; the views expressed herein are those of the authors and not necessarily those of the U.S. government).

testing as a measure of oxygen consumption is routinely used to determine candidacy for transplantation. The currently accepted indication for transplantation is a peak $\text{VO}_2 < 10$ mL/kg per minute in patients with adequate β -blockade who achieved anaerobic threshold. Patients with a VO_2 between 10 and 14 mL/kg per minute are more problematic, and decisions to list for transplantation should be individualized. The use of VO_2 as a discriminatory variable requires experience and attention to detail in testing performance. It is important to note that patients tolerating β -blockade demonstrate improved survival with equivalent VO_2 . It is also notable that appropriate patient selection assumes maximal effort to achieve a plateau of performance. In populations with limited functional status a respiratory exchange ratio > 1.05 is generally considered a maximal exercise test. Peak VO_2 also varies with age and gender and is normalized for body weight, with heavier patients having a lower VO_2 at comparable levels of performance. In the era prior to widespread use of β -blockers and angiotensin-converting enzyme inhibitors, a VO_2 maximum of $< 50\%$ was shown to be a significant predictor of cardiac death. Nonetheless, isolated peak VO_2 should not be used as the sole criterion for transplant eligibility.

- Right heart catheterization provides information on cardiac output, ventricular filling pressures, and pulmonary vascular resistance (PVR) and is an absolute prerequisite to consideration for transplantation. A pulmonary vascular resistance greater than 5 Wood units, an indexed PVR greater than 6 Wood units, or a transpulmonary gradient greater than 16 to 20 mm Hg have been considered relative contraindications to transplant (1 Wood Unit = $80 \text{ dynes} \cdot \text{s/cm}^5$). Candidacy for transplantation is less dependent on the absolute measures of PVR than on the responsiveness of the pulmonary vascular bed to therapy. Heart failure patients with pulmonary artery systolic pressures greater than 50 mm Hg and either a PVR > 3 Wood units or a transpulmonary gradient > 15 mm Hg are routinely challenged with multiple vasodilators to ascertain whether the elevated pulmonary pressures are reactive. Most patients with acute decompensated heart failure have elevated left-sided filling pressures with secondary pulmonary venous hypertension. Pharmacologically unloading the left ventricle with sodium nitroprusside while maintaining a systolic blood pressure of > 85 mm Hg is generally considered evidence of a reactive vascular bed and does not preclude transplantation.

- A significant minority of patients have evidence of fixed pulmonary hypertension.
- Patients without evidence of an anatomic substrate are treated with aggressive diuresis and short-term inotropy with the phosphodiesterase inhibitor milrinone. If subsequent provocative testing demonstrates continued non-reactivity, dobutamine is added to the inotropic support for synergy. Such vasodilatory conditioning generally improves pulmonary vascular resistance, but these patients remain at higher risk for acute cardiac death prior to transplant and, in our experience, remain at significant risk for elevated pulmonary artery pressures after transplantation. It is important to recognize that the reversibility of PVR in patients with low left ventricular ejection fraction cannot be assessed without unloading the left ventricle. Fixed pulmonary hypertension has been effectively treated with mechanical circulatory support, allowing isolated cardiac transplantation in patients initially thought to require a combined heart–lung procedure.
- Renal dysfunction is among the most significant clinical variables complicating the decision to transplant and one of the most significant morbidities after transplant.
- Currently, renal dysfunction is rarely a contraindication to transplant and have actively pursued combined heart and kidney transplant in patients at high risk for end-stage renal disease in the early postoperative interval. Outcomes for combined transplant are comparable to those of isolated cardiac allografts. Regardless of approach, the decision to exclude patient candidacy secondary to significant renal dysfunction or to simultaneously transplant a renal allograft requires careful consideration of the cause of preoperative renal insufficiency, the degree to which renal insufficiency is irreversible, and the probability of progressive renal failure after transplant.

Neurohormonal Markers of Heart Failure

- The natural history of heart failure is characterized by systemic neurohormonal activation in response to the structural and functional remodeling of decreased ejection fraction and progressive volume overload. Optimal medical therapy of heart failure is designed to ameliorate these neurohormonal changes: β -blockade of adrenergic pathways,

diuresis to reduce volume overload and natriuretic hormone production, and various inhibitors of the renin–angiotensin system including angiotensin-converting enzyme inhibitors and angiotensin receptor blockade.

- Analysis of the Randomized Evaluation of Strategies for Left Ventricular Dysfunction trial data demonstrated that temporal increases in brain natriuretic and N-terminal atrial natriuretic peptide during medical therapy were associated with concurrent reductions in ejection fraction and increases in end-diastolic and systolic volume.
- Brain natriuretic is often used as a marker to evaluate the adequacy and response to acute heart failure therapy and consider it a physiologic marker of volume overload. C-reactive protein (CRP), a nonspecific marker of inflammation, is considered a sensitive marker of the neurohormonal milieu in acute heart failure and a more sensitive marker of prognosis. In patients with decompensated heart failure, CRP is most elevated (CRP >15%–18 mg%) and associated with poor outcomes regardless of ejection fraction.

Heart Failure Survival Score

- The Heart Failure Survival Score is a clinical descriptor derived from a Cox proportional hazards regression model of noninvasively derived measurements describing ambulatory patients with advanced heart failure. The prognostic variables include resting heart rate, mean systemic blood pressure, left ventricular ejection fraction, serum sodium, peak oxygen consumption, intraventricular conduction delay defined as a QRS complex >120 ms, and the presence or absence of ischemic cardiomyopathy (see Table 55.1). Based on the absolute value of the sum of weighted variables, three risk-stratified groups were identified: high risk (score <7.19, 35% 1-year survival with medical therapy), medium risk (score 7.20–8.09, 60% 1-year survival), and low risk (score >8.10, 88% 1-year survival with medical therapy).

Organ Allocation

The current allocation system for donor hearts is designed to prioritize patients with the most urgent medical need of transplantation—potential recipients with mechanical circula-

tory assist devices and patients requiring multiple inotropes or a single high-dose inotrope (dobutamine >7.5 µg/kg/min or milrinone >0.5 µg/kg/min) are listed as status 1A. Patients requiring a single continuous low-dose inotrope to maintain hemodynamics and end organ perfusion are listed as 1B. Patients with end-stage heart disease who fail to meet either of these criteria are listed as status 2. Because of the increasing efficacy of medical therapy, the survival benefit of transplantation to United Network for Organ Sharing status 2 patients has been questioned.

POSTOPERATIVE COMPLICATIONS

Acute Allograft Loss

- Within 30 days of transplantation, causes of death include graft failure (primary and/or nonspecific) accounting for 40%, multiorgan system failure (14%), and noncytomegalovirus (non-CMV) infection (13%)

Right Ventricular Dysfunction and Allograft Failure

- Whereas acute right ventricular (RV) failure at the time of allograft implantation is an uncommon but highly morbid condition with historical mortalities approaching 30% to 50%, RV dysfunction after allograft implantation is common. Nearly 20% of orthotopic heart transplants demonstrate some degree of RV dysfunction as manifested by tricuspid regurgitation. Tricuspid regurgitation has recently been shown to be a predictor of late survival after cardiac transplantation, suggesting that early RV dysfunction is a marker of poor outcome. The etiology of transplant RV dysfunction is poorly understood but is clearly multifactorial and includes primary aspects of donor organ biology (e.g., primary RV graft dysfunction), inherent injury secondary to the procurement process (e.g., ischemia–reperfusion injury), and specific characteristics of recipient pathophysiology (e.g., elevated pulmonary vascular resistance).
- Heart donors with cerebrovascular accident as the cause of death have consistently demonstrated a significant

negative impact on 1-year post-transplantation mortality, and experimental data have supported the concept that donor brain death contributes to RV dysfunction after cardiac transplantation. Animal studies have demonstrated a significant decrease in RV function after transplantation in hearts retrieved from a brain-dead donor whereas RV function is maintained or increased after implantation of normal hearts even in recipients with chronic pulmonary hypertension. Furthermore, large animal models assessing the intrinsic myocardial mechanics of transplanted hearts independent of the severe changes in peripheral loading conditions that accompany the catecholamine storm of brain death (elevated peripheral and pulmonary vascular resistance) demonstrate a nearly 40% reduction in RV contractility without a similar decrease in left ventricular contractility. This suggests that RV dysfunction is primarily related to the status of the donor heart, and although elevated pulmonary vascular resistance will increase the severity of postoperative RV dysfunction, it is unlikely that elevated PVR independently creates RV dysfunction.

- The early biology of transplanted hearts is defined by denervation and diastolic dysfunction. Loss of afferent parasympathetic vagal tone and corresponding lowering of myocardial catecholamine levels in response to sympathetic denervation results in higher resting heart rates and a blunted response to hypovolemia and decreased preload. A poorly understood but useful consequence of denervation is increased presynaptic sensitivity to β -adrenergic stimulation. The transplanted heart is also “stiff,” and restrictive physiology is expected in the immediate postoperative period. Elevated diastolic ventricular filling pressures generally diminish within weeks of transplantation, but persistent diastolic dysfunction may represent donor–recipient size mismatch, myocardial injury from harvest ischemia, intrinsic characteristics of the donor heart (e.g., hypertension), or evidence of rejection.
- Because of limited therapies, prophylaxis for acute allograft dysfunction is a preferable clinical strategy. It is our practice to start inhaled nitric oxide (NO) (20 ppm) prior to weaning from cardiopulmonary bypass to lower pulmonary vascular resistance in patients with preoperative PVR >3 Wood units. All patients exit the operative theater on low- to moderate-dose epinephrine (0.02–0.06 $\mu\text{g/kg/min}$), and patients receiving chronic afterload reduction preoperatively (e.g., intravenous milrinone) are simultaneously started on low-dose norepinephrine (0.02–0.04 $\mu\text{g/kg/min}$). Patients are atrially paced (92 beats per minute [bpm]), or atrio-ventricular (AV) sequentially paced, in the immediate postoperative period. In the absence of significant tricuspid regurgitation and RV dysfunction, NO is weaned in the immediate postoperative period, and patients are generally extubated within 6 hours of exiting the operating room. Caution should be used in weaning NO, as rebound pulmonary hypertension has been observed. We have not found this to be a significant clinical problem outside the pediatric population. Inotropic support is maintained for the initial 24 hours and weaned off between 24 and 36 hours as determined by clinical exam.
- Clinical exam and echocardiogram effective for evaluating ventricular function, filling pressures, and RV strain and right heart catheters are generally placed for specific diagnostic questions and rarely guide clinical management. Right heart catheterization and biopsy is performed in general within 7 to 14 days of transplant.

Ischemia–reperfusion Injury

- Traditional views hold that the obligatory ischemia of organ procurement induces endothelial dysfunction, lipid peroxidation with loss of membrane integrity, free radical superoxide production, dysregulation of intracellular and mitochondrial calcium flux, and neutrophil activation with allograft infiltration. Reperfusion at the time of allograft implantation is thought to extend the inflammatory injury with subsequent apoptosis and delayed cell death contributing to graft dysfunction

Rejection and Immunosuppression

- With the exception of homozygous twins, all allografts are incompatible. This incompatibility is defined by the predominant mechanism of allorecognition—humoral or cellular—and the temporal pattern of allograft rejection. *Hyperacute rejection* occurs within minutes to hours of allograft reperfusion and is a rare form of perioperative graft loss caused by preformed antibodies directed against donor human leukocyte antigen or endothelial antigen. Complement activation results in intravascular thrombosis and ischemic graft dysfunction. There is no medical therapy, as graft loss is nearly immediate, and salvage requires mechanical circulatory support (extracorporeal life support [ECLS] or ventricular assist device [VAD]) and consideration for retransplantation.
- *Acute rejection* is historically considered a T cell–mediated process with perivascular infiltration of lymphocytes and macrophages and variable degrees of myonecrosis. It can occur anytime after transplantation but is most commonly diagnosed within the first 6 months—nearly 60% of heart recipients—and is the most common form of rejection within days to weeks after allograft implantation.
- *Chronic rejection* is characterized by circumferential myointimal proliferation and progressive coronary artery vasculopathy. Nearly half of all heart transplants demonstrate angiographically recognizable cardiac allograft vasculopathy (CAV) by year five.

BALANCED RISK: IMMUNOSUPPRESSION AND INFECTION

- Coronary artery vasculopathy is a probable complication of under-immunosuppression, whereas early infection and late malignancy are probable complications of over-immunosuppression. These opposing problems represent the major failure of contemporary thoracic transplantation.
- In spite of institutional preferences, all protocols shared immunosuppressive strategies for the *induction* of immune tolerance at the time of allograft implantation and for the *maintenance* of chronic immune suppression over time. *Rescue* (antirejection) therapy in response to histologic rejection remains very problematic, as there is no direct relationship between microscopic evidence of allograft rejection, allograft dysfunction, and patient survival.
- A list of most common solid transplantation immunosuppression drugs is available elsewhere in this book.

Infection Prophylaxis and Perioperative Risk

- Pneumonia is the most common presentation with a historical incidence of approximately 14% to 28% and an overall mortality of 23% to 31%. Hospitalization at the time of transplantation, postoperative endotracheal intubation for more than 1 day after transplantation, reintubation after transplantation, evidence of pretransplant pulmonary infection, use of antilymphocyte induction therapy, and prolonged and excessive use of steroids (>80 mg/day during the first month) are considered significant risk factors. It is important to note that nearly 20% of heart transplantations occur in patients on mechanical assist devices and that nearly half of all VAD recipients experience infectious complications.
- However, the recent deaths of organ recipients receiving allografts from patients with undiagnosed trypanosomal infection (www.CDC.org) underscores the increasing globalization of the donor population and the need for increasingly sophisticated screening technologies. A common prophylaxis treatment of bacterial, viral, and fungal pathogens are listed below:
 - Vancomycin (10–15 mg/kg every 12 h) and piperacillin/tazobactam (3.375 gm IV every 6 h) are empiric bacterial prophylaxis. Therapy is stopped at 72 hours after review of donor cultures.
 - Cytomegalovirus seropositivity is not a contraindication for either donor or recipient. Leukocytes are the source of CMV infection, and seronegative blood products should be used in seronegative patients and patients with seronegative allografts. Primary infection, a seropositive (CMV+) organ into a seronegative (CMV-) recipient, is associated with the greatest risk of CMV disease. These patients receive prophylaxis with CMV immune globulin (CytoGam, CMV-IVIG) at 150 mg/kg IV for 7 days followed by valganciclovir (Valcyte) for 1 year (450 mg twice daily [BID] dosed for renal function). Seropositive patients who receive either CMV-positive or CMV-negative allografts are at moderate to low risk of reactivation disease as are seronegative recipients of CMV-negative transplants. These patients receive prophylactic coverage for 6 months with Valcyte (450 mg orally BID). Any patient receiving treatment for histologic rejection receives 6 months of prophylactic Valcyte in the context of increased immunosuppression. Active CMV disease is treated with CytoGam (50–150 mg/kg IV daily) and a relative withdrawal of immunosuppression to facilitate immunocompetence.
- Hepatitis B surface antigen seropositivity in potential recipients has been associated with hepatic inflammation or cirrhosis in 37% of heart recipients and is a relative contraindication to transplantation. Currently, all patients receive hepatitis B vaccine prior to transplantation (HBsAg-positive, HBsAb IgM-positive, HBcAb-negative). We routinely use HBcAb-positive donor hearts in the context of HBsAg seronegativity as we consider this a sign of prior exposure and not active disease.
- Positive hepatitis C serologies (Hep C Ab+), if confirmed by nucleic acid testing, is considered evidence of active donor infection. It is our practice not to use organs from donors with presumed active hepatitis C because of high conversion rates (>50%) in recipients and poor outcomes. Active hepatitis C in patients with end-stage heart disease is not an absolute contraindication to transplant. Favorable hepatitis C viral genotype and low to undetectable viral titre by quantitative polymerase chain reaction (PCR) identifies a group of patients with outcomes comparable to those of thoracic transplant recipients without viral infection. We have also challenged hepatitis C seropositive patients before transplant with low-dose calcineurin inhibitors (target level of 5–8 ng%) and mycophenolate (1,000 mg BID). Patients without a significant rise in viral titer by quantitative PCR over 3 months have not demonstrated evidence of active viral disease after transplantation.
- All patients receive trimethoprim/sulfamethoxazole (*Septra*) for *Pneumocystis carinii* prophylaxis. Fluconazole (100 mg orally every week) is given for mucocutaneous candidiasis prophylaxis as long as patients are receiving steroids, and patients with evidence of fungal colonization (e.g., *Aspergillus* spp.) are maintained on voriconazole.
- In the absence of allograft dysfunction, the decision to treat moderate histologic (2R) rejection with pulse steroids deserves discussion. There are no compelling data that treatment of mild to moderate rejection significantly influences allograft survival, and there is significant evidence that increased steroids and antilymphocyte therapy increase the incidence of infection. Given the variability of histologic interpretation and the inherent possibility of non-representative biopsy tissue, the decision to treat histological rejection should be approached with caution as this represents the most significant variable in transplant infections.

CHAPTER 56 ■ LUNG TRANSPLANTATION

- The past decade has seen a steady increase in the percentage of older patients on the waiting list. Over the past several years, the average waiting time to transplant has decreased, the number of deaths on the list has decreased, and the number of transplants has increased (Fig. 56.1). These data are the product of changes in lung allocation policy, better patient management while on the list, and the efforts of organ procurement organizations (OPOs) and hospitals to recognize and optimize potential lung donors.

PERIOPERATIVE CARE OF LUNG TRANSPLANTATION

- The typical recipient is an adult 50 to 64 years of age. Recipient diagnosis and criteria for “ideal” lung donors are listed in Figure 56.2 and Tables 56.1 and 56.2, respectively. Median waiting time to transplant is nearly 7 months. Survival rates after lung transplant have gradually improved the main determinants of outcome including recipient age, diagnosis, history of prior transplant, and severity of illness at the time of transplant. Adjusted survival rates at 1, 3, and 5 years are currently 85%, 66%, and 51%, respectively.
- Once the recipients have been declared eligible for lung transplantation (Table 56.3), there are four lung transplant surgical procedures being considered: (i) single-lung transplantation (SLT), (ii) bilateral sequential lung transplantation (BLT), (iii) combined heart–lung transplantation (HLT), and (iv) bilateral lobar transplantation from living related donors. Although recipient history of previous talc pleurodesis still gives many transplant centers pause, a history of other chest surgeries is not a contraindication to lung transplantation.
- Historically, SLT used to be the most applied technique, but lately, more centers are adopting BLT as the transplant procedure of choice.

- Table 56.4 details the numerous side effects, interactions, and dosing of the immunosuppressive medications.

PULMONARY FUNCTION AND GAS EXCHANGE

- Both SLT and BLT patients have significant improvement in pulmonary function tests (PFTs) and in gas exchange post transplantation. The peak improvement in PFTs is achieved at 1 to 3 months after SLT, but after BLT, improvement may not be achieved until 4 to 6 months post transplant. The factors associated with the delay in achieving peak values are reperfusion injury, postoperative pain, altered chest wall mechanics, and respiratory muscle dysfunction after transplant surgery.
- After SLT in patients with chronic obstructive pulmonary disease (COPD), the forced expiratory volume in 1 s (FEV₁) significantly improves to about 45% to 60% of the predicted value, and lung volumes approach the normal predicted values. The chest radiograph in COPD recipients of SLT shows hyperinflated native lung with a flat diaphragm and mild herniation across the midline. The transplanted allograft is a normal-sized lung—although it appears small compared to the native lung—with a physiologically domed diaphragm.
- After SLT in patients with idiopathic pulmonary fibrosis (IPF), the vital capacity improves to about 70% to 80% of the predicted value. Compared to a fibrotic native lung on the contralateral side, the chest radiograph shows a normal-sized lung allograft. After BLT, the chest radiograph and spirometry values approximate predicted values for the recipient size (Fig. 56.3). After lung transplantation, arterial oxygenation rapidly returns to normal, but hypercapnia may take a

few days before returning to normal. Supplemental oxygen is unnecessary for most patients at the time of hospital discharge.

HEMODYNAMICS

- Both SLT and BLT result in immediate and sustained normalization—or near normal in SLT—of pulmonary artery

TABLE 56.1

DISEASE-SPECIFIC GUIDELINES FOR REFERRAL

Chronic obstructive pulmonary disease

FEV₁ (forced expiratory volume in 1 s) <25% of predicted postbronchodilator, especially when associated with mild or moderate pulmonary artery hypertension
Frequent severe exacerbations
BODE index (body mass index [B], airflow obstruction [O], dyspnea [D], and exercise capacity [E]) of ≥ 7

Cystic fibrosis

FEV₁ <30% of predicted
PaCO₂ >50 mm Hg
Frequent severe exacerbations
Rapid decline in lung function (especially in females)

Idiopathic pulmonary fibrosis

Vital capacity (VC) <65% predicted
10% decline in VC or in diffusion capacity in the last 12 mo
Initiation of oxygen therapy

Pulmonary arterial hypertension

NYHA (New York Heart Association) functional class III or IV
Cardiac index <2 L/min/m²
Mean right atrial pressure >12 mm Hg
Failure of medical therapy to improve hemodynamic indexes or functional class

Eisenmenger syndrome

NYHA III or IV despite optimal medical therapy (especially if patients are discontented with their current quality of life)

TABLE 56.2

CRITERIA FOR “IDEAL” LUNG DONORS

PaO₂ >300 mm Hg on FiO₂ = 1.0 and 5 cm H₂O continuous positive airway pressure
Less than 20 pack-years smoking history
Clear chest radiograph
Minimal secretions on bronchoscopy
Negative viral serology (HIV, hepatitis B and C infections)
Age younger than 55–60 years

pressures in PPH recipients, barring significant reperfusion injury. This is associated with near total or total resolution of the associated tricuspid valve insufficiency and is accompanied by an immediate increase of the cardiac output with a gradual remodeling of the right ventricle. The right ventricle decreases in size and regains normal function over the next few days to weeks. This hemodynamic improvement is sustained after successful transplantation. The advantage of BLT over SLT for patients with pulmonary vascular disease is that airway injury is better tolerated in BLT. Due to the resultant severe ventilation/perfusion mismatch, airway injury (caused by pneumonia, or acute or chronic rejection) results in profound hypoxemia in patients with severe pulmonary hypertension who undergo SLT.

EXERCISE CAPACITY

- Peak exercise performance, as measured by cycle ergometry, is characteristically reduced in both SLT and BLT

TABLE 56.3

GENERAL GUIDELINES FOR SELECTION OF RECIPIENTS

Indications

End-stage lung disease with average life expectancy <2 y
Failed medical and surgical therapy
Severe functional limitation, but ambulatory
Upper age limit has recently been liberalized to include ≤ 69 years

Absolute contraindications

Significant extrapulmonary end organ damage
Acute critical illness
History of cancer in the last 5 y
Active psychosis or history of noncompliance with therapy
Cigarette smoking in the last 6 mo
History of substance abuse with risk factors for recidivism
Nonambulatory, with poor rehabilitation potential
Inadequate social support
Systemically active collagen vascular diseases
Extrapulmonary infections (human immunodeficiency virus, hepatitis B, C active infections)

Relative contraindications

Mechanical ventilation
Extensive pleural adhesions from previous surgical procedures (especially talc)
Airway colonization with bacteria panresistant to all antibacterials
Body mass index >30

TABLE 56.4

COMMONLY USED IMMUNOSUPPRESSIVE MEDICATIONS

Drug	Dosing and adjustments	Side effects	Drug interactions
Cyclosporine and tacrolimus	Every 12 h	Commonly occur with both: nephrotoxicity, hypertension, neurotoxicity (tremors, headaches, rarely seizures), hyperkalemia, hyperlipidemia, hypomagnesemia Occur only with tacrolimus: myalgias, hyperglycemia Occur only with CyA: hemolytic-uremic syndrome, hirsutism, gingival hyperplasia	Blood levels are increased with all macrolide antibiotics (except azithromycin), azole antifungals, and calcium channel blockers (except nifedipine). Blood levels are decreased by anticonvulsants and rifampin.
Sirolimus	Every 24 h	Cytopenias, hyperlipidemia (mainly hypertriglyceridemia)	Same drug interactions as tacrolimus and cyclosporine: Blood levels are increased with all macrolide antibiotics (except azithromycin), azole antifungals (voriconazole contraindicated with sirolimus), and calcium channel blockers (except nifedipine). Blood levels are decreased by anticonvulsants and rifampin.
Azathioprine	Every 24 h Decrease dosage in the event of renal or hepatic insufficiency.	Cytopenias, hepatotoxicity, pancreatitis, nausea	Increased bone marrow suppression with allopurinol, ganciclovir, and antithymocyte globulin.
Mycophenolate mofetil	Every 12 h Decrease dosage in the event of renal or hepatic insufficiency.	Abdominal cramps, diarrhea, vomiting, cytopenias	No significant interactions.
Prednisone	0.3–0.5 mg/kg/d in the first 3 mo, then tapered afterward.	Hypertension, hyperglycemia, weight gain, myopathy, osteoporosis, cataracts, mood swings, and hyperlipidemia	No significant interactions.

recipients as late as 1 or 2 years after the surgery. These patients have subnormal peak work rate, peak oxygen consumption, and early lactate threshold on incremental exercise testing. Maximal oxygen consumption is significantly

FIGURE 56.3. Spirometry values in cystic fibrosis patients undergoing bilateral lung transplantation (BLT) ($n = 5$). FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity. (Courtesy of Division of Pulmonary Medicine, University of Florida, Gainesville, FL).

increased after lung transplantation, but it typically is 40% to 60% of the maximal predicted value. Interestingly, the limitation to exercise is not cardiac or ventilatory in nature, and, surprisingly, the maximal oxygen consumption attained during exercise testing is similar whether the recipients are of SLT or BLT. Reduced mitochondrial oxidative capacity and peripheral oxygen use in the skeletal muscles of lung transplant recipients may be secondary to the deconditioning associated with chronic lung diseases or cyclosporine-associated impairment in skeletal muscle mitochondrial respiration.

COMPLICATIONS AFTER LUNG TRANSPLANTATION

- Most allografts have reperfusion lung injury manifesting as pulmonary edema within the first 24 hours after transplantation. The injury is mild to moderate, and the edema is transient in most cases. However, in 5% to 10% of cases, the lung injury is severe enough to cause acute respiratory distress syndrome or severe primary graft failure.

- It is presumed to reflect ischemia–reperfusion injury, but hyperacute rejection (caused by preformed antibodies in the recipient) is the cause for the severe injury in a small subset of patients with this complication. The chest radiograph and clinical scenario are almost identical in all these etiologic factors, that is, all have widespread interstitial and alveolar infiltrates in the allograft(s) and severe hypoxemia. The diagnosis of reperfusion injury is established by excluding other causes of graft dysfunction: hyperacute or acute rejection, pneumonia, volume overload, and thrombosis of the pulmonary venous anastomosis.
- Inhaled nitric oxide, independent lung ventilation, and extracorporeal membrane oxygenation have been attempted with variable success. The mortality rate reportedly ranges between 40% and 60% in cases of severe hypoxemia. The clinical course in survivors is protracted, but some of the survivors are able to ultimately attain normal allograft function. Variables associated with increased mortality in patients with reperfusion lung injury are age, severity of gas exchange impairment, and severity of hemodynamic failure.

Airway Complications

- Airway complications requiring intervention occur in 7% to 15% of bronchial anastomosis.
- Most airway complications manifest in the first 100 days after transplantation. They may present as wheezing, exertional dyspnea, or decline in FEV₁. As the bronchial arteries are not reconnected at the time of transplantation, the bronchial mucosa distal to the anastomosis could be affected by bronchial artery reperfusion injury. This manifests as bronchial mucosal injury with ischemic mucosal surface. The mucosal injury may heal with minimal sequelae, thereby resulting in airway stricture, or, if the bronchial artery ischemia injures the underlying cartilaginous support of the bronchus, it may cause bronchomalacia. Alternatively, bronchial stenosis may be caused by overgrowth of the scar tissue at the site of the bronchial anastomosis. Thus, airway complications may be at the anastomotic site or a few centimeters distally.
- Bronchial mucosal injury has the bronchoscopic appearance of a pseudomembrane, which is sometimes superinfected with fungal organisms. Most airway complications are amenable to correction with stent placement, balloon dilation, or cautery.

Infections

- Infection, the most common cause of death in the first 12 months after lung transplantation, is also a common cause of death in patients afflicted with obliterative bronchiolitis (OB).
- Most recipients will have at least one infection requiring therapy with an antimicrobial agent during the first 12 months after transplantation.
- Respiratory tract pathogens are the most common source of bacterial infections after transplantation. Microbes from donor lungs cause a significant number of early episodes of bacterial pneumonia, but the incidence has decreased because antibacterial prophylaxis is used at the time of trans-

FIGURE 56.4. Vital capacity in idiopathic pulmonary fibrosis patients after single lung transplant ($n = 7$). (Courtesy of Division of Pulmonary Medicine, University of Florida, Gainesville, FL).

plantation. *Pseudomonas* and the *Enterobacteriaceae* cause most bacterial infections after discharge from the transplant hospitalization; infections caused by *Staphylococcus* and *Haemophilus* are also common. Viral infections are the second most common cause of infections; cytomegalovirus (CMV) infection is the most common among the viral causes. The incidence of CMV infection or reactivation has been reported to be 40% to 75%, which is much higher than that for other solid organs. The patients at highest risk of infection and morbidity are CMV-seronegative recipients from a seropositive lung donor. The case fatality rate of CMV infection is reported to be about 5%. Herpes simplex (HSV) and varicella-zoster (VZ) infections are also quite common. HSV and VZ are mostly caused by reactivation of a latent viral infection. Acquired respiratory viral infections are mostly secondary to respiratory syncytial virus (RSV), influenza, and parainfluenza viruses. These viral infections may cause cough, wheezing, or, in extreme cases, acute respiratory distress syndrome. Parvovirus has been reported to cause refractory anemia in recipients of solid organ transplants.

- The most common cause of fungal infection is *Candida albicans*, with *Aspergillus* a close second. The lung allograft is a common site of infection; the spectrum of disease ranges from necrotic bronchitis (Fig. 56.4) to invasive fungal pneumonia. The incidence of *Pneumocystis carinii* pneumonia (PCP), approximately 80% prior to prophylaxis, has decreased to between 5% and 10% since the institution of long-term prophylaxis.

Acute Rejection

- Acute rejection denotes the infiltration of the allograft by lymphocytes; severity of the rejection is classified by pathologic criteria.
- Acute rejection may present as decline in airflows, cough, oxygen desaturation with exercise, or, rarely, as low-grade temperature elevation. The chest radiograph may be clear and unchanged or may represent a pulmonary edema pattern. While the classic triple maintenance immunosuppressive regimen remains cyclosporine (CyA), prednisone, and AZA, acute rejection episodes are treated with a course of pulse steroids consisting of three daily doses of methylprednisolone, dosed at 15 mg/kg/day, followed by oral prednisone taper and optimization of the CyA and AZA doses. Patients

TABLE 56.5

STAGING OF BRONCHIOLITIS OBLITERANS SYNDROME (BOS)

BOS-p (potential BOS): 10%–19% decline in forced expiratory volume in 1 s (FEV₁) compared with the peak FEV₁
 Stage 1: 20%–33% decline in FEV₁ compared with the peak FEV₁
 Stage 2: 33%–50% decline in FEV₁ compared with the peak FEV₁
 Stage 3: >50% decline in FEV₁ compared with the peak FEV₁

resistant to pulse steroid therapy are treated with antilymphocyte antibodies—polyclonal antithymocyte globulin or monoclonal OKT3—and are often switched from CyA to tacrolimus.

Chronic Rejection (Bronchiolitis Obliterans)

- *Chronic lung rejection* is used synonymously with *bronchiolitis obliterans syndrome* (BOS). BOS is a progressive and irreversible decline in airflow, ultimately resulting in respiratory failure. The disease has a variable course: some patients experience a rapid decline in airflow, whereas others experience either slow progressive decline or intermittent decline in airflow punctuated by long periods of stable lung function. BOS is staged by the magnitude of the loss of lung function. BO is the histologic equivalent of chronic lung rejection, and the histologic diagnosis is difficult because transbronchial biopsy specimens are not sufficiently sensitive for diagnosis.
- After the exclusion of other factors confounding bronchoscopy and transbronchial biopsy, the diagnosis is made by pulmonary function tests. Bronchoscopy is performed to exclude anastomotic complications, infections, acute rejection, or disease recurrence in the allograft. If the decline in FEV₁ is >20% compared to the peak FEV₁ attained after transplantation, and the bronchoscopy—with transbronchial biopsy—excludes confounding factors, the clinical scenario is then diagnostic of BOS. Moreover, if the decline in FEV₁ is associated with acute rejection on transbronchial biopsy but does not reverse with augmentation of immunosuppression, it is also consistent with BOS (Table 56.5).
- BOS occurs in approximately 50% of recipients 5 years after transplantation (Fig. 56.5). It is the most common cause of death in patients surviving >1 year. The median survival after

FIGURE 56.5. Freedom from obliterative bronchiolitis (OB). (From Taylor DO, Edwards LB, Boucek MM, et al. Registry of the International Society for Heart and Lung Transplantation: twenty-third official adult heart transplantation report—2006. *J Heart Lung Transplant.* 2006;25(8):869–879).

the diagnosis of BOS approximates 2 years. In most patients, BOS is characterized by a relentless decline in airflows, albeit at variable rates in different patients, and ultimately results in respiratory failure. In SLT recipients, BOS is associated with a significantly lower survival when it occurs in IPF patients rather than COPD patients. Recurrent episodes of acute lung rejection are a definite risk factor for BOS; CMV pneumonitis is a probable risk factor. In a retrospective study, mismatching at the HLA-A locus was found to be a risk factor for BOS.

- BOS presents as cough that later becomes productive, followed by progressive exertional dyspnea. The chest radiograph is clear, but in the advanced stages will show bronchiectasis and interstitial infiltrates. Studies have shown that augmentation of immunosuppression will not reverse the decline in most cases; furthermore, it probably places patients at increased risk of infection, with very little impact on the natural history of the disease. Retransplantation has been attempted for this complication but with variable success.

Posttransplant Lymphoproliferative Disease (PTLD)

- The reported incidence of PTLD after lung transplantation varies between 2% and 6%. The presentation and pattern of organ involvement is related to the time of onset. In the first year, intrathoracic involvement is the most common presentation; gastrointestinal tract involvement predominates later. The incidence of PTLD increases in proportion to the intensity of immunosuppression, especially when antilymphocyte antibodies are used.

CHAPTER 57 ■ LIVER TRANSPLANTATION

- Liver transplantation remains the only therapy for end-stage, chronic liver disease and irreversible, fulminant liver failure. It is increasingly being performed for patients with localized, unresectable hepatocellular carcinoma with promising results. Since 2002, the number of patients waiting for liver transplantation has slowly increased to near 13,000. The age distribution of those waiting has changed more dramatically, with ages between 50 and 64 years making up the majority (Fig. 57.1).
- The total number of liver transplants being performed has steadily increased over the past decade, with 6,441 transplants in 2005. This increase is primarily due to the increase in deceased donor livers available for transplant. Living donor liver transplantation (LDLT) accounted for 5% of liver transplants performed in 2005, down from a peak of 10% in 2001 (Fig. 57.2). This decrease may be due in part to the increased utilization of extended criteria donor (ECD) livers and concerns about the morbidity and mortality risks associated with living donor liver transplantation.
- Liver allocation for adults depends primarily on disease severity as determined by the Model for End-Stage Liver Disease (MELD) (Table 57.1). The MELD formula uses easily obtained laboratory data—total bilirubin, serum creatinine, and international normalized ratio—and is highly predictive of death on the waiting list. Important exceptions are made for selected patients with hepatocellular carcinoma and other groups of patients for whom the MELD score does not reflect disease severity. Despite performing transplants in much older patients, utilizing more ECD livers, and employing an allocation system that gives priority to the sickest patients, the results of liver transplantation continue to be encouraging.

PERIOPERATIVE CARE OF LIVER TRANSPLANTATION

Cardiovascular Issues

- The cardiac physiology of liver failure is characterized as a hyperdynamic profile with a high cardiac output. If there is any degree of dysfunction, it has been assumed in the past that the patient suffered from alcohol chronic toxicity, which is responsible for 30% of dilated cardiomyopathies. However, it is becoming evident that a significant amount of systolic dysfunction and even more diastolic dysfunction is present in patients with ESLD of all causes, including nonalcoholic. In addition, the potential for coronary artery disease has been underappreciated previously in the potential liver transplant patient. Current studies suggest that the prevalence of coronary artery disease in patients with ESLD is at least as common and probably more so than in the general population. Patients may also be less symptomatic despite moderate to severe coronary heart disease. At least 50% of patients with coronary artery disease will suffer significant morbidity and mortality while undergoing a liver transplantation.
- Patients with liver failure demonstrate blunted cardiac response to stimuli such as hemorrhage, hypovolemia, and administration of inotropic drugs.
- Adrenergic receptor desensitization occurs so the normal inotropic and chronotropic responses to isoproterenol and dobutamine are attenuated.

Pulmonary Disorders in Liver Failure

- Approximately 40% of cirrhotic patients have hepatopulmonary syndrome, with approximately 8% to 15% developing impaired oxygenation. Essentially, the patient develops pulmonary arteriovenous dilations due to the increased presence of vasodilators. The gold standard in diagnosis is a contrast echocardiogram demonstrating intrapulmonary shunting. There is no effective treatment for this disease, but transplantation results in an 85% resolution or significant improvement. The duration of time until that improvement occurs can be quite variable, anywhere between a few days to 14 months postoperatively. Unfortunately, there are no good indicators to predict reversibility. Baseline room air arterial oxygenation of ≤ 50 mm Hg has been shown to worsen survival despite liver transplantation.

- Conversely, portopulmonary hypertension is essentially pulmonary hypertension, which occurs in 2% to 5% of cirrhotic patients. It does not correlate with the degree of portal hypertension or liver failure. Using a cutoff of 40 mm Hg for right ventricular systolic pressure, the sensitivity of echocardiogram is 80% and the specificity is 96%.
- The treatment of portopulmonary hypertension is not at all the same as for other types of pulmonary artery hypertension. At the present time, diuretics and epoprostenol have been the best studied and the most likely to provide benefit. Recommended therapies for pulmonary artery hypertension, such as anticoagulation, calcium channel blockers, β -blockers, and endothelin receptor antagonists, can have adverse effects either on the prognosis of portopulmonary hypertension or on liver failure in general. A transjugular intrahepatic portosystemic shunt is contraindicated in this setting. Sildenafil may have some benefit, but it does increase the production of endogenous nitric oxide and can further exacerbate systemic hypotension.
- When the mean pulmonary artery pressure is >50 mm Hg, liver transplantation is contraindicated, as the mortality has been documented to be 100%. It is considered a contraindication due to the fact that transplantation will decrease the amount of circulating prostaglandins and result in worsening of the disease. Below a mean pulmonary artery pressure of 35 mm Hg, proceeding with liver transplantation can occur without delay. Between 35 and 50 mm Hg, optimizing the patient's status with diuretics and epoprostenol is indicated prior to liver transplantation.

Hepatorenal Syndrome

- Hepatorenal syndrome (HRS) is a functional type of renal impairment that occurs in 11.4% of patients with liver failure

within 5 years of the first episode of significant ascites. There are two types, which are both potentially reversible with liver transplantation. HRS 1 is rapidly progressive, with a doubling of initial creatinine to above 2.5 mg/dL or 50% reduction of creatinine clearance to less than 20 mL/minute, which occurs in less than 2 weeks. The mortality rate is nearly 100% within 10 weeks of development. HRS 2 is associated with a more moderate, steady decline in renal function. The 1-year probability of survival is 38.5% with HRS 2, but the mean survival of HRS 1 is only 7 ± 2 days. A more complete discussion of this topic is found in the chapter on liver failure. Therefore, the focus here will be regarding the goals of therapy during liver transplantation in patients with HRS.

- The most successful management to prevent further injury during surgery is to alter the physiology that led to the development of HRS. The effect of peripheral and splanchnic vasodilation from cytokines and nitric oxide, as well as the intrarenal vasoconstriction that occurs in response to intravascular depletion are both aspects of liver failure that combine to produce this syndrome. Obviously, euvolemia is a primary goal, and in most studies looking at prevention and improvement of HRS, albumin is used as an adjuvant therapy.
- Vasopressin analogues administered with albumin to patients with both types of HRS have been shown to improve glomerular filtration rate and creatinine levels.
- The major risk associated with vasopressin analogues is the potential for ischemia, which has been shown to be clinically significant with only ornipressin. Terlipressin is not currently available in the United States, however.
- The combination of octreotide and midodrine has been shown to have some beneficial effects on renal function and mortality in HRS; however, patients treated with vasopressin had improved survival rates and were more likely to receive a liver transplant. There is no literature that has investigated the combined effects of all three agents. In a very small study, norepinephrine had comparable efficacy to vasopressin without any adverse side effects. In patients with liver failure who develop hypotension, norepinephrine and vasopressin are agents that should be considered first line with less concern regarding renal side effects. Patients who do not respond to the above therapies will likely require some form of renal replacement therapy. Continuous venovenous hemodialysis (CVVHD) is the treatment of choice since it causes less hypotension, with a decreased potential to create ongoing injury compared to hemodialysis performed three times a week. However, once a patient has received any type of dialysis for HRS lasting longer than 12 weeks, there is a risk that renal dysfunction will either continue after transplantation or will recur within a few years.

Fulminant Hepatic Failure

- The abrupt onset of liver failure within 8 weeks in a previously healthy patient has been the traditional definition of fulminant failure, but modern discussion centers on potentially decreasing the time period to 2 weeks to correlate with the prognosis. There are several potential causes, but acetaminophen is by far the most common. The mortality rate is 80% without liver transplantation.
- Table 57.2 summarizes the King's College criteria for liver transplantation. The MELD score has a higher sensitivity and negative predictive value, but a very high false-positive rate

TABLE 57.2

KING'S COLLEGE CRITERIA FOR LIVER TRANSPLANTATION IN FULMINANT HEPATIC FAILURE

Acetaminophen

- pH <7.3 (irrespective of encephalopathy)

Or all three of the following:

- Grade III or IV encephalopathy
- PT >100 sec or INR >6.5
- Serum creatinine >3.4 mg/dL

All other causes

- PT >100 s or INR >6.5 (irrespective of encephalopathy)

Or any three of the following:

- Age <10 or >40 years
- Cause: non-A, non-B hepatitis; halothane; idiosyncratic drug reaction; Wilson disease
- Length of time from jaundice to encephalopathy >7 days
- PT >50 seconds or INR >3.5
- Serum bilirubin >17.5 mg/dL

PT, prothrombin time; INR, international normalized ratio.
From O'Grady JG, Alexander GJ, Hayllar KM, et al. Early indications of prognosis in fulminant hepatic failure. *Gastroenterology*. 1989;97:439–445, with permission.

so it may be better to use it in conjunction with King's College criteria to avoid transplantation in patients who may recover spontaneously.

- Infection occurs in 80% of patients with fulminant hepatic failure (FHF), and thus a high index of suspicion and regular surveillance are important. Some centers use prophylactic antibiotics, but this increases the risk of fungal infections, which occur in 30% of patients with FHF. Hemodynamically, FHF is associated with a high cardiac output and vasodilation similar to sepsis, making infection difficult to discern. Optimizing intravascular volume is the main goal in management, but vasopressors may be necessary. Fluid management may be complicated by renal failure since this occurs in 40% to 50% of patients.
- Encephalopathy inversely correlates with prognosis. Table 57.3 summarizes the four stages of encephalopathy that are seen in FHF. Cerebral edema occurs in most cases that progress to stage 4. Typical symptoms of cerebral edema

TABLE 57.3

HEPATIC ENCEPHALOPATHY IN FULMINANT HEPATIC FAILURE

Stage	Mental status	EEG
I	Confusion, slow mentation and affect, slurred speech, disordered sleep	Normal
II	Accentuation of stage I, drowsy, inappropriate, loss of sphincter control	Slowing
III	Marked confusion, sleeps mostly but arousable, incoherent	Abnormal
IV	Not arousable; may or may not respond to painful stimuli	Abnormal

EEG, electroencephalograph.

are the Cushing reflex, decerebrate rigidity, dysconjugate eye movements, and a loss of pupillary reflexes. Intracranial pressure (ICP) monitoring should be considered if the patient develops stage 3 or 4 encephalopathy due to the development of increased ICP in the setting of systemic hypotension. Cerebral perfusion pressure (CPP) of >60 mm Hg is necessary to maintain intact neurologic function. Liver transplantation in the setting of CPP <40 mm Hg for 2 hours or more is contraindicated. Concern for intracranial bleeding associated with the placement of an ICP monitor has precluded use in most liver transplant centers. Recently, factor VIIa has been shown to be effective in transiently correcting coagulopathy to allow for safer placement of this monitor. Patients with elevated ICP are candidates for mannitol, mild hyperventilation, and barbiturate or propofol infusions while maintaining systemic blood pressure in an attempt to optimize CPP.

BLOOD PRODUCT USE

- Patients with liver failure have a decrease in all factors except von Willebrand. Platelets are also reduced secondary to hypersplenism, bone marrow suppression, and decreased thrombopoietin production in ESLD. Attempts to correct coagulation defects in patients undergoing liver transplantation result in a hypervolemic state, which can lead to an increase in blood transfusion.
- Thromboelastography is used because most serum component markers of coagulation do not reflect the intricate dynamics of whole blood clotting to guide transfusion.
- Aprotinin use in liver transplantation has been shown to decrease red blood cell transfusion in several randomized trials. During the anhepatic phase of surgery, the suprahepatic and infrahepatic vena cava may be cross-clamped. This is a stage during which there is rapid increase in tissue-type plasminogen activator in the absence of α -2-antiplasmin and plasminogen activator inhibitor. Therefore, plasmin activity increases, and fibrinolysis can ensue. Aprotinin acts to inhibit plasmin. The concern regarding the use of aprotinin on a prophylactic basis is due to scattered case reports of thrombotic episodes such as clots on pulmonary artery catheters and an increased rate of vein graft occlusions in cardiac surgery.
- Given the crude understanding of coagulation in the presence of liver disease, potential aprotinin administration should be reserved for documented fibrinolysis during the reperfusion stage. The lowest effective dose documented in the literature is 500,000 kallikrein inactivation units (KIU) as a bolus, with 150,000 KIU/hour, with equal efficacy to higher doses in limiting the number of blood products transfused. If pulmonary embolism occurs, supportive care and thrombolysis may lead to better outcomes compared to embolectomy.
- Factor VIIa is a novel way to increase the thrombin burst and acutely improve coagulation on a short-term basis secondary to rapid factor consumption. Theoretically, it requires an activated platelet so coagulation occurs at the site of bleeding and not systemically. It has been studied in cirrhotic patients in trials for gastrointestinal bleeding and liver transplantation. Neither showed any difference in the degree of bleeding or required transfusions. However, cirrhotic patients are likely to be factor VII deficient. There has been no dose-ranging study to look at efficacy related to the degree of serum levels achieved.

FLUIDS AND ELECTROLYTES

- Along the lines of avoiding hypervolemia, minimizing fluid use is the goal during liver transplantation. There is no particular type of fluid that conclusively shows benefit. ESLD patients have a decreased ability to metabolize lactate and are prone to lactic acidosis, especially during the required interruption of blood flow for performing the vascular anastomosis of the liver transplant. The exclusive use of lactate-containing solution is likely unwise.
- Hyponatremia at ≤ 127 mEq/L occurs in 3.5% of liver transplant candidates. A change in serum sodium approaching 20 mEq/L is much more likely to produce central pontine myelinolysis than a change closer to 7 mEq/L. Central pontine myelinolysis is a source of mortality after liver transplantation. Normal saline solutions are actually somewhat hyponatremic and hyperchloremic to serum, and excessive use will lead to hyperchloremic acidosis. Albumin administration has shown benefit during paracentesis and in the long-term management of patients with ESLD. Patients with significant renal dysfunction and/or those undergoing dialysis at the time of transplantation will most likely require CVVHD during liver transplantation. Although this is helpful to manage electrolyte abnormalities, it is not quick. This is particularly the case with metabolic acidosis in which patients often require the addition of a dilute bicarbonate infusion, which may be faster and safer. However, CVVHD can be used to both remove and administer fluid expeditiously. A heating system should be used during CVVHD since serum is exchanged at about the rate of 22 to 30 L in 24 hours, and patients can become hypothermic, which can exacerbate baseline coagulopathy. To prevent the system from developing clots, citrate is often used, as opposed to heparin, in patients with significant coagulopathy. Between this condition and the amount of citrate that may be administered from blood products, calcium supplementation is often required.

POSTTRANSPLANT COMPLICATIONS

Primary Nonfunction

- There is no clear definition or uniform diagnostic criteria for this diagnosis, but generally it includes patients who die or require retransplantation within 1 week without a definite technical or immunologic cause. Patients appear to rapidly go back into hepatic failure with high levels of aminotransferases, prolonged prothrombin time, hepatic encephalopathy, hypoglycemia, and lactic acidosis.
- There are currently no definitive preventative strategies or treatments. Donor age older than 50 years and macrovesicular steatosis of >60% are possible risk factors, but these have not been shown to be consistently so.

Vascular Occlusion

- Studies concerning the incidence of portal vein thrombosis (PVT) at the time of liver transplant show that it occurs in about 12% of patients. The presence of a pre-existing thrombosis makes surgery more challenging and increases the risk of

TABLE 57.4

IMMUNOSUPPRESSIVE MEDICATION IN LIVER TRANSPLANTATION

Medication	Side effects
Steroids	Acne, obesity, hypertension, bone loss, hyperglycemia, bone disease, cataracts, adrenal suppression, muscle wasting
Calcineurin inhibitor (cyclosporine, tacrolimus)	Neurotoxicity, nephrotoxicity, hypertension, hyperglycemia, lipid abnormalities
Mycophenolate	Nausea, diarrhea, leukopenia, thrombocytopenia, anemia
Azathioprine	Gastrointestinal ulceration, myelosuppression
MTOR inhibitor (sirolimus, everolimus)	Increased cholesterol and triglycerides, proteinuria, potentially nephrotoxic ^a
Murine monoclonal antibody (OKT3)	Fever, rigor, headache, dyspnea, nausea, diarrhea, flash pulmonary edema
Rabbit polyclonal antibody (thymoglobulin)	Similar to OKT3, leukopenia, thrombocytopenia, serum sickness
Anti-interleukin-2 receptor (basiliximab)	Minimal to none

^aPatients on sirolimus and a calcineurin inhibitor in combination may exhibit more nephrotoxicity than is seen with the latter drug alone. From Hirose R, Vincenti F. Immunosuppression: today, tomorrow and withdrawal. *Semin Liver Dis*, 2006;26(3):201–210, with permission.

rethrombosis after transplantation, but it has not been shown to alter mortality. The incidence of PVT presenting after transplantation is less than 1%. In addition to a prior history of PVT, the risk factors include a hypercoagulable state, perioperative hypotension, and allograft cirrhosis. Acutely, it can lead to hepatic failure, but chronically there is a more insidious presentation involving portal hypertension with ascites and varices. Hepatic vein thrombosis is very unusual except in patients who have undergone transplantation for Budd-Chiari syndrome with subtherapeutic anticoagulation, and it typically takes months to years to develop.

- The most common vascular complication is hepatic artery thrombosis (HAT), which occurs somewhere between 3% and 9%. In addition, mortality is common without retransplantation, with an incidence of about 30%. If HAT is tolerated by the liver surviving solely on portal flow, then complications occur usually after 1 month with the development of bile duct strictures since virtually all biliary perfusion comes from the hepatic artery. For patients who cannot be supported solely on portal flow, their presentation is much more acute with severe graft dysfunction or primary non-function.
- Risk factors for HAT include small caliber or complex arterial structure of both the donor and recipient. Increased donor age and a recipient/donor ratio greater than 1.25 can put the recipient at risk for HAT. Medical issues that may predispose to HAT include cytomegalovirus infection, rejection, tobacco use, and hypercoagulable states. Urgent revascularization can be attempted for early presentation of HAT-associated graft dysfunction. This can be accomplished angiographically or surgically. However, about 50% of patients in this scenario will require retransplantation. Patients who do receive some type of intravascular therapy have difficulty maintaining long-term hepatic artery patency.

Rejection

- Not only is rejection less common in liver transplantation than in other solid organ transplants, but less rejection occurs in the latter group when performed in the setting of a con-

current or previous liver transplant. Nonetheless, transplantation tolerance is not attainable consistently. It has been shown that patients can be weaned off corticosteroid immune suppression 3 to 4 months after transplantation, but complete cessation of immune suppression is associated with about a 30% incidence of rejection. The commonly used immunosuppressive agents in liver transplantation, with their side effects, are listed in Table 57.4.

- Acute rejection occurs within the first 5 to 15 days after transplantation. It is manifested by fever, graft enlargement, tenderness, leukocytosis with increased eosinophils, and reduced bile production. Biopsies are done only when symptoms are present because the morphologic features consistent with acute rejection can be present in a significant percentage of patients in the early posttransplant period. Treatment for acute rejection is 3 to 5 days of 500 to 1,000 mg of methylprednisolone daily, with about 75% resolution. A second course is sufficient for treatment in an additional 10%. The rest require some type of antilymphocyte therapy, with a rare case requiring retransplantation. Patients who develop rejection in the setting of complete immunosuppressive cessation have been shown to have an increased risk of steroid-resistant rejection.
- Early complications of the biliary tract are leaks and strictures. Anastomotic leaks and strictures are the most serious and are usually related to ischemic necrosis of the donor distal bile duct. These can be managed with endoscopic or percutaneous stenting and require surgery only if a major leak is present. The vast majority of these problems present within the first 2 months after transplantation.

Live Donor or Living-Related Liver Transplantation

- Unique to this type of transplantation is small-for-size syndrome. Essentially, the patient has poor bile production, delayed synthetic function, prolonged cholestasis, and intractable ascites. These patients are at risk for sepsis and have an increased mortality. A similar situation may affect patients who receive a split liver.

CHAPTER 58 ■ PANCREATIC TRANSPLANTATION

- Pancreas transplantation offers selected diabetic patients the prospect of glucose control, avoiding—and, in some cases, reversing—the devastating complications of the disease. Most pancreata are transplanted simultaneously with a kidney (SPK), although a significant fraction are transplanted alone (PTA) or at some time after a kidney (PAK) transplant. Deceased donor pancreas remains a relatively underutilized organ resource; only 19% of available deceased donor pancreata are recovered and transplanted. A few percent are procured, processed, and transplanted as islet cell transplants. The reasons for this underutilization are multifactorial, and include regional variation in the number of potential recipients, donor and organ quality, and competition for kidneys with other patients.
- In 2005, 903 SPK transplants, 344 PAK transplants, and 195 PTA transplants were performed. These totals have changed little over the last several years. Figure 58.1 depicts the trend for SPK transplants over the past decade. Similarly, patient and graft survival has improved, with 5-year patient survival approaching 90%.
- There are three broad categories of recipients: SPK, PAK, and PTA.
 - *SPK transplants:* Most SPK transplants have been done with both organs coming from the same cadaveric donor. Because a large number of patients are waiting for a kidney, unless priority is given to SPK candidates, waiting times tend to be long (years). Thus, to avoid two operations and a long wait, a simultaneous kidney and segmental pancreas transplant from a living donor can be done. Only a few centers offer this option. There has been a report from Japan of successful islet transplantation from a live donor. Therefore, a simultaneous living-donor islet kidney transplant may become a viable option in the future. If a living donor is suitable for or only willing to give a kidney, another option is a simultaneous living-donor kidney and cadaveric pancreas transplant. For these options, the living kidney donor usually must be available on a moment's notice (the same as for the recipient), as the cadaveric pancreas must be transplanted soon after procurement. Alternatively, a recipient of a scheduled living-donor kidney transplant could also receive a cadaveric pancreas simultaneously if one became available fortuitously. If not, and only a kidney is transplanted, the recipient becomes a PAK candidate.
 - *PAK transplants:* For nephropathic diabetic patients who have already undergone a kidney transplant from a living or a cadaveric donor, a PAK transplant can be performed. Most PAK transplants today are done in patients who previously received a living-donor kidney because suitable uremic diabetic patients without a living donor will undergo a cadaveric pancreas transplant. Although a PAK means a uremic diabetic patient requires two operations to achieve both a dialysis-free and insulin-independent state, the two

transplants done separately are smaller procedures than a combined transplant. The interval between the living-donor kidney and cadaveric pancreas transplant depends on several factors, including recipient recovery from the kidney transplant and donor availability, but the outcome is similar for all intervals more than 1 month. PAK is the largest pancreas transplant category at the University of Minnesota.

- *PTA:* For recipients with adequate kidney function, a solitary pancreas transplant can be performed from either a living or a cadaveric donor. Because the waiting time for a cadaveric pancreas is relatively short at the present time, living-donor pancreas transplants are done infrequently, but are particularly indicated if a candidate has a high panel-reactive antibody and a negative cross-match to a living donor. Most PTA candidates have problems with glycemic control, hypoglycemic unawareness, and frequent insulin reactions. A successful PTA not only obviates these problems, but also improves the quality of life, and may ameliorate secondary complications, thus increasing the applicability of PTA.

PERIOPERATIVE CARE OF PANCREAS TRANSPLANTATION

- After an uncomplicated pancreas transplant, the recipient is transferred to the postanesthesia care unit or the surgical intensive care unit. Centers that have a specialized monitored transplant unit (with central venous and arterial monitoring capabilities) transition the postoperative recipients through the postanesthesia care unit to the transplant unit. Others transfer directly to the surgical intensive care unit for the first 24 to 48 hours. Care during the first few hours after transplant is similar to care after any major operative procedure. Careful monitoring of vital signs, central venous pressure, oxygen saturation, and hematologic and laboratory parameters is crucial. The following factors are unique to pancreas recipients and should be attended to:
 - *Blood glucose levels:* Any sudden, unexplained increase in glucose levels should raise the suspicion of graft thrombosis. An immediate ultrasound examination must be done to assess blood flow to the graft. Maintenance of tight glucose control (<150 mg/dL) using an IV insulin drip is important to “rest” the pancreas in the early postoperative period.
 - *Intravascular volume:* Because the pancreas is a “low-flow” organ, intravascular volume must be maintained to provide adequate perfusion to the graft. Central venous pressure monitoring is used to monitor intravascular volume status. In some cases, such as patients with depressed cardiac function, pulmonary artery catheter monitoring may be required during the first 24 to 48 hours. If the hypovolemia is

FIGURE 58.1. Number of simultaneous pancreas-kidney transplants (SPK) and size of active waiting list per year. (Source: 2006 Annual Report of the U.S. Organ Procurement and Transplantation Network and the Scientific Registry of Transplant Recipients: Transplant Data 1996–2005. Rockville, MD: Health Resources and Services Administration, Healthcare Systems Bureau, Division of Transplantation, Tables 1.7 and 8.1a. The data and analyses reported in the 2006 Annual Report of the U.S. Organ Procurement and Transplantation Network and the Scientific Registry of Transplant Recipients have been supplied by the United Network for Organ Sharing and Arbor Research under contract with the Department of Health and Human Services. The authors alone are responsible for reporting and interpreting these data; the views expressed herein are those of the authors and not necessarily those of the U.S. government.)

associated with low hemoglobin levels, then washed packed red blood cell transfusions should be given. Otherwise, colloid or crystalloid replacement can be used.

- **Maintenance IV fluid therapy:** The choice of IV fluid is usually 5% dextrose in half normal saline. The use of dextrose is not contraindicated and may be of benefit, as long as IV insulin is used to maintain good blood glucose control. In SPK recipients, whose IV rate is based on urine output, dextrose should be eliminated if the urine output is high (more than 500 mL/h). Maintenance solution for bladder drainage (BD) recipients should include 10 mEq of HCO_3^- added to each liter to account for the excess HCO_3^- loss. Sodium lactate can be used as an alternative.
- **Antibiotic therapy:** Broad-spectrum antibiotic therapy (with strong gram-negative coverage) and antifungal therapy are instituted before the incision is made in the operating room, and then continued for 3 days (for antibiotics) and 7 days (for antifungal), respectively. At the University of Minnesota, since the introduction of this protocol, we have noted a decrease in postoperative abdominal infections. Cytomegalovirus (CMV) and antiviral prophylaxis is similar to that for other solid organs.
- **Octreotide:** The use of octreotide in pancreas recipients helps reduce the incidence of technical complications. This benefit should be weighed against evidence, in rat studies, that shows decreased pancreatic islet blood flow with octreotide use, although clinically no detrimental effects of octreotide use have been documented. A dose of 100 to 150 μg IV or subcutaneously three times a day is administered for 5 days after transplant. Dose adjustments may be made for nausea, which is the predominant side effect.
- **Anticoagulation:** The use of low-dose heparin in the early postoperative period (days 0–5) decreases the risk of graft thrombosis. An intraoperative dose of 70 units/kg is given, followed by an IV infusion of 3 units/kg started at 4 hours

postoperatively and gradually increased up to 7 units/kg (depending on hemodynamic stability and hemoglobin levels). Enteric-coated aspirin (8 mg) is started on day 1 and continued for 6 months. At the University of Minnesota, this protocol decreased the thrombosis rate from about 12% to 6%, but increased the relaparotomy rate due to bleeding from 4% to 6%. Segmental pancreas transplants (as in living-donor transplants) have a higher thrombosis risk and therefore therapeutic heparinization (with a target partial thromboplastin time of 50) for 5 days and Coumadin therapy (with a target international normalized ratio of 2–2.5) are recommended for 6 months. The higher risk of thrombosis is due to the smaller vessels in a segmental graft.

IMMUNOSUPPRESSION

- One common immunosuppression regimen is shown in Table 58.1.

SURGICAL COMPLICATIONS

- **Bleeding:** Postoperative bleeding is a frequent reason for early relaparotomy in pancreas recipients. The incidence ranges from 6% to 8%. This risk is increased by the use of anticoagulation in the immediate postoperative period. Frequent physical examinations and monitoring of hemoglobin help detect bleeding early. Heparin may be temporarily suspended to stabilize the patient. If bleeding continues, early operative intervention is indicated. If bleeding stops or slows down, heparin should be restarted at a lower rate and judiciously increased as tolerated.
- **Thrombosis:** The incidence of thrombosis after transplant ranges from 5% to 13%. The risk is increased after segmental

UNIVERSITY OF MINNESOTA STANDARD IMMUNOSUPPRESSION PROGRAM FOR PANCREAS TRANSPLANTATION

SPK Transplantation	PAK & SPLK Transplantation	PTA	Rejection
Antithymocyte globulin (1.25 mg/kg) ^a 5 doses First dose intraoperative Give methylprednisolone 500 mg, 250 mg, and 100 mg before first, second, and third doses, respectively.	Antithymocyte globulin (1.25 mg/kg) ^a 7 doses First dose intraoperative Give methylprednisolone 500 mg, 250 mg, and 100 mg before first, second, and third doses, respectively.	Antithymocyte globulin (1.25 mg/kg) ^a 7–10 doses First dose intraoperative Give methylprednisolone 500 mg, 250 mg, and 100 mg before first, second, and third doses, respectively.	Methylprednisolone Day 0: 500 mg IV Day 1: 250 mg IV Day 2: 125 mg IV Antithymocyte globulin 1.25 mg/kg IV ^a × 5–7 d Give premedication. Monitor ALC. ^b <i>Resistant rejection</i>
Tacrolimus 2 mg PO BID Start when creatinine <3 mg/dL or postoperative day 5, whichever is later. If tacrolimus is delayed, continue TMG until tacrolimus levels are therapeutic: levels 8–10 ng/mL for 3 mo, then 5–8 ng/mL.	Tacrolimus 2 mg PO BID Start postoperatively. If tacrolimus is delayed, continue TMG until tacrolimus levels are therapeutic: levels 8–10 ng/mL for 3 mo, then 5–8 ng/mL.	Tacrolimus 2 mg PO BID Start postoperatively. If tacrolimus is delayed, continue TMG until tacrolimus levels are therapeutic: levels 8–10 ng/mL for 3 mo, then 5–8 ng/mL.	OKT3 qd × 5–7 doses First dose = 5 mg IV Subsequent doses = 2.5 mg IV Give premedication. Monitor CD3. ^c
Mycophenolate Start postoperatively, 1 g PO BID.	Mycophenolate Start postoperatively, 1 g PO BID.	Mycophenolate Start postoperatively, 1 g PO BID.	Note: Renal rejection on the steroid avoidance protocol should be treated with thymoglobulin (mild) or OKT3 (moderate/severe or vascular).

SPK, simultaneous pancreas–kidney; PAK, pancreas after kidney; SPLK, simultaneous cadaver pancreas–live-donor kidney; PTA, pancreas transplantation alone; TMG, antithymocyte globulin; ALC, absolute lymphocyte count.

^aRound up antithymocyte globulin dose to the nearest 25.

^bALC levels: If zero, hold antithymocyte globulin; if 0.1, give half-dose antithymocyte globulin; if 0.2 or above, give full dose.

^cCD3 levels (if using OKT3): Monitor effectiveness of antibody therapy. Absolute CD3 level should drop to <100 mm³. Antithymocyte globulin and OKT3 require “premedication.”

pancreas transplants because of the small caliber of vessels. Most thromboses are due to technical reasons. A short portal vein (requiring an extension graft) or atherosclerotic arteries in the pancreas graft increases the risk for thrombosis. In the recipient, a narrow pelvic inlet with a deeply placed iliac vein, atherosclerotic disease of the iliac artery, a technically difficult vascular anastomosis, kinking of the vein by the pancreas graft, significant hematoma formation around the vascular anastomosis, and a hypercoagulable state are some of the factors that increase the risk for thrombosis. The most common form of hypercoagulable state is factor V Leiden mutation in the Western population. The incidence ranges from 2% to 5% but may be as high as 50% to 60% in patients with a history (self or family) of thrombosis. Other causes of hypercoagulable state include antithrombin deficiency, protein C or S deficiency, activated protein C resistance, and anticardiolipin antibodies.

- **Duodenal leaks:** The incidence of duodenal leaks ranges from 4% to 6%. A leak from the anastomosis of the duodenum to the bowel almost always leads to a relaparotomy. Gross peritoneal contamination due to an enteric leak necessitates a graft pancreatectomy. The diagnosis is made by elevated pancreatic enzymes associated with acute abdomen. The differ-

ential diagnosis is pancreatitis, abdominal infection, or acute severe rejection. A Roux-en-Y anastomosis to the pancreatic duodenum may be preferred if the risk of leak is thought to be increased during intraoperative inspection of the pancreas. Other novel techniques such as a venting jejunostomy (Roux-en-Y) have been used in selected recipients.

- **Duodenal leaks in BD recipients** are usually managed non-operatively with prolonged catheter decompression of the urinary bladder. The diagnosis is made using plain or computed tomography cystography. The size and extent of the leak cannot always be assessed by the imaging studies. Large leaks may require operative intervention, such as a repair or enteric conversion.
- **Major intra-abdominal infections:** The incidence of intra-abdominal infections requiring reoperation ranges from 4% to 10%. Opening the duodenal segment intraoperatively, with associated contamination, predisposes to this high rate. Fungal and gram-negative infections predominate. With the advent of advanced interventional radiologic procedures to drain intra-abdominal abscesses, the incidence of reoperations is fast decreasing. If the infection is uncontrolled or widespread, then graft pancreatectomy followed by frequent washouts may be necessary.

- **Renal pedicle torsion:** Torsion of the kidney has been reported after the SPK transplants. The intraperitoneal location of the kidney (allowing for more mobility) predisposes to this complication. Additional risk factors are a long renal pedicle (more than 5 cm) and a marked discrepancy between the length of artery and vein. Prophylactic nephropexy to the anterior or lateral abdominal wall is recommended in intraperitoneal transplants to avoid this problem.
- **Others:** Other surgical complications that may require laparotomy also decreased from 9% to 1%. Improved anti-infective prophylaxis, surgical techniques, immunosuppression, and advances in interventional radiology have all contributed to this disease.

NONSURGICAL COMPLICATIONS

- **Pancreatitis:** The incidence of posttransplant pancreatitis varies based on the type of exocrine drainage. BD recipients with abnormal bladder function are at increased risk secondary to incomplete bladder emptying or urine retention causing resistance to the flow of pancreatic exocrine secretions. Other causes of pancreatitis include drugs (corticosteroids, azathioprine, cyclosporine), hypercalcemia, viral infections (CMV or hepatitis C), and reperfusion injury after prolonged ischemia. Pancreatitis is usually manifested by an increase in serum amylase and lipase with or without local signs of inflammation. The treatment usually consists of catheter decompression of the bladder for a period of

2 to 6 weeks, depending on the severity. In addition, octreotide therapy may be used to decrease pancreatic secretions. The underlying urologic problem, if any, should be treated. If repeated episodes of pancreatitis occur, an enteric conversion of exocrine drainage may be indicated.

- **Rejection:** The incidence of rejection is discussed in the Results section earlier in this chapter. The diagnosis is usually based on an increase in serum amylase and lipase and a decrease in urine amylase in BD recipients. A sustained significant drop in urinary amylase from baseline should prompt a pancreas biopsy to rule out rejection. In ED recipients, one has to rely on serum amylase and lipase only. A rise in serum lipase has recently shown to correlate well with acute pancreas rejection. Other signs and symptoms include tenderness over the graft, unexplained fever, and hyperglycemia (usually a late finding). Diagnosis can be confirmed by a percutaneous pancreas biopsy. In cases in which percutaneous biopsy is not possible due to technical reasons, empiric therapy may be started. Rarely, open biopsy is indicated. Transcystoscopic biopsy, which was used in the past, has been largely abandoned.
- **Others:** Other findings include infectious complications such as CMV, hepatitis C, extra-abdominal bacterial or fungal infections, posttransplant malignancy such as posttransplant lymphoproliferative disorder, and other rare complications such as graft-versus-host disease that occur in pancreas transplantation. The diagnosis and management of these complications is similar to those of other solid-organ transplants.

CHAPTER 59 ■ RENAL TRANSPLANTATION

- More than 46,000 patients were on the active waiting list for a kidney transplant in 2005. In that year, approximately 16,000 kidney transplantations were performed. The total number of kidney transplantations has gradually increased, as has the fraction of those kidneys transplanted with other organs. Live-donor kidneys accounted for approximately 41% of those transplants, and the remainder of transplanted kidneys originated from deceased donors. Policy changes continue to refine deceased donor kidney allocation to better utilize this scarce resource. Additionally, novel live donor-recipient matching strategies have been developed that offer the prospect of some relief to this shortage. As shown in Figure 59.1, the disparity between the number of those waiting for a kidney and those transplanted continues to increase despite increases in both living and deceased organ donation over the last decade.
- Kidney transplantation confers a clear survival advantage for patients with end-stage renal failure compared to long-term hemodialysis. For live-donor kidney recipients, 5-year patient and graft survival are 90% and 80%, respectively

PERIOPERATIVE CARE IN KIDNEY TRANSPLANTATION

- Renal transplantation is carried out in the standard fashion through an incision that exposes the iliac fossa. The donor renal vessels are sutured in an end-to-side fashion to the external iliac artery and vein, and a ureteroneocystostomy is created. Patients are monitored with continuous electrocardiography and central venous pressure in the immediate postoperative period. Blood pressures are carefully monitored, as most patients have underlying hypertension, and administration of immunosuppressive medications such as corticosteroids can affect blood pressure control. In addition, pain, catecholamine release, and fluid status may contribute to difficulties with blood pressure control. Though adequate blood pressure control is important for the integrity of the renal arterial anastomosis, it is equally important to avoid hypotension and therefore prevent renal hypoperfusion and graft thrombosis.

FIGURE 59.1. Number of kidney transplantations and size of active waiting list per year. TX, transplant. (Source: 2006 Annual Report of the U.S. Organ Procurement and Transplantation Network and the Scientific Registry of Transplant Recipients: Transplant Data 1996–2005. Rockville, MD: Health Resources and Services Administration, Healthcare Systems Bureau, Division of Transplantation, Tables 1.7 and 5.1a. The data and analyses reported in the 2006 Annual Report of the U.S. Organ Procurement and Transplantation Network and the Scientific Registry of Transplant Recipients have been supplied by the United Network for Organ Sharing and Arbor Research under contract with the Department of Health and Human Services. The authors alone are responsible for reporting and interpreting these data; the views expressed herein are those of the authors and not necessarily those of the U.S. government.)

- Urine output is carefully monitored on an hourly basis via an indwelling urinary catheter. This urinary catheter also serves to protect the ureteroneocystostomy during the early postoperative period. Any increase in intravesical pressure due to incomplete emptying of the bladder could compromise the newly created anastomosis between the ureter and bladder. Hematuria occurring early after transplantation may be due to bleeding at the ureteral anastomosis, in the bladder, or along the urethra. This can be managed with gentle flushing of the urinary catheter with 20 to 30 mL of sterile saline. Changing the urinary catheter to one of a larger caliber may also help remove clots. Three-way urinary catheters are also used to facilitate continuous bladder irrigation should other measures fail to treat the hematuria.
- Blood glucose monitoring is also done on a regular basis. Many transplant recipients have underlying diabetes mellitus, and all patients may have hyperglycemia exacerbation related to administration of steroids and other immunosuppressive agents. Use of continuous insulin infusion and frequent blood glucose monitoring may be necessary to maintain good glycemic control. Optimal control of hyperglycemia in the postoperative period and in critically ill patients has been shown to decrease morbidity and mortality.
- Particular attention should be paid to the volume and electrolyte status, as the urine output in the immediate posttransplantation period can vary from oliguria (frequently due to delayed graft function) to several liters as a result of generous fluid replacement during the surgery and also due to solute-induced osmotic diuresis. Live-donor allografts typically have excellent immediate function and may have prompt and marked diuresis. Most transplantation centers utilize a center-specific protocol with a fixed-rate maintenance of intravenous fluids usually with 0.9% normal saline at 50 mL/hour or 100 mL/hour together with replacement fluid at two-thirds or one-half of previous hour urine output. Some recipients may need hourly fluid replacement on a milliliter-for-milliliter basis to keep up with fluid losses. Kidneys from expanded donors or donation after cardiac death or with longer cold ischemia times may not have immediate function due to acute tubular necrosis (ATN). These recipients should be kept on a maintenance volume of intravenous fluids, and the central venous pressure can be used to guide fluid status (Fig. 59.2). Other factors to consider would include the timing of the last dialysis and the amount of urine produced by the patient before transplantation. Hemodialysis treatment shortly before the transplantation surgery may render a

recipient relatively hypovolemic during the perioperative period. Patients who have not yet been started on renal replacement therapy or who make a normal amount of urine may not have issues with hypovolemia.

- Postoperative evaluation of electrolytes should include monitoring of serum sodium, potassium, bicarbonate, calcium, magnesium, and phosphorous. Though some patients require bicarbonate supplements, potassium supplements are usually not necessary. However, supplementation may be required in patients with large-volume posttransplantation diuresis.
- Prophylaxis with subcutaneous heparin to prevent deep venous thrombosis and H_2 receptor blockers or proton pump inhibitors to prevent gastric and/or duodenal ulcers are often administered. Patients should be evaluated for the need for dialysis based on their electrolyte, metabolic, and volume status.

Early Complications

- The most common complication early after transplantation is an inappropriately low urine output. The differential diagnosis includes (a) obstruction of urine flow anywhere between the renal pelvis and the collection bag; (b) graft hypoperfusion; (c) urinary leak; (d) renal parenchymal disease, usually ATN; and (e) acute rejection in immunologically sensitized patients. If a brisk diuresis was observed in the operating room or has been recorded in previous hours, a sudden reduction in urine flow should immediately raise suspicion of a mechanical problem. Graft thrombosis is rare, but any hope of graft salvage requires immediate return to the operating room.

Delayed Graft Function and Acute Tubular Necrosis

- Delayed graft function (DGF) or acute renal dysfunction in the immediate posttransplantation period has been a serious and frequent problem in cadaver renal transplantation and occurs in up to 30% of the recipients and up to 35% to 40% in expanded-criteria-donor and donation-after-cardiac-death kidney recipients, respectively. However, this diagnosis should be considered only after all other causes are eliminated. ATN is the most common histologic feature in patients with DGF. The risk factors associated with an increased incidence of DGF include donor hypovolemia or hypotension, particularly in the presence of nephrotoxic drugs or

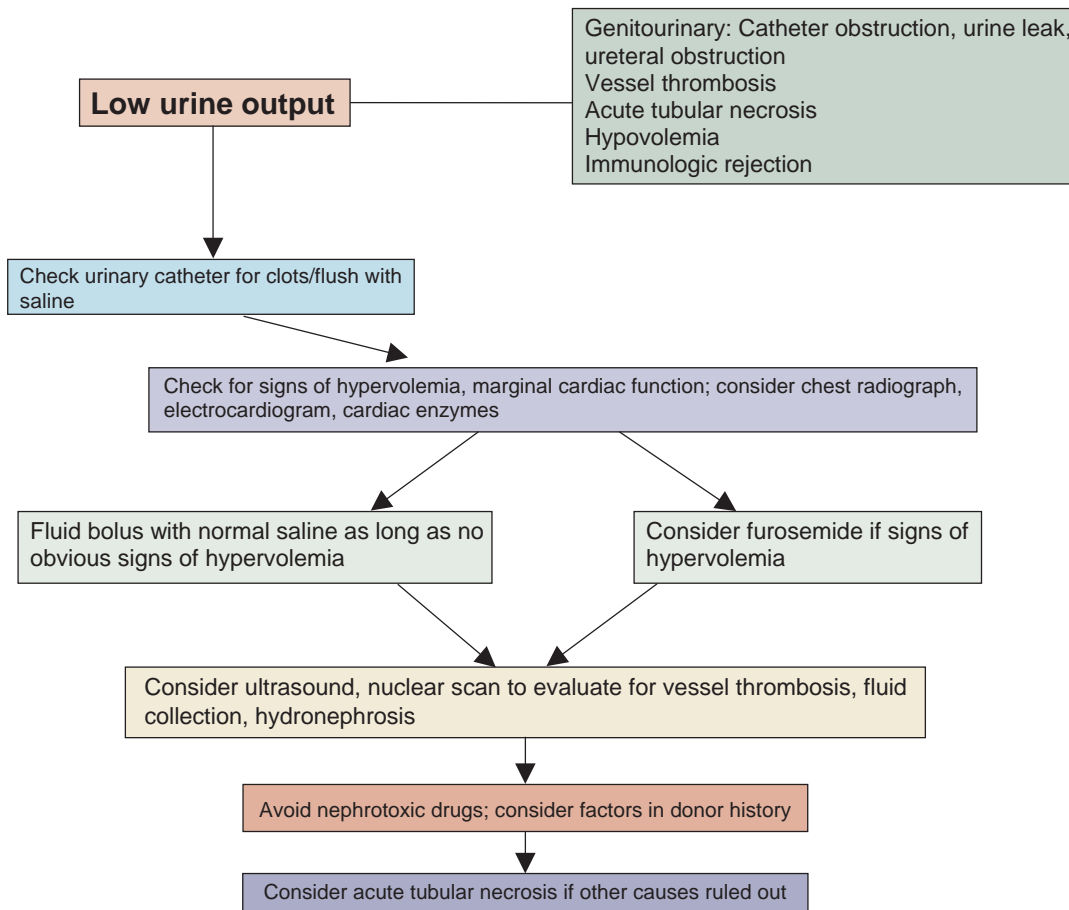

FIGURE 59.2. Algorithm for management of low urine output after renal transplantation.

vasopressors; prolonged cold or warm ischemia times; kidneys procured from older donors and from donors with hypertension or vascular occlusive disease; injury incurred during procurement, preservation, or implantation; and a high (>50%) panel reactive antibody level in the recipient. Live-donor kidneys are much less likely to have DGF than deceased donor kidneys. The pathophysiology leading to DGF is complex and incompletely understood and appears to be due to ischemia–reperfusion injury. The short-term and long-term deleterious effects on graft survival that have been demonstrated in patients developing this disorder relate to its association with acute and chronic rejection. Therefore, protocols were developed to administer antilymphocyte antibodies for the preemptive treatment of acute rejection, during this period of graft dysfunction, when a diagnosis of rejection could be difficult. This led to the development of protocols termed *sequential quadruple immunosuppressive therapy*, where patients receive antibody induction followed by maintenance immunosuppression, usually with three agents.

IMMUNOLOGIC CAUSES OF EARLY GRAFT DYSFUNCTION

- Hyperacute rejection is a rare and largely preventable cause of immediate graft failure. It is caused by preformed antibodies present in the recipients' serum at the time of transplantation

against donor antigens. These antibodies are the consequence of previous exposure to donor antigens due to blood transfusions, prior transplantation, or pregnancy. It also occurs when transplantation is attempted across ABO-incompatible barriers. The events that lead to hyperacute rejection may occur with such rapidity that the kidney becomes visibly ischemic while the patient is still on the operating table. It always occurs within 24 hours of transplantation. Renal histology shows fibrin thrombi occluding the glomerular capillaries and small vessels with extensive tissue necrosis. Although plasmapheresis and anticoagulation have been advocated, there is no established effective treatment and interventions are seldom successful. A kidney with hyperacute rejection should always be removed promptly. The current cross-match techniques, because of their increased sensitivity, have greatly diminished the incidence of hyperacute rejection. *Antibody-mediated (CD4-positive) acute rejection* is another form of early rejection that can occur in previously sensitized patients but with an initial negative cross-match. This form of acute rejection is potentially reversible if diagnosed early and treated aggressively with plasmapheresis and intravenous immunoglobulin.

Immunosuppression

- The different phases of immunosuppressive therapy after transplantation are (a) induction immunosuppression in the

immediate posttransplantation period when potent therapy is required to prevent rejection; (b) maintenance immunosuppression for long-term therapy to prevent allograft rejection but at the same time preserving host defense mechanisms against infections; and (c) intensification of the immunosuppressive therapy for the treatment of an acute rejection episode.

- Antilymphocyte antibodies are ideally suited for use as induction immunosuppressive agents and some for the treatment of acute rejection. They have been available for use as immunosuppressive agents since the late 1960s. All early forms of antilymphocyte antibodies were polyclonal, which are made by injecting human lymphocytes into horses, goats, rabbits, or sheep. In contrast to polyclonal antibodies, a monoclonal antibody is highly specific and recognizes a single antigen epitope. They have a greater potency at lower doses and have a more predictable and consistent effect. Monoclonal antibodies that are currently approved for use in transplantation are directed either at cell surface receptors such as the CD3/T-cell receptor complex (OKT3), or the interleukin-2 (IL-2) receptor (IL-2R; daclizumab and basiliximab). Current maintenance immunosuppression protocols often use the combination of a calcineurin inhibitor, an antimetabolite, and corticosteroids. However, the principles of the different regimens are similar: more intense immunosuppression in the induction phase with gradual reduction in immunosuppression in the maintenance phase. The immunosuppression protocol and institution implements should provide a balance between preventing rejection and avoiding the consequences of overimmunosuppression such as infection and malignancy.

MINIMIZING OPPORTUNISTIC INFECTIONS IN THE TRANSPLANT RECIPIENT

Viral Infections

- Cytomegalovirus is the most important viral infection affecting transplant recipients. Treatment options are available in Table 59.1. Other viral infections that may occur in the immunosuppressed renal allograft recipient include Epstein-Barr virus, which may lead to the development of Epstein-Barr virus–positive lymphomas; herpes simplex virus (types I and II); hepatitis B virus; hepatitis C virus; varicella-zoster virus; and the influenza virus. Treatment of viral infections depends on the type of virus and the extent of the disease. All transplant recipients should receive an annual influenza immunization.

Fungal Infections

- Fungal infections are a major concern in the immunosuppressed renal allograft recipient. As with the general population, *Candida albicans* infections resulting from endogenous flora are common. However, with immunosuppression, these infections can rapidly develop into more serious infections. Other fungal pathogens seen in transplant recipients include nocardiosis, aspergillosis, *Cryptococcus*, histoplasmosis, coccidiomycosis, blastomycosis, and mucormycosis. Treatment of fungal infections include the use of antifungals specific to the organism, surgical excision (especially in the case of mucormycosis), and reduction in the overall immunosuppression. Careful consideration should be given to the choice of the antimicrobial agent because of drug interactions (azole antifungals) or additive nephrotoxicity (amphotericin B). Invasive fungal infections in transplant recipients are associated with a high risk of graft loss and mortality. Early diagnosis and aggressive treatment can preserve organ function and can be lifesaving.

Other Opportunistic Infections

- Urinary tract infections are a frequent complication of renal transplantation. Although urinary tract infections are frequently asymptomatic, they constitute the major source of bacteremia in this patient population. Therefore, all urinary tract infections, even asymptomatic ones, should be treated appropriately. Fortunately, renal dysfunction is an uncommon complication of urinary tract infections in the transplant recipient. It usually occurs with severe pyelonephritis involving the allograft, usually in the setting of ureteric obstruction or vesicoureteral reflux. Chronic urinary tract infections may require daily prophylactic antibiotic administration.
- Renal allograft recipients, especially patients with poor allograft function with a background of intensive acute and chronic immunosuppressive therapy for recurrent rejection episodes, are susceptible to a large range of infections. Empiric treatment should be initiated at the first sign of infection, as infections can be aggressive and worsen rapidly.

GASTROINTESTINAL COMPLICATIONS

- A wide variety of gastrointestinal complications may occur after transplantation due to infections with organisms such as cytomegalovirus (CMV), *Candida* spp., and

TABLE 59.1

CYTOMEGALOVIRUS (CMV) RISK STRATIFICATION AND TREATMENT OPTIONS

Risk status	Donor CMV IgG serostatus	Recipient CMV IgG serostatus	Usual drug of choice	Dose	Duration
High	Positive	Negative	Valganciclovir	450 mg QD	90–180 d
Moderate	Positive	Positive	Valganciclovir	450 mg QD	90 d
	Negative	Positive	Valganciclovir	450 mg QD	90 d
Low	Negative	Negative	Valacyclovir	500 mg BID or TID	30 d

Clostridium difficile; adverse effects associated with immunosuppressive agents; posttransplantation complications of pre-existing conditions such as diverticulitis; and other complications such as acute appendicitis, gastrointestinal bleeding, colonic or small-bowel perforations, pancreatitis, and ischemic colitis.

Peptic Ulcer Disease

- Gastroduodenal ulcers presenting after transplantation can be attributed to a variety of causes including pre-existing ulcer history, viral pathogens (CMV in 15%, herpes simplex in 2%), and immunosuppressive agents, mainly corticosteroids.

Bowel Perforations

- Colonic perforation should be suspected in the presence of one or more of the following: abdominal pain, fever, increased white blood cell count, tenderness, and pneumoperitoneum. These clinical criteria may be blunted in the presence of poor renal function, use of high-dose corticosteroids, or the overall state of immunosuppression

Acute Pancreatitis

- Acute pancreatitis is an infrequent but severe complication after renal transplantation. A review of the literature has documented an incidence of 2.3% with a mortality rate of 61.3% in 3,253 renal transplant recipients. Several etiologic factors have been considered. Azathioprine has been reported to cause pancreatitis with rapid improvement after cessation and with recurrence of symptoms with reinstitution. Corticosteroids and cyclosporine have also been reported to cause pancreatitis; however, this association is not as convincing. Other causes of pancreatitis include hyperparathyroidism, CMV infection, biliary tract disease, alcoholism, and hyperlipidemia.

HEMATOLOGIC COMPLICATIONS

- Neutropenia is a frequent complication after transplantation, often as a result of the adverse effects of immunosuppressive medications. Antithymocyte globulin can cause transient decreases in neutrophils that often rebound after cessation of therapy. Maintenance immunosuppression with mycophenolic acid, sirolimus, and prophylaxis with ganciclovir and cotrimoxazole contribute to the development of neutropenia due to their myelosuppressive effects. Careful dose reduction of these agents and/or use of granulocyte-stimulating factors are often required for persistent neutropenia. Of particular importance is that neutropenia can be a sign of CMV infection; therefore, this should always be excluded in transplant recipients with persistent neutropenia.
- Anemia is a frequent occurrence in the early posttransplantation period as a result of pre-existing anemia of end-stage renal disease, surgical blood loss, and immunosuppressive medications. Thrombocytopenia is also a frequent occurrence in renal allograft recipients and often is caused by

the immunosuppressive medications. Antithymocyte globulin, valganciclovir, and dapsone can cause transient decreases in platelets. Withholding doses or dose adjustments of the responsible agent may be required for thrombocytopenia. Platelet recovery is rapid, often returning to baseline within days

CARDIAC AND VASCULAR DISEASES

- The management of transplantation patients with coronary artery disease is similar to that of other patients and should include noninvasive exercise or resting diagnostic testing, coronary arteriography, or both. Of particular note: If cardiac catheterization is necessary, femoral arterial puncture on the ipsilateral side to the renal transplant should be avoided whenever feasible to reduce the risks of mechanical injury and atheroembolization to the renal allograft.

Cerebrovascular and Peripheral Vascular Disease

- Cerebrovascular disease occurs in 1% to 3% of all renal allograft recipients. There is also an increased risk of peripheral vascular disease. A thorough history to elicit symptoms associated with cerebrovascular and peripheral vascular disease and examination of the carotid arteries and peripheral circulation should be performed annually, and the presence of a carotid bruit should be further investigated with duplex ultrasonography and magnetic resonance angiography. In the presence of more than 60% stenosis of the carotid artery, the patient should be referred to the neurovascular surgeon for further evaluation.
- Successful transplantation does not reduce the rate of atherosclerosis initiated in renal failure. Factors contributing to the high incidence of vascular disease include hypertension, hyperlipidemia, obesity, cigarette smoking, and the presence of pre-existing diabetes mellitus or the development of post-transplantation diabetes mellitus.

Hypertension

- Hypertension is a common complication of renal transplantation and remains an important risk factor for mortality from cardiovascular disease. Posttransplantation hypertension is a major risk factor for graft survival. It is unclear, however, whether this is because of the deleterious effects of hypertension on the structure and function of the renal allograft or whether hypertension is a marker of underlying renal disease. The causes of hypertension in renal transplant recipients include acute and/or chronic allograft rejection; recurrent or *de novo* transplant glomerulonephritis; transplant renal artery stenosis; high renin output state from diseased native kidneys; immunosuppressive agents such as steroids, cyclosporine, and tacrolimus; obesity; hypercalcemia; and new-onset essential hypertension.

Hyperlipidemia

- Elevations in triglycerides, low-density lipoproteins, apolipoprotein B, and total cholesterol levels are common. The pathogenesis of hyperlipidemia in renal transplant recipients is poorly understood and appears to be multifactorial. The numerous factors that have been shown to be associated with hyperlipidemia after renal transplantation are age, body weight, gender, pretransplantation lipid levels, renal dysfunction, proteinuria, concomitant use of diuretics or β -blockers, diabetes, steroid use, and cyclosporine and sirolimus use.

New-onset Diabetes after Transplantation

- New-onset diabetes after transplantation (NODAT) has been reported in 3% to 40% of transplant recipients with an even higher incidence occurring in African Americans, Hispanics, and patients with a family history of diabetes mellitus, increasing with recipient age and weight. NODAT has been attributed to the use of immunosuppressive agents, especially with tacrolimus and corticosteroids; however, cyclosporine has also been implicated. Patients with NODAT have a poor outcome in terms of patient and graft survival, with increased mortality resulting from cardiovascular and possibly infectious complications.

GRAFT DYSFUNCTION AND GRAFT FAILURE

- The differential diagnosis of acute allograft dysfunction can be divided into (a) early, occurring <90 days after transplantation, and (b) late, occurring >90 days after transplantation. It can be further differentiated into medical and surgical problems as outlined in Table 59.2. Some of the more common medical and surgical problems are discussed below.

TABLE 59.2

CAUSES OF GRAFT DYSFUNCTION AND FAILURE

	Early (0–90 days after transplantation)	Late (>90 days after transplantation)
Medical	Hyperacute rejection	Acute rejection
	Delayed graft function	Calcineurin inhibitor toxicity
	Acute rejection	Chronic rejection
	Acute calcineurin inhibitor nephrotoxicity	Dehydration
	Dehydration	Other drug toxicities
	Other drug toxicities	Infection
	Infection	BK virus nephropathy
Mechanical	<i>De novo</i> /recurrent disease	<i>De novo</i> /recurrent disease
	Lymphocele	Renal artery stenosis
	Ureteric obstruction	Ureteric obstruction
	Urine leak	Urine leak
	Vascular thrombosis	Vascular thrombosis

Acute Rejection

- Factors significantly associated with the development of acute rejection are human leukocyte antigen (HLA) mismatch, anti-HLA antibodies reactive to >50% of a lymphocyte panel, retransplantation, African American race, and recipient age younger than 16 years. The classic clinical features associated with acute rejection are fever, oliguria, weight gain, edema, hypertension, and the presence of an enlarged, tender graft. However, these features are frequently absent, and the most common presentation may be an asymptomatic rise in serum creatinine. An increase in serum creatinine >20% is often the cardinal feature of rejection. Percutaneous needle biopsy of the allograft is the most reliable method of diagnosis of acute rejection. The principles and the management of acute rejection include rapid diagnosis, accurate classification, and prompt administration of antirejection therapy.

Chronic Rejection

- Chronic rejection is characterized clinically by a progressive decline in renal function, persistent proteinuria, and hypertension. The course of chronic rejection is slow and insidious. Chronic rejection often occurs in conjunction with other histologic causes of allograft dysfunction: acute rejection, calcineurin inhibitor nephrotoxicity, and recurrent or *de novo* glomerular diseases. There is no treatment for chronic rejection at the present time.

Urologic Complications

- Urologic problems have been reported in between 2% and 20% of all renal transplantations. These complications can include urinary retention, urine leak, and ureteral stenosis.

Vascular Complications

- Vascular complications including vessel thrombosis or stenosis have been reported in 2% to 12% of all renal transplants. Vascular complications in general are significantly associated with ATN and graft loss. Early graft dysfunction should be evaluated for vascular complications with ultrasound with Doppler.

Lymphocele

- A lymphocele is a collection of lymphatic fluid around the allografted kidney that can occur due to leakage of small lymphatic channels around the iliac vessels at the time of the transplantation. The incidence of lymphoceles has been reported from 0.02% up to 26% after renal transplant. Consequences of lymphoceles can include distention due to the fluid collection and venous or ureteral obstruction and graft compromise. Treatment of lymphoceles can include percutaneous techniques with drainage and sclerosis of the cavity or may include operative marsupialization via the laparoscopic or open technique. Laparoscopic techniques are less invasive, have less morbidity, and are generally the first line of therapy.

Stones

- Calculi may have been present in the donor kidney or may develop after transplantation. Predisposing factors include obstruction, recurrent urinary tract infection,

hypercalciuria, hyperoxaluria, internal stents, and non-absorbable suture material. Open removal of a calculus from the transplanted kidney is rarely necessary. Complete stone removal is usually possible by standard urologic techniques.

CHAPTER 60 ■ CRITICAL CARE ASPECTS OF STEM CELL TRANSPLANTATION

- Bone marrow and blood cell transplants are widely used to treat aplastic anemia, leukemias, lymphomas, myeloma, and immunodeficiency disorders. Transplants are also increasingly used to treat other bone marrow disorders such as sickle cell disease and thalassemia. Morbidity and mortality associated with transplants usually result from regimen-related toxicity, such as adverse effects of drugs and radiation given pretransplant, complications of graft-versus-host disease (GVHD), and infections resulting from bone marrow failure.
- Pretransplant evaluation of recipients typically includes the following:
 - Measurement of the left ventricular ejection fraction, which should be at least 40%
 - Pulmonary function tests, including diffusing capacity (DLCO), and forced vital capacity, which should be more than 50% of predicted
 - Hepatic transaminases, which should be less than twice normal
 - Creatinine clearance, which should be more than 50 mL/minute
 - A pretransplant performance score consistent with an independent life

PERIOPERATIVE CARE OF STEM CELL TRANSPLANTATION

- In the setting of allotransplants, the pretransplant conditioning regimen needs to moderate or eliminate recipient immunity to prevent graft rejection. When the allotransplant recipient has cancer, the pretransplant conditioning regimen must also eradicate it. Most allotransplant conditioning regimens contain cyclophosphamide and busulfan, or total-body radiation. Antilymphocyte antibodies, such as antilymphocyte globulin, antithymocyte globulin, or alemtuzumab (anti-CD52), are often used in reduced-intensity conditioning regimens or in alternative donor transplants. In immunodeficiency disorders—for example, severe combined immunodeficiency, pretransplant conditioning is not necessary, as the host is already immune deficient.
- For autotransplants, the choice of pretransplant conditioning regimen is based on anticancer effect, a steep dose-

response curve, lack of cross-resistance with other drugs, and low non-bone marrow dose-limiting toxicities. In general, these regimens contain alkylating drugs, such as melphalan or cyclophosphamide, combined with two or three other drugs. Immunosuppression is unnecessary and an unwanted side effect of therapy. Radiation is not used in autotransplants, as the effective anticancer doses exceed non-bone marrow dose-limiting toxicity.

- Pretransplant conditioning regimens are typically empirically determined (Table 60.1).

BONE MARROW AND BLOOD CELL INFUSION

- Bone marrow and blood cells may be frozen in dimethyl sulfoxide for later use. The intracellular contents of cells destroyed in the freezing and thawing processes—and dimethyl sulfoxide itself—may cause hypotension, anaphylaxis, or dysrhythmias, including transient heart block. To avoid complications, subjects are premedicated with diphenhydramine hydrochloride (Benadryl) and methylprednisolone sodium succinate (Solu-Medrol). Intubation equipment and epinephrine should be available at the bedside when cells are infused. If hypotension occurs, the infusion is slowed or temporarily interrupted until the blood pressure stabilizes. If the bone marrow or blood cells have not been frozen, the risk of anaphylaxis is similar to a standard blood transfusion, and premedication is unnecessary.
- Approximately 1.2% of cultures obtained during these processes are found to contain bacteria. Most cultures show coagulase-negative *Staphylococcus spp.*, which colonize the skin; pathogenic gram-negative bacteria are occasionally present. Thus, despite positive culture results, most centers reinfuse the stem cells after appropriate antibiotic coverage.

FLUIDS AND HYPOTENSION

- High-dose chemotherapy and radiation damage vascular endothelial cells, resulting in extravascular leakage of fluids. Furthermore, GVHD and cytokines such as tumor necrosis

TABLE 60.1

TOXICITY OF CONDITIONING REGIMEN DRUGS

Drug/dose	Extramedullary dose-limiting toxicity	Other toxicities
BCNU	Interstitial pneumonitis	Renal insufficiency, encephalopathy, nausea, vomiting, VOD
Busulfan	Mucositis, VOD	Seizures, rash, hyperpigmentation, nausea, vomiting, pneumonitis
CCNU (lomustine)	Interstitial pneumonitis	Renal insufficiency, encephalopathy, nausea, vomiting, VOD
Cyclophosphamide	Heart failure	Hemorrhagic cystitis, SIADH, nausea, vomiting, pulmonary edema, interstitial pneumonitis
Cytarabine	Mucositis, cerebellar ataxia	Pulmonary edema, conjunctivitis, rash, fever, hepatitis, toxic epidermal necrolysis
Cisplatin	Renal insufficiency, peripheral neuropathy	Nausea, vomiting, renal tubular acidosis, hypomagnesemia
Carboplatin	Ototoxicity, hepatitis	Renal insufficiency, hypomagnesemia, peripheral neuropathy
Etoposide	Mucositis	Nausea, vomiting, hemorrhagic cystitis, pneumonia, hepatitis
Ifosfamide	Encephalopathy, renal insufficiency	Hemorrhagic cystitis, renal tubular acidosis
Melphalan	Mucositis	Nausea, vomiting, hepatitis, SIADH, pneumonitis, renal insufficiency
Mitoxantrone	Cardiotoxicity	Mucositis
Paclitaxel	Mucositis	Peripheral neuropathy, bradycardia, anaphylaxis
Thiotepa	Mucositis	Intertriginous rash, hyperpigmentation, nausea, vomiting

VOD, veno-occlusive disease; SIADH, syndrome of inappropriate antidiuretic hormone.

factor, interleukin 2, and interferon-gamma contribute to a posttransplant capillary leak syndrome.

- If hypotension develops, emphasis should be placed on early invasive cardiovascular monitoring, inotropic support, and irradiated packed red blood cell transfusion to maintain intravascular oncotic pressure. Aggressive hydration may precipitate pulmonary and peripheral edema, even with normal pulmonary artery wedge pressure and right atrial pressure.

ELECTROLYTE BALANCE

- Electrolyte abnormalities are common in transplant recipients, resulting from the underlying disease, prophylactic hydration for hemorrhagic cystitis, diarrhea, parenteral nutrition, renal insufficiency, diuretics, and other medications.

BLOOD PRODUCT TRANSFUSIONS

- Subjects receiving transplants are immunocompromised and at risk for transfusion-associated GVHD. All cellular blood products contain white blood cells, including immune-competent T cells, and should be irradiated (25 Gy).
- Furthermore, all allotransplant recipients should receive cytomegalovirus-negative (CMV-negative) blood product transfusions, especially when the recipient is CMV-seronegative
- In the allotransplant setting, special consideration is needed regarding ABO compatibility between recipient and donor. This complexity of blood product transfusion support should be viewed in terms of whether there is a major or minor ABO incompatibility between the recipient and donor (Tables 60.2 and 60.3). Despite using ABO-compatible platelets, many subjects fail to respond to platelet transfusions early after transplant. Causes include fever, hepatic veno-occlusive disease (VOD), drugs, infection, disseminated intravascular

coagulation, and microangiopathic hemolytic anemia related to cyclosporine and/or GVHD.

INFECTION PREVENTION

- Standards for prevention of infection vary from strict isolation in laminar airflow (LAF) rooms to none. In LAF rooms, the subject is in a sterile environment; anyone who enters must be gloved and gowned, and the patient's food is sterilized or has a low microbial content secondary to autoclave or microwave treatment. Prophylactic oral antibiotics are given to destroy enteric pathogens, which not only are reservoirs for infection, but also may function as superantigens that increase the severity of GVHD.
- The minimal standards to prevent bacterial infections include the following:
 - A transplant unit set aside from general hospital, patients, and visitor traffic
 - High-efficiency particulate air filtration to prevent iatrogenic *Aspergillus* species infection
 - Careful handwashing before entering a patient's room
 - A diet without fresh salads, vegetables, or fruits, as these may be contaminated with gram-negative bacteria, or without pepper, as this may be contaminated with an *Aspergillus* species. Bacterial prophylactic measures are generally discontinued when the neutrophil count is $>0.5 \times 10^9$ cells/L.
- Tactics to prevent fungal infections include the use of oral triazoles such as itraconazole or fluconazole, given orally or intravenously for the first month after transplant.
- Subjects with prior aspergillus infection are at high risk of recurrence, especially in the presence of the following:
 - Prolonged neutropenia after transplant
 - A more advanced cancer state
 - A 6-week or shorter interval from beginning systemic anti-*Aspergillus* therapy to the transplant
 - Severe acute GVHD

TABLE 60.2

DONOR-RECIPIENT ABO INCOMPATIBILITY

Major ABO incompatibility	Minor ABO incompatibility	Major and minor ABO incompatibility
Recipient has antibody to donor	Donor has antibody to recipient	Recipient has antibody to donor and donor has antibody to recipient
<i>Immediate hemolysis</i> Prevent by RBC depletion of marrow	Prevent by plasma depletion of marrow	Prevent by RBC and plasma depletion of marrow
<i>Delayed hemolysis</i> Occurs 2–4 weeks after SCT + Direct antiglobulin test Risk increased with high recipient isohemagglutinin titer	Occurs day 9–day 16 after SCT + Direct antiglobulin test Risk increased with T cell–depleted marrow	+ Direct antiglobulin test
<i>Delayed erythropoiesis</i> Plasma exchange, erythropoietin, steroids		Plasma exchange, erythropoietin, steroids

RBC, red blood cell; SCT, stem cell transplantation; +, positive.

- Persons with prior aspergillosis should receive amphotericin, voriconazole, or caspofungin early after transplant.
- Herpes simplex reactivation is usually prevented by using intravenous or oral acyclovir for the first month after transplant. Treatment thereafter results in frequent acyclovir resistance and delays the development of natural immunity.

FEVER AND NEUTROPENIA

- In transplant recipients with fever—temperature $\geq 38^{\circ}\text{C}$ —and a neutrophil count $<0.5 \times 10^9$ cells/L—one should

try to identify an infection source using a chest radiograph, blood and urine cultures, and physical examination with emphasis on line sites and perineal, oropharyngeal, and sinus regions. Usually, no focal source is found, and broad-spectrum antibiotics are begun. The choice of antibiotics may include an antipseudomonal penicillin, aminoglycoside, and vancomycin or a third-generation antipseudomonal cephalosporin. Recurrent or persistent fever for 3 to 5 days without source in a person with granulocytes $<0.5 \times 10^9$ cells/L is an indication for empiric antifungal therapy with amphotericin.

TABLE 60.3

ABO TYPE OF BLOOD COMPONENTS USED IN PATIENTS WHO HAVE RECEIVED AN ABO-INCOMPATIBLE TRANSPLANT

Donor	Recipient	Red cells	Platelets ^a	FFP
<i>Major ABO incompatibility</i>				
A	O	O	A	A
B	O	O	B	B
AB	O	O	A	AB
AB	A	A	A	AB
AB	B	B	B	AB
<i>Minor ABO incompatibility</i>				
O	A	O	A	A
O	B	O	B	B
O	AB	O	A	AB
A	AB	A	A	AB
B	AB	B	B	AB
<i>Major and minor ABO incompatibility</i>				
A	B	O	B	AB
B	A	O	A	AB

FFP, fresh frozen plasma.

^aOccasionally, owing to nonavailability of platelets of the requested group, group O platelets (labeled as “low titer,” (i.e., low titer of anti-A and anti-B) may be used for patients of any group). When full ABO conversion has taken place, all patients receive products of their new ABO group.

MUCOSITIS

- The severity of mucositis depends on the components of the preconditioning regimen. The non–bone marrow dose-limiting toxicity of etoposide, busulfan, cytarabine, thiopeta, and paclitaxel is mucositis. Radiation also contributes to mucositis.
- Management of mucositis includes good oral hygiene using, for example, saline, chlorhexidine, and nystatin rinses, and topical analgesics. Opioids are often needed and should be given intravenously by schedule or using patient-controlled analgesia. Severe mucositis may require prophylactic intubation for airway protection. Ultimately, the resolution of mucositis generally correlates with recovery of the neutrophil count bone marrow.

DIARRHEA

- Diarrhea in transplant recipients may be caused by high-dose chemoradiotherapy, other drugs such as antibiotics, and bacterial or viral infections, and GVHD. The pretransplant conditioning regimen is the most common cause of diarrhea within 2 to 3 weeks after transplantation. Nevertheless, an infectious cause should always be considered, including *Clostridium difficile* and *Escherichia coli* (0157:H7), CMV, herpes simplex, adenoviruses, rotaviruses, echoviruses,

astroviruses, Norwalk virus, Coxsackie virus, *Strongyloides* spp., *Giardia* spp., and *Cryptosporidium* spp.. GVHD also causes diarrhea; the diagnosis can be confirmed by intestinal biopsy showing loss of crypts, vacuolization of crypt epithelium, karyorrhectic apoptotic debris, microabscesses and, in severe cases, ulceration and denudation of the epithelium.

- Therapy is directed toward appropriate antibiotics for infections and immunosuppression for GVHD. Conditioning regimen- and GVHD-associated diarrhea may respond to octreotide, a somatostatin analogue whose mechanism of action is partly through the inhibition of secretory hormones. Some viral infections—for example, CMV—respond to ganciclovir, foscarnet, or cidofovir.

HEMORRHAGIC CYSTITIS

- Hemorrhagic cystitis, occurring 2 to 3 weeks after transplant, usually results from drugs in the pretransplant conditioning regimen, such as cyclophosphamide, ifosfamide, or etoposide. Prophylaxis for hemorrhagic cystitis includes hydration and diuretics to maintain urine output at 0.2 mL/kg/hour.
- Complications of hemorrhagic cystitis are uncontrolled bleeding and clotting of the ureters or urethra, resulting in acute kidney failure. Obstruction of the ureters by clots may be asymptomatic or cause kidney colic from ureteral spasm. Severe pain may occur in the back or flank and radiate into the groin or genitals.
- Therapy of hemorrhagic cystitis consists of using a Foley catheter to irrigate the bladder with normal saline at 250 mL/hour to prevent intravesicular clotting. Platelets should be maintained at more than 50×10^9 cells/L with platelet transfusions, and red blood cell transfusion should be given to replace blood loss.
- Hemorrhagic cystitis seen more than 2 weeks after transplant can result from pre-transplantation conditioning or viral infection due to, for example, adenovirus, CMV, JC or BK viruses of the bladder epithelium. Except for CMV, there are no effective antiviral drugs.

VENO-OCCLUSIVE DISEASE OF THE LIVER

- VOD of the liver is caused by drugs and/or radiation in the pretransplant conditioning regimen within 1 to 3 months after transplant.

TABLE 60.4

CLINICAL CRITERIA FOR VENO-OCCLUSIVE DISEASE OF THE LIVER

McDonald criteria—Seattle	Jones criteria—Johns Hopkins
<i>Before day 30: Any two of the following</i>	<i>Before day 21: Any two of the following</i>
Bilirubin $>27 \mu\text{mol/L}$ = 1.7 mg/dL	Bilirubin $>34 \mu\text{mol/L}$ = 2.0 mg/dL
Hepatomegaly	Hepatomegaly
Ascites or weight gain	Ascites
	Weight gain

- VOD, with a reported incidence of 1% to 56%, is a clinical diagnosis suggested by elevated bilirubin, weight gain, ascites, and tender hepatomegaly (Table 60.4). Therapy for VOD is predominantly supportive, but its prognosis is poor when bilirubin is more than 15 to 20 mg/dL.

RESPIRATORY FAILURE

- Transplant recipients who develop respiratory failure and require mechanical ventilation have a poor prognosis. Respiratory failure within the first 30 days is usually caused by pretransplant conditioning, regimen-related epithelial cell damage, and/or infection.
- Early in the course of respiratory distress, efforts should be directed to preventing intubation. Although not evaluated in prospective studies and therefore of unproven benefit, management may include early invasive hemodynamic monitoring, red blood cell transfusions to maintain hemoglobin more than 12 g/dL, ultrafiltration to decrease intravascular volume, and anticytokine monoclonal antibodies or cytokine receptor antagonists. Use of high-dose corticosteroids is controversial. Transplant recipients are especially susceptible to pulmonary infections because of bone marrow failure, immunosuppressive drugs, mucositis, aspiration, and bronchial epithelial cell damage with impaired ciliary motility. Gram-negative and -positive pneumonias are common in the first 30 days after transplantation. Fungal infections of the lung also occur early after transplant, and isolation of *Aspergillus* species in a nasal or sputum culture should prompt initial therapy with amphotericin, voriconazole, or caspofungin.

TABLE 60.5

GRAFT-VERSUS-HOST DISEASE, GRAFT FAILURE, AND DISEASE-FREE SURVIVAL FOR TRANSPLANTS WITH SIBLING-MATCHED OR UNRELATED DONORS

Degree of HLA match	GVHD grade III or IV (%)	Acute Chronic GVHD (%)	Graft failure (%)	DFS-AML or all in remission (%)	DFS-CML in chronic phase (%)	DFS-AML or all in relapse (%)	DFS-CML in transformation (%)	DFS-AA (%)
Sibling 6/6	7–15	30–35	<2	50–60	60–80	20	10–35	78–90
Related 5/6	25–30	50	7–9	40–60	60–80	20	10–35	25–40
Related 4/6	45–50	50	21	10–40	—	10	10–30	—
Haplo-identical	50–100	>50	20	10–40	—	10	10–30	—
Unrelated 6/6	45–50	55	6	45	40	20	20	30–40

GVHD, graft-versus-host disease; DFS, disease-free survival; AML, acute myelogenous leukemia; CML, chronic myelogenous leukemia; ALL, acute lymphoblastic leukemia; AA, aplastic anemia.

- Viral pneumonia is rare early after transplant; the most common etiologic agent when this does occur is herpes simplex.

HEART FAILURE

- Heart failure may result from volume overload or impairment of left ventricular function from sepsis or toxicity from pretransplant conditioning regimen drugs such as cyclophosphamide, ifosfamide, and/or anthracyclines. The end result is loss of voltage, heart failure, and/or pericardial effusion. Therapy is usually supportive or aimed to reverse ventricular decompensation as described elsewhere without a reason to alter therapy.

KIDNEY FAILURE

- Renal insufficiency is usually a multifactorial process whose cause includes the underlying disease—for example, cast nephropathy in myeloma, a prerenal decrease in glomerular filtration, intrinsic renal dysfunction, or postrenal obstruction. The most common reason for renal insufficiency early in the posttransplant period is drug-related, especially with use of aminoglycosides, cyclosporine, and amphotericin. Post-kidney transplant renal failure may result from hemorrhagic cystitis with ureteral or urethral obstruction due to blood clots, retroperitoneal hemorrhage, urate nephropathy, or drugs that undergo intratubular crystallization and obstruction such as acyclovir, ciprofloxacin, and triamterene.

GRAFT FAILURE (ENGRAFTMENT)

- Generally, graft failure is defined as a neutrophil count $\leq 0.5 \times 10^9$ cells/L by day 28. Causes of graft failure include too few normal hematopoietic cells, damage to the bone marrow microenvironment, immune-mediated graft rejection, or drug- or virus-related immunosuppression.

TABLE 60.6

INCIDENCE OF GRADES III–IV ACUTE GRAFT-VERSUS-HOST DISEASE IN CHRONIC MYELOGENOUS LEUKEMIA ACCORDING TO THE NUMBER OF MISMATCHED CLASS I AND CLASS II ALLELES

	0 Class I (%)	1 Class I (%)	≥ 2 Class I (%)	Total (%)
0 Class II	32	29	36	32
1 Class II	45	31	55	45
≥ 2 Class II	67	67	86	74
Total	34	30	44	35

Note: There were 467 chronic myelogenous leukemia unrelated donor–recipient pairs.

- The minimal number of bone marrow or blood cells needed for sustained engraftment is unknown. There are several reasons for this:
 - It is not known what hematopoietic cells are responsible for sustained engraftment.
 - Different hematopoietic cells may operate under different circumstances and in different persons.
 - After autotransplants, there is no need for sustained engraftment in the context of autologous bone marrow recovery.
 - There is no validated method to identify the hematopoietic cell or cells responsible for sustained engraftment.
- Because of these limitations, surrogate markers are used to assess the hematopoiesis-restoring functionality of grafts. Most commonly used are CD34 and mononuclear cells.

ACUTE GRAFT-VERSUS-HOST DISEASE

- The principle manifestations of acute GVHD are rash, diarrhea, and jaundice, present individually or in combination. Acute GVHD is an allogeneic response mediated by donor

TABLE 60.7

GRADING OF ACUTE GRAFT-VERSUS-HOST DISEASE

Organ	Grade	Severity of individual organ involvement description
Skin	+1	A maculopapular eruption involving <25% of the body surface
	+2	A maculopapular eruption involving 25%–50% of the body surface
	+3	Generalized erythroderma
	+4	Generalized erythroderma with bullous formation and often with desquamation
Liver	+1	Moderate increase of AST (150–750 IU) and bilirubin (2.0–3.0 mg/dL)
	+2	Bilirubin rise (3.1–6.0 mg/dL) with or without an increase in AST
	+3	Bilirubin rise (6.1–15 mg/dL) with or without an increase in AST
	+4	Bilirubin rise (>15 mg/dL) with or without an increase in AST
Gut		Diarrhea, nausea, and vomiting graded +1 to +4 in severity. The severity of gut involvement is assigned to the most severe involvement noted.
	+1	Diarrhea >500 mL/d
	+2	Diarrhea >1,000 mL/d
	+3	Diarrhea >1,500 mL/d
	+4	Diarrhea >2,000 mL/d or severe abdominal pain with or without ileus

AST, aspartate transaminase.

TABLE 60.8

OVERALL GRADE OF GRAFT-VERSUS-HOST DISEASE^a

Grade	Skin	Gut		Liver	ECOG performance
I	+1 to +2	0		0	0
II	+1 to +3	+1 to +2	and/or	+1 to +2	0 to 1
III	+2 to +4	+2 to +4	and/or	+2 to +4	2 to 3
IV	+2 to +4	+2 to +4	and/or	+2 to +4	3 to 4

ECOG, Eastern Cooperative Oncology Group.

^aIf no skin disease, the overall grade is the higher single organ grade.

Adapted from Glucksberg H, Storb R, Fefer A, et al. Clinical manifestations of graft versus host disease in human recipients of marrow from HL-A-matched sibling donors. *Transplantation*. 1974;18:295–304.

T cells, which recognizes recipient tissues as foreign. The incidence and severity of acute GVHD increase with increasing recipient age and human leukocyte antigen (HLA) and non-HLA disparity between the recipient and donor (Tables 60.5 and 60.6).

- Skin involvement in acute GVHD results in a maculopapular, erythematous rash, often beginning on the palms and soles and which may become systemic. In severe cases, acute GVHD with skin involvement may be pruritic with bullae. The skin involvement in acute GVHD may be precipitated by exposure to sunlight and/or drugs. Histologically, one can see the dermal-epidermal border disrupted by vacuolar degeneration of epithelial cells, dyskaryotic bodies, acantholysis (i.e., separation of cell–cell contact), epidermolysis (separation of the epidermal and dermal layers), and lymphocytic infiltration. These clinical and histologic findings are not unique to acute GVHD and may occur from drug allergy or the effects of the high-dose chemotherapy and radiation used in the pre-transplant conditioning regimen.
- Gastrointestinal involvement with acute GVHD results in diarrhea, often accompanied by cramping abdominal pain. In severe cases, the diarrhea may be bloody or associated with a paralytic ileus. Histologically, lymphocytes and apoptotic cells are present, and intestinal crypts are lost, which leads

to epithelial denudation. Evaluation of gastrointestinal tract signs and symptoms should include stool cultures for bacteria, fungi, and viruses, especially CMV. Sigmoidoscopy with biopsy may be helpful if the diagnosis is in doubt and platelet levels are sufficient. Acute GVHD with hepatic involvement presents as jaundice and an elevated alkaline phosphatase with or without elevated transaminases. The differential diagnosis includes VOD or infections with CMV or *Candida* spp. and may require a transjugular liver biopsy for accurate diagnosis. In acute GVHD, the liver biopsy may show T-cell infiltration of the portal triad, with apoptosis of epithelial cells lining the biliary tree.

- Acute GVHD and infections from immunosuppression are major causes of early death after allotransplant. Consequently, acute GVHD prophylaxis is needed for all allotransplant recipients.
- Clinical staging of acute GVHD considers individual tissue/organ involvement scores, which are combined for an overall grade (Tables 60.7 and 60.8). Grade 1 acute GVHD is not clinically important and requires no specific therapy. Grades 2 through 4 acute GVHD are typically treated with corticosteroids such as methylprednisolone, 1 to 2 mg/kg/day, with or without cyclosporine. Acute GVHD unresponsive to this approach has a poor prognosis.

SECTION X ■ SPECIAL PATIENT POPULATION

CHAPTER 61 ■ THE OBSTETRIC PATIENT: GENERAL

- Review is focused mainly on the most life-threatening pathophysiologic processes (Tables 61.1 and 61.2):
 - Thrombosis and thromboembolism
 - Hypertensive disease of pregnancy
 - Hemorrhage
 - Amniotic fluid embolism
 - Peripartum cardiomyopathy
 - Pulmonary edema

PHYSIOLOGIC CHANGES ASSOCIATED WITH PREGNANCY

Body Constitution

- Optimal weight gain in pregnancy is currently a matter of debate
 - Generally, weight gain of 6 kg attributed to fetus, placenta, and uterus
 - Remainder attributed to increase in maternal blood, interstitial fluid volume, and fat
 - Gestational weight gain of more than 12 kg in women of normal prepregnant weight is related to the lowest risk for complications during delivery

- Women who exceed 18 kg of weight gain during pregnancy are considered at greater risk for maternal (preeclampsia, gestational diabetes) and fetal (increased incidence of operative delivery) complications

Metabolism and Respiration

- Key physiologic changes of respiration in pregnancy are:
 - Increased minute ventilation—caused by increased respiratory center sensitivity and drive
 - Compensated respiratory alkalosis
 - Low expiratory reserve volume
 - Vital capacity and measures of forced expiration are well preserved
 - Women with severe lung diseases tolerate pregnancy well
 - Except for those with pulmonary hypertension or chronic respiratory insufficiency from parenchymal or neuromuscular disease
 - Lung volumes measured in pregnant women and compared to nonpregnant women or those in the postpartum state
 - Well preserved in the majority of cases
 - Residual volume tends to decrease slightly, which leads to a small increase or stability of the vital capacity

- Most consistent change in static lung volumes with pregnancy is the reduction in the functional residual capacity (FRC) and expiratory reserve volume
 - As uterus enlarges, FRC decreases by 10% to 25% of the previous value, starting about the 12th week of pregnancy
 - Normal reduction in FRC is accentuated further in the supine position
 - Reduction in FRC is due to a decrease in chest wall compliance, up to 35% to 40%
- Lung compliance remains normal
- Expiratory muscle strength is in the low-normal range
- Decreased chest wall compliance is the result of the enlarging uterus increasing the abdominal pressure, leading to reduced FRC
- Diaphragm elevates about 4 cm, and the circumference of the lower rib cage increases about 5 cm
- Decreased FRC leads to an increased area of apposition of the diaphragm to the chest wall, which improves the coupling of the diaphragm and chest wall
 - Thus, increased tidal volume of pregnancy achieved without an increase in the respiratory excursions of the diaphragm
- Rib cage undergoes structural changes
 - Progressive relaxation of the ligamentous attachments of the ribs causes the subcostal angle of the rib cage to increase early in pregnancy
 - Persists for months into the postpartum period
 - Increased elasticity mediated by the polypeptide hormone, relaxin, increased during pregnancy and responsible for the softening of the cervix and relaxation of the pelvic ligaments

Changes in Arterial Blood Gases

- Hormonal changes of pregnancy lead to remarkable respiratory changes throughout its course (Table 61.3)
- Mean arterial PO₂ during pregnancy consistently >100 mm Hg
 - No alterations of dead space-to-tidal volume ratio (V_D/V_T) and shunt.

Cardiovascular System

- Most important hemodynamic change in the maternal circulation during pregnancy is an increase in the cardiac index of more than 30% (Tables 61.4 and 61.5)

Red Blood Cell, Plasma, and Blood Volume

- Increased plasma volume evident by sixth week of gestation
 - By the end of the first trimester of 15% above nonpregnant women
 - Subsequently a steep increase of this parameter until 28 to 30 weeks of gestation to a final volume at term of 55% above the nonpregnant level
- Red blood cell mass decreases during first 8 weeks of gestation
 - Increases to nearly 30% above the nonpregnant level at term
- Result in 45% increase of total blood volume and a reduction of the hemoglobin concentration and hematocrit to values of approximately 11.6 g/100 mL and 35.5%, respectively
- Estrogens, progesterone, and placental lactogen elevate aldosterone production either directly or indirectly, and are responsible for the increase of plasma volume during pregnancy
 - Hyperaldosteronism of pregnancy can result in retention up to 500 to 900 mEq of sodium and an increase of 6,000 to 8,000 mL of total body water, 70% of which is extracellular
 - Elevated red blood cell volume after 8 to 12 weeks can be attributed to increased serum erythropoietin
 - Erythropoiesis may also be stimulated by prolactin, progesterone, and placental lactogen

Colloid oncotic pressure (COP)	–10	—	—
COP–PAOP	–25	—	—

^aPercentage change from nonpregnant state.^bPercentage change without regional anesthesia (local anesthetic).

Plasma Proteins and Colloid Osmotic Pressure

- Total serum protein concentration decreases from a nonpregnant value of 7.3 to 6.5 g/100 mL at term gestation
- Change due primarily to a decline of the albumin concentration
 - Decreases from a nonpregnant level of 4.4 to 3.4 g/100 mL at term
 - Maternal colloid osmotic pressure decreases in parallel with the decline in serum albumin concentration from nonpregnant values of 25 to 26 to approximately 22 mm Hg at term

Aortocaval Compression

- Angiographic studies show that the aorta and inferior vena cava can be significantly compressed by the gravid uterus in the supine position
- Complete obstruction of the inferior vena cava at the level of the bifurcation in 80% of patients in late pregnancy
- Partial obstruction of the aorta at the level of the lumbar lordosis (L3–L5) demonstrated in patients between the 27th week of pregnancy and term gestation
- Term pregnant woman, when placed in the lateral decubitus position, exhibits a right ventricular filling pressure (central venous pressure) similar to that of a nonpregnant woman
 - Suggests that venous return in this position is maintained by the collateral circulation despite partial caval obstruction
 - In plain supine position right atrial pressure falls substantially, demonstrating that collateral circulation cannot compensate for complete or nearly complete caval obstruction
 - Evident by 20 to 28 weeks of gestation
 - Results in a decrease of stroke volume and cardiac output of approximately 25%

- 20% reduction of uterine blood flow
- Reliably improved by a tilt to the left of at least 25 degrees
- Despite the reduction of cardiac output and stroke volume, a position change from lateral to supine can be associated with elevation of blood pressure
 - Results from an increase of systemic vascular resistance
 - Due to compression of the aorta by the gravid uterus
 - Enhanced sympathetic nervous system outflow

TABLE 61.5**NORMAL CARDIAC SYMPTOMS AND SIGNS IN PREGNANCY****Symptoms**

Fatigue
Dyspnea
Decreased exercise tolerance
Light-headedness
Syncope

Signs**General:**

Distended neck veins
Peripheral edema
Hyperventilation

Heart:

Loud S₁; increased split S₁
Loud S₃
Systolic ejection murmur
Continuous murmurs (venous hum, mammary souffle)

Chest radiograph:

Increased pulmonary vasculature
Horizontal position of heart

Electrocardiogram:

Left axis deviation
Nonspecific ST-T-wave changes
Mild sinus tachycardia

- In approximately 5% of women a substantial drop in blood pressure occurs (“supine hypotensive syndrome”)
 - Associated with bradycardia (usually following a transient tachycardia) and maternal symptoms, low systemic perfusion such as of pallor and sweating, possibly followed by cardiocirculatory collapse
 - May be exacerbated by neuraxial block, the preferred method of providing anesthesia in pregnant women
- Based on the observations above, the intensivist should always consider in his or her emergency treatment plan the proper positioning of the pregnant patient and its influence on hemodynamics.

THROMBOSIS AND THROMBOEMBOLISM IN PREGNANCY

- Venous thromboembolism (VTE)
 - Includes deep venous thrombosis (DVT) and pulmonary embolism, occurs in approximately 1 in 1,000 pregnancies
 - Women five times more likely to develop VTE during pregnancy than during a nonpregnant state
 - Fatal pulmonary embolism (PE) remains a leading cause of maternal mortality in the Western world
 - Rate of PE in pregnancy is five times greater than that for nonpregnant women of the same age
 - Seen in about 1 in 100 deliveries
 - Risks even higher in the puerperium

Risk Factors and Predisposition to Venous Thrombosis

- Compared to nonpregnant females, pregnant women have a 10-fold risk of a thrombotic episode (Table 61.6)
- Pregnancy associated with increased clotting potential, decreased anticoagulant properties, and decreased fibrinolysis
 - Accompanied by two to three times increased concentration of fibrinogen
 - 20% to 1,000% increase in factors VII, VIII, IX, X, and XII, all of which peak at term
 - Levels of von Willebrand factor (vWf) increase up to 400% by term
 - Free protein S levels decline significantly (up to 55%) during pregnancy due to increased circulating levels of carrier molecular, complement four binding proteins

TABLE 61.6

RISK FACTORS FOR VENOUS THROMBOEMBOLISM (VTE) DURING PREGNANCY

Cesarean delivery
History of prior VTE
Family history of VTE
Inherited or acquired thrombophilia
Obesity
Older maternal age
Higher parity
Prolonged immobilization

- Thus pregnancy associated with increase in resistance to activated protein C
- Levels of plasminogen activation inhibitor-1 increase three to four times during pregnancy
 - Plasma plasminogen activation inhibitor-2 values—negligible before pregnancy—reach concentrations of 160 mg/L at delivery
- Pregnancy also associated with venous stasis in the lower extremities due to compression of the inferior vena cava and pelvic veins by the enlarging uterus and hormone-mediated increases in deep vein capacitance secondary to increased circulating levels of estrogen and local production of prostacyclin and nitric oxide
- Important hereditary risk factors that can increase DVT risk are:
 - Antithrombin III deficiency
 - Protein S and C deficiency
 - G1691A mutation of the factor V gene
 - G20210A mutation of the factor II gene

Diagnosis of VTE During Pregnancy

- In pregnant women presenting with:
 - Lower extremity edema
 - Back pain
 - And/or chest pain
- Prevalence of VTE is less than in the general population because of the high frequency of these complaints in the pregnant woman
 - D-dimer assays—used to exclude VTE in healthy nonpregnant individuals—usually positive late in pregnancy
 - Radiologic studies not been validated in pregnancy
 - Potential risks to the fetus, particularly in terms of ionizing radiation exposure, need to be considered
 - Compression ultrasonography (CUS) of the proximal veins has been recommended as the initial test for suspected DVT during pregnancy
 - When results equivocal or an iliac vein thrombosis is suspected, magnetic resonance venography (MRV) can be used
- Approach to the diagnosis of PE is similar in the pregnant and nonpregnant
 - Ventilation/perfusion (V/Q) scanning confers relatively low radiation exposure to the fetus, a risk less than that of missing a diagnosis of PE in the mother
 - When V/Q study is indeterminate in a pregnant woman without demonstrated lower extremity thrombosis, it is usually followed by angiography.
 - Brachial approach carries less radiation exposure to the fetus than spiral CT

Prevention of Thrombosis During Pregnancy

- Optimal anticoagulation regimen not established
 - Low-molecular-weight heparins (LMWHs) the anticoagulant of choice
 - They do not cross the placenta (like unfractionated heparin [UFH])
 - Have better bioavailability

- Carry less risk of osteoporosis and heparin-induced thrombocytopenia than UFH
- LMWHs safe alternatives to UFH as anticoagulants during pregnancy
- Recent practice trend to switch patients to the longer-acting, subcutaneous UFH a few weeks before delivery to allow use activated partial thromboplastin time as a diagnostic test to assess anticoagulation pre- and postlabor
- VTE prophylaxis with elastic compression stockings may be used for entire pregnancy
 - Appropriate for in-hospital patients at increased risk of VTE, and may be combined with the use of LMWH
- Vena cava filter placement a potentially important but poorly evaluated therapeutic modality in the prevention of pulmonary emboli
 - Randomized trials to establish the appropriate role of vena cava filters in the treatment of venous thromboembolic disease are lacking

Thrombolytic Therapy for Pulmonary Embolism

- Indications for thrombolytic therapy for PE controversial
 - Incidence of intracranial hemorrhage as high as 2% to 3% with systemic thrombolytic therapy
 - Fatality rates in patients with PE presenting in cardiogenic shock as high as 30%
 - Thrombolytic therapy should be considered in this circumstance, although evidence is limited
 - Approximately 10% of symptomatic pulmonary emboli are rapidly fatal
 - 2% of patients were first diagnosed with PE at autopsy
 - Of patients diagnosed with PE before death, 5% to 10% have shock at presentation
 - Associated with a mortality of 25% to 50%
 - Echocardiographic evidence of right ventricular dysfunction at presentation
 - Suggested as indication for thrombolytic therapy
 - Recent randomized trial failed to demonstrate a survival benefit with thrombolysis in patients with this finding.
 - Mortality rates with conventional therapy are conflicting.
 - Routine thrombolysis cannot be justified in all patients.

HEMORRHAGE

- Peripartum hemorrhage remains a significant cause of maternal and fetal morbidity and mortality.
 - In industrialized nations, massive obstetric hemorrhage ranks among the top three causes of maternal death despite modern improvements in obstetric practice and transfusion services.
- Peripartum hemorrhage includes a wide range of pathophysiologic events.
 - Antepartum bleeding occurs in nearly 4% of pregnant women.
 - Causes of serious antepartum bleeding are:
 - Abnormal implantation (placenta previa, accreta)

TABLE 61.7

MANAGEMENT OF SEVERE POSTPARTUM HEMORRHAGE

Conservative Management

General Measures

- Administration of supplemental oxygen
- Placement of adequate intravenous access lines
- Intravenous hydration
- Blood typing and cross-matching
- Placement of arterial line for repeated blood sampling

Pharmacologic Measures

- Oxytocin
- Methylergonovine
- 15-Methyl prostaglandin F₂-α

Surgical Management

Vascular Ligation

- Uterine artery
- Hypogastric artery
- Ovarian artery

Hysterectomy

- Supracervical
- Total

- Placental abruption
- Uterine rupture
- Main reason for postpartum bleeding:
 - Uterine atony when myometrial contraction is inadequate
 - Blood flow perfusing the uterus at term is up to 600 mL/minute
- Patients with hemodynamic instability or massive hemorrhage require prompt resuscitative measures (Table 61.7):
 - Administration of supplemental oxygen
 - Placement of two large-bore intravenous (IV) lines
 - IV hydration
 - Blood typing and cross-matching for the replacement of packed red blood cells (PRBCs)
 - Delay in the correction of hypovolemia, diagnosis and treatment of impaired coagulation, and surgical control of bleeding are avoidable factors in most maternal mortality cases caused by hemorrhage.
 - If transfusion must be given before full cross-matching, type-specific uncross-matched blood can be used.
 - If placenta not delivered when hemorrhage begins, it must be removed
 - Placenta accreta diagnosed if placental cleavage plane indistinct
 - In this situation, the patient should be prepared by the intensivist or the anesthesiologist for probable urgent hysterectomy
 - Firm bimanual compression of uterus (with one hand in the posterior vaginal fornix and the other on the abdomen) can limit hemorrhage until help obtained
- Hemorrhage after placental delivery:
 - Should prompt vigorous fundal massage while the patient is rapidly given 10 to 30 units of oxytocin in 1 L of intravenous crystalloids
 - Uterotonic agents such as oxytocin routinely used in management of uterine atony
 - If fundus does not become firm, uterine atony is the presumed (and most common) diagnosis

- While fundal massage continues
- Patient may be then given 0.2 mg of methylergonovine (Methergine) intramuscularly (IM), with dose repeated at 2- to 4-hour intervals if necessary
 - May cause undesirable adverse effects such as cramping, headache, and dizziness
 - Coexisting severe hypertension is an absolute contraindication to its use
- Injectable prostaglandins may also be used when oxytocin fails
- Prostaglandin E and prostaglandin F₂ stimulate myometrial contractions
 - Have been used IM or IV for refractory hemorrhage due to uterine atony
 - Carboprost (Hemabate), 15-methyl prostaglandin F₂-α, may be administered IM or intramyometrially in dose of 250 μg every 15 to 90 minutes, to a maximum dose of 2 mg
 - 68% of patients respond to a single carboprost injection; 86% respond to a second dose
 - Oxygen desaturation has been reported with the use of carboprost, so patients should be monitored by pulse oximetry
- Use of a hydrostatic balloon has been advocated as an alternative to uterine packing for controlling hemorrhage due to uterine atony
 - Inflated Rusch balloon can conform to the contour of the uterine cavity and provides an effective tamponade
 - Life-threatening hemorrhage can also be treated by arterial embolization by interventional radiology
 - Finally, in cases of continuing hemorrhage, surgical techniques can be used to avoid a hysterectomy, such as bilateral uterine artery ligation or internal iliac artery ligation

AMNIOTIC FLUID EMBOLISM (AFE)

- Entry of amniotic fluid into the maternal circulation recognized in 1926
- True incidence of AFE not known, estimated to be between 1 in 8,000 and 1 in 80,000 pregnancies

Clinical Presentation

- Classic presentation of amniotic fluid embolism is described as a sudden, profound, and unexpected cardiovascular collapse followed, in many cases, by irreversible shock and death
 - Only known predisposing factor to this life-threatening complication is multiparity, which accounts for 88% of the cases
 - A smaller percentage of cases (51%) had respiratory-related presenting symptom
 - Hypotension is present in 27% of surviving cases
 - Coagulopathy comprising 12%
 - Seizures 10%
 - Fetal bradycardia (17%) and hypotension (13%) the next most common presenting features (Table 61.8)

TABLE 61.8

CLINICAL PRESENTATION OF AMNIOTIC FLUID EMBOLISM

Acute cardiorespiratory collapse
Acute respiratory distress
Hypotension
Hemorrhage/coagulopathy
Seizures
Fetal distress

Etiology and Pathophysiology

- Squamous cells can appear in the pulmonary blood of heterogeneous populations of both pregnant and nonpregnant patients who have undergone pulmonary artery (PA) catheterization
 - Presence of these cells probably the result of contamination by epithelial cells derived from the cutaneous entry site of the PA catheter
 - Isolated finding of squamous cells in the pulmonary circulation of pregnant patients, with or without coexisting thrombotic pulmonary embolism, seen as a contaminant and not indicative of maternal exposure to amniotic fluid
- Amniotic fluid could act as a direct myocardial depressant
 - *In vitro* observation document that amniotic fluid decreases myometrial contractility
 - Humoral factors, including proteolytic enzymes, histamine, serotonin, prostaglandins, and leukotrienes, may contribute to the hemodynamic changes and consumptive coagulopathy associated with AFE
 - Pathophysiologic mechanism similar to distributive or anaphylactic shock

Diagnosis and Management

- AFE syndrome a diagnosis of exclusion (Table 61.9)
- Treatment is essentially supportive
 - Hemodynamic instability treated with optimization of preload by rapid volume infusion

TABLE 61.9

DIFFERENTIAL DIAGNOSIS OF AMNIOTIC FLUID EMBOLUS: EXCLUSION CRITERIA

Thrombosis
Air embolus
Septic shock
Acute myocardial infarction
Peripartum cardiomyopathy
Anaphylaxis
Aspiration
Placental abruption
Transfusion reaction
Local anesthetic toxicity

- α -receptor agonist such as phenylephrine useful to maintain adequate aortic perfusion pressure (90 mm Hg systolic) while volume is infused
- Coagulopathy treated with aggressive administration of blood component therapy
- If maternal cardiopulmonary resuscitation (CPR) must be initiated, and the fetus is sufficiently mature and is undelivered at the time of the cardiac arrest, a perimortem cesarean section should be immediately instituted.

PERIPARTUM CARDIOMYOPATHY (PPCM)

- A rare disease of unknown cause that strikes women in the childbearing years and is associated with a high mortality rate

Definition

- PPCM defined by the development of left ventricular or biventricular failure in the last month of pregnancy or within 5 months of delivery in the absence of other identifiable cause
 - In the United States can affect women of various ethnic backgrounds at any age
 - More common in women 30 years of age
 - Strong association of PPCM with gestational hypertension and twin pregnancy
 - Raise level of suspicion for this condition in pregnant women who develop symptoms of congestive heart failure

Etiology and Diagnosis

- Possible causes proposed for PPCM
 - Myocarditis
 - Abnormal immune response to pregnancy
 - Maladaptive response to the hemodynamic stresses of pregnancy
 - Stress-activated cytokines
 - Prolonged tocolysis
- Diagnosis of PPCM requires the exclusion of more common causes of cardiomyopathy
 - Confirmed by standard echocardiographic assessment of left ventricle systolic dysfunction
 - Including depressed fractional shortening and ejection fraction documentation

Treatment and Prognosis

- Initiated using standard clinical protocols for heart failure
 - Angiotensin-converting enzyme inhibitors should be avoided prenatally
- Long-term clinical prognosis is usually defined within 6 months after delivery
 - Approximately half of 27 women studied had persistent left ventricular dysfunction beyond 6 months, with a cardiac mortality rate of 85% over 5 years
- As compared with the group in whom cardiac size returned to normal by the same time interval, with no mortality
 - Identification of the underlying cause of heart failure in the pregnant patient is important factor influencing long-term survival

CHAPTER 62 ■ CARDIAC DISEASE AND HYPERTENSIVE DISORDERS IN PREGNANCY

HYPERTENSIVE DISEASE OF PREGNANCY

Diagnosis

- Hypertensive disorders of pregnancy include:
 - Chronic hypertension
 - Preeclampsia/eclampsia
 - Preeclampsia superimposed on chronic hypertension
 - Gestational hypertension
- Preeclampsia is a pregnancy-specific, multisystem disorder that is characterized by the development of hypertension and proteinuria after 20 weeks of gestation (Table 62.1)
 - Complicates approximately 5% to 7% of pregnancies

- Incidence of 23.6 cases per 1,000 deliveries in the United States
- Diagnostic criteria for preeclampsia include:
 - New onset of elevated blood pressure and proteinuria after 20 weeks of gestation
 - Severe preeclampsia indicated by more substantial blood pressure elevations and a greater degree of proteinuria
 - Other features of severe preeclampsia include oliguria, cerebral or visual disturbances, and pulmonary edema or cyanosis (Tables 62.2 through 62.4)
- Chronic hypertension defined by elevated blood pressure that predates the pregnancy
 - Is documented before 20 weeks of gestation or is present 12 weeks after delivery

TABLE 62.1**RISK FACTORS FOR PREECLAMPSIA**

Maternal	Fetal
<ul style="list-style-type: none"> • First pregnancy • New partners • Age younger than 18 y or older than 35 y • Chronic hypertension • Prior history of preeclampsia • Family history of preeclampsia • Pregestational diabetes • Obesity • Thrombophilias • Systemic erythematosus • Renal disease 	<ul style="list-style-type: none"> • Multiple gestations • Molar pregnancies (can cause preeclampsia at <20 wk gestation) • Fetal hydrops • Triploidy

- Eclampsia, a severe complication of preeclampsia, is a new onset of seizures in a woman with preeclampsia

Therapy

- Initial therapeutic goals during labor are focused on preventing seizures and controlling hypertension.
- Magnesium sulfate is the medication of choice to prevent eclamptic seizures for either preeclampsia or eclamptic seizures.
 - Shown to be superior to phenytoin (Dilantin) and diazepam (Valium) for the treatment of eclamptic seizures.

TABLE 62.2**PHYSICAL EXAMINATION OF SEVERELY PREECLAMPTIC PATIENT**

- **Funduscopy**
 - Arteriolar spasm (focal or diffuse)
 - Retinal edema
 - Retinal hemorrhages (superficial and flame shaped, or deep and punctate)
 - Retinal exudates (hard or “cotton wool”)
 - Papilledema
- **Cardiovascular**
 - Heart failure (rales, elevated jugular venous pressure, S₃) or aortic dissection
 - New or increased murmur of mitral regurgitation
 - Bruits
- **Neurologic**
 - Hypertensive encephalopathy: Disorientation
 - Depressed consciousness (Glasgow coma scale <13)
 - Focal deficits, generalized or focal seizures
- **Abdominal**
 - Palpation for liver tenderness or increase in size
- **Fetal**
 - Assessment of fetal well-being (fetal heart rate strip, biophysical profile)

- With systolic blood pressures of 160 to 180 mm Hg or higher, or diastolic blood pressures of 105 to 110 mm Hg should receive immediate antihypertensive therapy
 - Treatment goal is to lower systolic pressure to 140 to 150 mm Hg and diastolic pressure to 90 to 100 mm Hg
- Hydralazine (Apresoline) and labetalol (Normodyne, Trandate) are the antihypertensive drugs most commonly used.
- Nifedipine (Procardia) and sodium nitroprusside (Nitro-press) are potential alternatives.
 - Use is associated with significant adverse effects and risk of overdose.
 - Similarly, labetalol should not be used in women with asthma or congestive heart failure.
 - Angiotensin-converting enzyme inhibitors are also contraindicated.
 - In women with preeclampsia, blood pressure usually normalizes within a few hours after delivery but may remain elevated for 2 to 4 weeks.

Care and Management of the Hypertensive Parturient

- Some with severe preeclampsia will require admission in the intensive care setting for invasive monitoring and close supervision.
- Typical indications include:
 - Severe increase in blood pressure, with diastolic blood pressures >115 to 120 mm Hg or a systolic blood pressure >200 mm Hg refractory to initial antihypertensive therapy
 - Oliguria refractory to repeated fluid challenges
 - Eclamptic seizures
 - Respiratory insufficiency with pulmonary edema
- Initial physical examination should include a neurologic assessment, funduscopic examination, auscultation of the heart and lungs, and palpation of the abdomen (Tables 62.2 and 62.3)
- If magnesium sulphate is given, it should be continued for 24 hours following delivery or at least 24 hours after the last seizure.
 - Regular assessment of urine output, maternal reflexes, respiratory rate, and oxygen saturation is paramount while magnesium is infused.
 - Loading dose of 4 g should be given by infusion pump over 5 to 10 minutes, followed by a further infusion of 1 g/hour maintained for 24 hours after the last seizure.
 - Gradual antihypertensive therapy can be accomplished with a 25% reduction of mean arterial pressure within minutes to 2 hours, to 160/100 mm Hg (Table 62.5).

The Role of Arterial Lines, Central Venous Pressure Monitors, and Pulmonary Artery Catheters in Preeclamptic Patients

- Most severe preeclamptic patients have normal or hyperdynamic left ventricular (LV) function with normal pulmonary artery pressure.
- Central venous pressure (CVP) monitoring is usually adequate to assess volume status and LV function.

TABLE 62.3**CLINICAL FEATURES OF PREECLAMPSIA**

Symptoms	Headache	The headache that characterizes preeclampsia is typically frontal in location, throbbing in character, persistent, and not responsive to mild analgesia.
	Visual phenomena	The visual disturbances that characterize preeclampsia are presumed to be caused by cerebral vasospasm and are typically scintillations or scotomas. Longer-lasting visual field deficits and rarely transient blindness can result from edema, posterior reversible encephalopathic syndrome, and even infarction in the occipital region of the brain. Serous retinal detachments can also occur in preeclampsia and are related to retinal edema. Magnesium, which is commonly used to prevent seizures in preeclamptic women, can cause mild visual blurring or double vision but should not cause scotomas, scintillations, or visual loss.
	Epigastric pain	The epigastric or right upper quadrant discomfort that occurs in preeclampsia can be marked and may be out of proportion to the degree of liver enzyme abnormalities. It is believed to be caused by edema in the liver that stretches the hepatic capsule. In rare cases, it may be caused by hepatic infarction or rupture.
	Edema	Edema is present in more than 30% of normal pregnancies and is thus not a reliable sign of preeclampsia. Rapid weight gain (more than 1 pound per week in the third trimester) or edema in the hands or facial area (nondependent edema) is best viewed as a sign that should lead the clinician to evaluate the patient for other, more specific, evidence of preeclampsia.
Signs	Hypertension >140/90 mm Hg	Hypertension in preeclampsia is due to vasospasm and can be very labile. Ideally, blood pressure should be measured in the sitting position with a manual cuff, with the brachial artery at the level of the heart. There is a literature suggesting that some automated blood pressure cuffs may be less reliable in preeclampsia and that either a manual cuff or arterial line should be used to verify blood pressure in preeclamptic patients with severe hypertension. Although a rise in systolic/diastolic blood pressure of 30/15 mm Hg was once considered a criterion for diagnosing preeclampsia, it is now recognized that this definition lacks both sensitivity and specificity.
	Epigastric or right upper quadrant tenderness	Abdominal pain in preeclampsia is attributed to hepatic capsular stretching from edema. The degree of tenderness is often out of proportion to the degree of elevation of liver function tests. Epigastric tenderness is suggestive of severe preeclampsia and is associated with an increased risk of both maternal and fetal adverse outcomes.
	Hyperreflexia	Clonus is an important sign of preeclampsia but should be distinguished from the very brisk reflexes commonly seen in normal pregnancies.
	Retinal artery vasospasm on funduscopy	Retinal vasospasm, retinal edema (in the form of soft exudates), hemorrhage, and exudative retinal detachment are uncommon findings in preeclampsia. Papilledema is rare.

- Severely preeclamptic patients may develop cardiac failure, progressive and marked oliguria, or pulmonary edema.
- In such cases, a pulmonary artery (PA) catheter may be helpful for proper diagnosis and treatment, because right and left ventricular pressures may not correlate.
 - The rather limited literature about their use in obstetric populations is questioned.
 - No clear consensus exists as to their role in the management of preeclampsia.
 - Risks—especially on labor and delivery units where the personnel have less experience in their placement and interpretation—seem to outweigh the evidence justifying their use.
 - An urgent bedside echocardiogram may guide care.
- An arterial catheter monitor may be indicated for protracted severe hypertension during therapy with potent antihypertensive agents.
- Most patients satisfying the criteria for intensive care unit admission should be monitored with central venous access and an arterial catheter.

FETAL MONITORING IN THE INTENSIVE CARE SETTING

- Electronic fetal monitoring (EFM) is used in the management of labor and delivery in nearly three of four pregnancies in the United States.
 - Apparent contradiction between the widespread use of EFM and expert recommendations to limit its routine use indicates that a reassessment of this practice is warranted.
 - Question of whether fetal monitoring is of any substantial use in the critically ill mother or the mother undergoing surgery.
 - Continuous cardiotocography (CTG) during labor is associated with a reduction in neonatal seizures, but no significant differences in cerebral palsy, infant mortality, or other standard measures of neonatal well-being.
 - This monitoring technique was associated with an increase in cesarean sections and instrumental vaginal births.

TABLE 62.4**LABORATORY FEATURES OF PREECLAMPSIA**

Complete blood count with elevated hemoglobin and/or thrombocytopenia	<p>The “elevation of hemoglobin” seen with preeclampsia (which may manifest as a hemoglobin of 12 g/dL at 37 wk when it would be expected to be closer to 10 g/dL because of the physiologic dilutional anemia that is seen in pregnancy) is due to hemoconcentration. Much less commonly, hemoglobin may fall with preeclampsia due to a microangiopathic hemolytic anemia.</p> <p>Platelet consumption in preeclampsia can cause an increased mean platelet volume and thrombocytopenia and is an important manifestation of severe disease.</p> <p>In severe cases of preeclampsia or HELLP (a subset of preeclampsia), schistocytes (fragmented red cells) may be seen on peripheral smear and can lead to a mild drop in hemoglobin. Brisk hemolysis is rare, however, and should lead to the consideration of HUS or TTP.</p>
Elevated serum creatinine	<p>Typically serum creatinine is <0.8 mg/dL (70 μmol/L) in pregnancy and values greater than this are considered abnormal.</p> <p>Renal function impairment is caused by decreased renal blood flow and glomerular filtration rate secondary to swelling of intracapillary glomerular cells, fibrin deposition along the basement membranes, and afferent arteriolar spasm.</p>
Elevated serum uric acid	<p>Typically, serum uric acid is <5.0 mg/dL (280 μmol/L) in pregnancy. Uric acid is the most sensitive test for identifying preeclampsia, but it is still only elevated in approximately 80% of preeclampsia cases. Uric acid rises in this setting due to impaired excretion of uric acid in the renal tubules that is caused by preeclampsia-related changes in the renal microcirculation. Although an important sign of preeclampsia, the elevated uric acid level is distinct from an elevated creatinine, AST, or decreased platelet count in that the uric acid level is not generally believed to have any direct clinical consequences and should not be used as a marker of disease severity.</p>
Elevated liver enzymes	<p>Mild elevations of AST, typically <100 U/L, suggest hepatic involvement. Greater levels may be due to severe preeclampsia, HELLP syndrome, hepatic infarction, hepatic rupture, or superimposed acute fatty liver of pregnancy.</p>
Proteinuria	<p>Proteinuria is an essential diagnostic feature of preeclampsia. Urine dipsticks are routinely used to screen for proteinuria in asymptomatic patients. However, dipsticks lack the needed sensitivity and specificity to make them a reliable test for proteinuria in patients in whom the diagnosis of preeclampsia is suspected because of the presence of other features of this disease. When preeclampsia is suspected, a 24-hour urine test for proteinuria with creatinine and creatinine clearance should be obtained. Proteinuria is present if there is more than 300 mg of protein excreted over 24 hours. Total urinary creatinine should be measured to assess the adequacy of urine collection. The creatinine clearance can be used in conjunction with the serum creatinine as a measure of renal function.</p> <p>The use of a random spot urinary protein-to-creatinine ratio to diagnose proteinuria in pregnancy has had many advocates, but it remains unclear at this time whether this test can replace the 24-hour urine in pregnant patients with suspected preeclampsia.</p>
DIC screen	<p>Severe preeclampsia can rarely cause DIC, but it is almost always seen in association with thrombocytopenia. Checking INR, PTT, and fibrinogen degradation products is usually only done if the patient with preeclampsia has thrombocytopenia or is undergoing an invasive procedure.</p>

AST, aspartate aminotransferase; DIC, dissemination intravascular coagulation; HUS, hemolytic uremic syndrome; INR, international normalized ratio; PTT, partial thromboplastin time; TTP, thrombotic thrombocytopenic purpura.

TABLE 62.5**ANTIHYPERTENSIVE THERAPY IN PREECLAMPSIA**

- **Labetalol (Normodyne, Trandate)**
IV bolus, 20–40 mg IV. May repeat in 10 min. Usual effective dose is 50–200 mg, or continuous infusion of 2 mg/min (this regimen avoids reflex tachycardia).
- **Nitroglycerin**
Start at 10 μ g/min (6 mL/h). Titrate by 10–20 μ g/min to 400 μ g/min until desired effect.
- **Hydralazine (Apresoline)**
Initial dose: 5 mg IV. Maintenance: 5–10 mg IV every 20–30 min.
- **Other Antihypertensive Options**
Nicardipine, nitroprusside, phentolamine, fenoldopam, diazoxide

- When considering the use of EFM, the intensivist should consider the effects of many sedative, hypnotic, or analgesic drugs routinely used in the critical care setting on fetal heart rate variability.
- No systematic studies have been performed concerning the value of CTG during general anesthesia for nonobstetric surgery.
- It is assumed that uneventful sedation and analgesia provide adequate oxygenation and circulatory stability without having any influence on the fetus.

PULMONARY EDEMA IN PREGNANCY

- Pulmonary edema is a rare but well-documented complication of tocolytic therapy in pregnant women.
- Incidence of pulmonary edema related to β -mimetic tocolysis is estimated to be 0.15%.

- Etiology of the pulmonary edema is unclear, but is likely multifactorial.
- Both cardiogenic and noncardiogenic mechanisms have been proposed.
- Possible cardiogenic causes include:
 - Fluid overload
 - Catecholamine-related myocardial necrosis
 - Cardiac failure secondary to reduced diastolic compliance
 - Down-regulation of β -receptors

Treatment

- Immediate recognition and appropriate therapy can ameliorate the course of respiratory insufficiency in patients who develop pulmonary edema during tocolytic treatment.
- Therapy involves discontinuing the medication, ensuring adequate ventilation and oxygenation, correcting fluid imbalance and hypotension, and maintaining adequate cardiac output.
- Continuous assessment of the fetus' well-being is necessary.

Tocolytic Therapy

- The development of pulmonary edema during the course of β -adrenergic agonist treatment for preterm labor is an indication for discontinuing the treatment.
- Either switching to a different type of labor-inhibiting drug or terminating all efforts to prevent preterm delivery
- Magnesium sulfate, calcium channel blockers, or oxytocin antagonists are the most frequently used alternatives.

Ventilatory Support

- Mechanical ventilation principles are not different for the pregnant patient and are being standardized by evidence-based medicine and consensus conferences.

Fetal Considerations

- Fetal well-being must be interpreted within the context of maternal respiratory failure.
- Minimally, intermittent fetal monitoring is indicated.
- If refractory maternal hypoxemia and acidosis presents, and results in fetal distress, cesarean delivery to salvage the fetus should be considered.

CARDIAC DISEASE

Who is Most at Risk, and When is That Risk Greatest?

- Table 62.6 classifies the risk of various cardiac lesions in pregnancy.
- “Risk” for these patients refers to congestive heart failure, arrhythmias, stroke, and death.
 - About 13% of cardiac patients will suffer one of these outcomes in pregnancy.
 - The presence of pulmonary hypertension (PHTN) is always associated with increased risk.
 - Risk is commensurate to degree of severity of PHTN.
 - Other factors associated with an increased risk of cardiac complications in pregnancy include the following:

- **New York Heart Association (NYHA) functional class:** Perhaps most important predictor of pregnancy outcome
 - NYHA class I and II cardiac disease generally have a good prognosis during pregnancy.
 - NYHA class III and IV more likely to experience complications and may require special management at time of delivery.
- **Left-sided obstructive cardiac lesions:** Lesions such as aortic stenosis may result in difficulty accommodating the increased blood volume and cardiac output seen in pregnancy, and become increasingly symptomatic.
 - Regurgitant valvular lesions result in less difficulty in pregnancy.
 - Cardiac output (CO) in these cases may benefit from the decrease in systemic vascular resistance seen in pregnancy
- **Cyanosis**
- **LV systolic dysfunction**
- **Prior cardiac events or previous arrhythmia**

- Although pregnant women with cardiac disease may experience complications at any point during pregnancy, there are three periods of particular risk:
 - At the end of the second trimester when CO is increased to its peak
 - At time of labor and delivery when cardiac work may be increased dramatically by both pain and the autotransfusion of blood from the placenta and uterus with each contraction
 - During the first 72 hours following delivery when the uterine involution and resolution of pregnancy-related edema leads to mobilization of large amounts of fluid

General Management of Cardiac Patients during Pregnancy

- Management includes good preconception counseling to assess and inform the patient of the risks associated with a pregnancy.
 - No woman should be told that she “should never get pregnant.”
 - But a clear discussion of the risk is essential
 - With severe PHTN or Eisenmenger syndrome, patient should be strongly cautioned against pursuing a pregnancy.
 - Women with congenital heart disease (CHD) need to be informed that they are at increased risk of giving birth to a child with CHD.
- If she decides to pursue pregnancy after a clear discussion of risk:
 - Cardiac status must be clearly delineated and optimized.
 - Necessary investigations or interventions should be carried out prior to conception.
 - Regular visits with a medical specialist and an obstetrician trained in the care of high-risk pregnancies to watch for evidence of heart failure and arrhythmias are essential.
 - Consultation with an obstetric anesthesiologist prior to delivery is also prudent.
- Most cardiac medications can be used in pregnancy when indicated (Table 62.7).
- Angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and warfarin are known or strongly suspected to be human teratogens.

TABLE 62.6
PERIPARTUM RISK OF VARIOUS CARDIAC LESIONS

Risk category	Lesion
Lower-risk lesion	Mitral valve prolapse Mitral valve prolapse with regurgitation Atrial septal defect Ventricular septal defect with normal pulmonary pressures Trace to mild valvular regurgitation NYHA class I History of SVT with recent good control Pacer
Intermediate-risk lesion	Stable ischemic heart disease Mild to moderate pulmonary hypertension Moderate to severe valvular insufficiency NYHA class II Cardiomyopathy with ejection fraction 30%–50% Poorly controlled SVT
High-risk lesion	Unstable ischemic heart disease Moderate to severe left ventricular obstruction (e.g., aortic <1.5 cm ² or mitral valvular stenosis <2 cm ² , peak gradient IV outflow tract of >30 mm Hg) NYHA class III Cardiomyopathy with ejection fraction <30% Dilated aortic root/Marfan/Ehlers-Danlos Moderate pulmonary hypertension History of ventricular tachycardia with or without AICD Mechanical prosthetic heart valve History of TIA or CVA
Highest-risk lesion	Pulmonary hypertension >80 mm Hg Eisenmenger syndrome NYHA class IV Cyanosis

AICD, automated implantable cardioverter-defibrillator; CVA, cerebrovascular accident; NYHA, New York Heart Association; SVT, supraventricular tachycardia; TIA, transient ischemic attack.
 Items above can be used to calculate a risk index with 1 point being assigned for each and 0, 1, and >1 points being associated with a risk of some cardiac event during the entire pregnancy of 5%, 27%, and 75%, respectively. (Risk calculation adapted from Siu S, Sermer M, Colman JM, et al. Prospective multicenter study of pregnancy outcomes in women with heart disease. *Circulation*. 2001;104:515).

- Angiotensin-converting enzyme inhibitors/angiotensin receptor blockers: fetal anomalies, fetal loss, oligohydramnios, cranial ossification abnormalities, and neonatal renal failure
- Should not be used at any time in gestation
- Warfarin associated with a high risk of miscarriage and anomalies of the eyes, hands, neck, and central nervous system
- Amiodarone has had mixed data with respect to its safety in pregnancy, with some reports of congenital hypothyroidism, goiter, prematurity, hypotonia, and bradycardia.
- Studies
 - Ultrasound has a long history of safe use in pregnancy.
 - Radiation exposure associated with plain film radiographs, nuclear medicine scans, angiography, and computed tomography scans are all well below what is deemed acceptable during pregnancy.
 - Contrast agents appear to be well tolerated by the fetus.
 - Magnetic resonance imaging has not been associated with any ill effects in human pregnancies.
 - Fetal well-being is dependent on maternal well-being; more harm will generally be caused to a mother and

her fetus by withholding necessary investigations than by obtaining them.

- Mode of delivery should not generally be determined by medical concerns.
 - Need for cesarean deliveries is generally dictated by obstetric concerns.
 - Vaginal deliveries are generally viewed as the safest and best option for cardiac patients.
 - Keep neutral fluid balance over the course of their delivery period.
- Monitors
 - Intra-arterial lines are advisable for cardiac lesions for which moment-to-moment monitoring of blood pressure might be desirable, such as severe aortic stenosis.
 - Pulmonary artery catheter in the laboring patient remains unclear.
- Bacterial endocarditis prophylaxis is no longer recommended by the American Heart Association for vaginal or cesarean deliveries.
- Organisms associated with delivery unlikely to cause endocarditis.

TABLE 62.7

COMMONLY USED CARDIAC MEDICATIONS AND THEIR SAFETY IN PREGNANCY

	Use generally justifiable for this indication in pregnancy	Use justifiable in special circumstances for this indication in pregnancy	Use almost never justifiable for this indication in pregnancy
Arrhythmia	Digoxin β -Blockers (all probably safe but most avoid propranolol and atenolol, which may cause intrauterine growth restriction) Calcium channel blockers, especially verapamil and diltiazem (less known about amlodipine) Adenosine Quinidine Procainamide Lidocaine	Amiodarone Disopyramide, mexiletine, and flecainide (less is known about these agents in pregnancy but there is no evidence at this point of human teratogenesis; they should generally be considered second-line agents in pregnancy)	
Ischemia	Nitrates Low-dose (<100 mg) ASA β -Blockers Heparin (unfractionated or low molecular weight) Tissue plasminogen activator Streptokinase	HMG-coA reductase inhibitors ("statins") have concerning animal pregnancy data, but very limited reported human experiences thus far have been encouraging; should only be used in pregnancy when short-term benefits are clear Abciximab (and other glycoprotein IIb/IIIa inhibitors) dipyridamole, ticlopidine, and clopidogrel lack published human data; they are probably safe but should only be used in pregnancy when short-term benefits are clear	Warfarin
Heart failure	Furosemide Digoxin Hydralazine β -Blockers Dopamine Dobutamine	Nitroprusside (fetal cyanide toxicity possible at high doses)	ACE inhibitors Angiotensin II receptor blockers
Hypertension	Labetalol β -Blockers Nifedipine Hydralazine Methyldopa	Thiazide diuretics (in this category for the treatment of hypertension because of effects of blood volume in pregnancy) Clonidine, prazosin, verapamil, diltiazem, and amlodipine (in this category for the treatment of hypertension because of limited data on safety and the availability of many good alternatives with more data) Nitroprusside (fetal cyanide toxicity possible at high doses)	ACE inhibitors Angiotensin II receptor blockers

ASA, acetylsalicylic acid; ACE, angiotensin-converting enzyme.

Specific Lesions

Mitral Stenosis

- Rheumatic heart disease a common form of heart disease in pregnancy despite its declining incidence in the developed world.
- Mitral stenosis accounts for approximately 90% of the rheumatic valvular lesions in pregnancy.
- Often presents for the first time in pregnancy
- Risk factors include atrial fibrillation, pulmonary edema, and thromboembolic stroke.

- Most patients will experience some worsening of symptoms during pregnancy.
- Avoidance of tachycardia, increased PA pressure, decreased systemic vascular resistance, and increased central blood volume are essential to patient management.
- Many patients will benefit from β -blockade to improve filling time during pregnancy.
- Echocardiograms in these patients should be done once every trimester and with any change in status in these patients.

- Pulmonary edema should be treated with diuretics and β -blockade.
- Atrial fibrillation should be treated promptly to decrease tachycardia and the associated risk of a low cardiac output state or degeneration into more malignant dysrhythmias.
 - Rate control, full anticoagulation with heparin, and consideration of either medical or electrical cardioversion remain the core management principles.
- For labor, vaginal delivery or cesarean, excellent pain control is important and is best achieved with early establishment of regional anesthesia.

Aortic Stenosis

- Aortic stenosis (AS) is a valvular lesion rarely seen during pregnancy
 - Can be of rheumatic or congenital origin
 - Mild to moderate AS generally well tolerated in pregnancy.
 - Severe AS (defined as $<1.0 \text{ cm}^2$) carries a significant fetal and maternal risk.
 - Rate of complication varies from 10% to 31%.
 - Symptomatic aortic stenosis should be repaired prior to pregnancy
- Monitoring
 - Arterial lines are strongly advised.
 - PAC, while not proven, may be of benefit.
 - With severe AS, regional anesthesia has been avoided because of the resulting local anesthetic-induced sympathectomy, which can lead to bradycardia and decreased venous return.
 - Good results have been obtained in patients with severe AS managed during labor with a carefully titrated epidural anesthetic.

Mitral and Aortic Insufficiency

- Mitral insufficiency is the second most common valvular lesion seen in pregnancy.
 - Typically due to rheumatic heart disease
- Aortic insufficiency is less common.
 - May be due to rheumatic, infectious, or rheumatologic conditions
- When found in isolation, these lesions do well in pregnancy unless there is associated ventricular decompensation.
 - Treatments when symptomatic include diuretics, digoxin, or calcium channel blockers.
 - Angiotensin receptor blockers should not be used despite the benefits of afterload reduction.
 - Increases in systemic vascular resistance, decreased heart rate, atrial arrhythmias, and myocardial depressants may be poorly tolerated.
 - Most important peripartum issue for these patients is early regional anesthesia to prevent pain-associated increases in systemic vascular resistance.

Congenital Heart Disease

- Approximately 25% of heart disease in pregnancy is congenital.
- Categorized as left-to-right shunt, right-to-left shunt, and aortic lesions.
 - Left-to-right Shunt

- Most common CHD lesions are atrial septal defects (ASDs) and ventricular septal defects (VSDs), usually well tolerated in pregnancy.
- Risk of cardiac complications greatest in large defects.
 - CHF (due to increased blood volume in pregnancy leading to cardiac decompensation), atrial arrhythmias, shunt reversal (occurring due to sudden systemic hypotension), and thromboembolic disease are all possible complications seen with ASD and VSD in pregnancy.
- When symptomatic septal defects present in pregnancy principles of management include:
 - Acetylsalicylic acid (ASA) 81 mg daily to prevent thromboembolism
 - Diuretics and digoxin to treat heart failure
 - Avoidance of hypotension with epidural administration or postpartum blood loss
 - Rapid rate control with any arrhythmia
- Right-to-left Shunt and Pulmonary Hypertension
 - High-risk congenital disorders in pregnancy include right-to-left shunts.
 - Eisenmenger syndrome (any congenital heart lesion with a bidirectional or right-to-left shunt at the atrial, ventricular, or aortic level)
 - Any other lesions associated with significant PHTN
 - Women with uncorrected cyanotic heart disease have increased spontaneous abortion rates, pulmonary embolization, congestive heart failure, and CHDs in the fetus
 - High hematocrit ($\geq 65\%$) not only an indication of the severity of the cardiac disease
 - Has a poorer prognosis secondary to complications from hyperviscosity (decreased cardiac output, organ hypoperfusion, and thrombosis)
 - With Eisenmenger syndrome, reveals maternal mortality rates of 25% to 52%
 - Fetal loss as high as 44%
 - If they continue with the pregnancy, they may warrant hospitalization from 20 weeks onward.
 - Oxygen should be administered for dyspnea, and prophylactic heparin should be considered throughout pregnancy and for 6 weeks postpartum.
 - Mode of delivery should be determined on the basis of obstetric indications.
 - PAC can carry additional risks in patients with significant PHTN.
 - Should probably be avoided in these patients
 - Active efforts should be made to avoid sudden decreases in systemic vascular resistance, blood volume, and venous return. Increased pulmonary vascular resistance promotes right-to-left shunting.
 - Hypercapnia and hypoxia are to be avoided.
 - Best peripartum anesthesia not clear.
 - If regional anesthesia is used, care must be taken to prevent precipitous drops in venous return.
 - With PHTN and/or Eisenmenger syndrome, observe patients for 72 hours postpartum in a cardiac setting.
 - Many maternal deaths associated with these conditions occur during this period.

Aortic Disease

- Coarctation of the aorta and aortic manifestations of Marfan syndrome pose significant problems in pregnancy.

- Physiologic changes during pregnancy may promote aortic dissection in either of these conditions.
- Patients with coarctation of the aorta may also suffer from worsening hypertension or congestive heart failure in pregnancy.
- Marfan syndrome is often associated with aortic dilation, aortic valve regurgitation, and mitral valve disease.
 - Aortic dissection occurs in about 10% of patients with Marfan syndrome who become pregnant.
 - Most likely to occur if the aortic root measures beyond 4.5 cm in diameter
 - Ideally, the aorta is repaired prior to pregnancy.
 - Otherwise, serial echocardiography during pregnancy to watch for worsening dilation
 - Activity of patients with significant aortic dilation in pregnancy should be limited.
 - Patients should be prescribed β -blockers to decrease shear stresses on the vessel wall.
 - It is common practice for women with aortic roots dilated beyond 4.0 cm to deliver by cesarean to avoid additional stressors on the aorta associated with the pain and pushing of a vaginal delivery
 - The majority of dissections in these patients occur prior to labor's onset.
- Aortic coarctation in pregnancy associated with
 - Increased risk of worsening hypertension
 - Less commonly, congestive heart failure or preeclampsia
 - Much less likely to be associated with aortic dissection than Marfan syndrome
 - However, dissection can and does occur.
 - Keep blood pressure <160/100 mm Hg but not below 120/70 mm Hg
 - There may be a significant gradient between blood pressure measurement in the arm and the estimated blood pressure of the placenta circulation that is distal to the aortic narrowing.
 - β -blockers are the preferred antihypertensives.
 - Can undergo a vaginal delivery but should have a limited second stage (i.e., prolonged pushing should be avoided by the use of vacuum extractor or forceps)

Tetralogy of Fallot

- The most common cyanotic congenital heart disease
 - Consists of
 - Ventricular septal defect
 - Overriding aorta
 - Infundibular pulmonary stenosis
 - Secondary right ventricular hypertrophy
 - Uncorrected patients have significant complications in pregnancy.
 - Biventricular failure
 - Arrhythmias
 - Stroke
 - Risk of shunt reversal with worsening cyanosis
 - Preconception surgical repair should be undertaken if at all possible.
 - Those who proceed with a pregnancy unrepaired should be managed like patients with Eisenmenger syndrome.
 - Patients who have had surgical repair and have a good functional status generally tolerate pregnancy well.

- Main risks are right-sided heart failure and arrhythmias.
 - Volume status should be watched throughout pregnancy.
 - Complaints of palpitations or syncope are investigated with an event monitor.
 - Delivery should include cardiac monitoring.

Other Repaired Congenital Heart Conditions

- An increasing number of women with congenital heart problems that were repaired in childhood are reaching adulthood and undergoing pregnancy.
 - Generally, course in pregnancy is predictable by the parameters outlined earlier.
 - The majority have a good pregnancy outcome for both themselves and their infants if they enter the pregnancy with a good functional status.

Peripartum Cardiomyopathy (PPCM)

- Defined by National Heart, Lung, and Blood Institute as the new onset of systolic dysfunction occurring in the absence of other plausible causes anytime between the final month of pregnancy up to 5 months postpartum
 - Incidence between 1 in 3,000 and 1 in 15,000 pregnancies
 - May be increasing
 - Most commonly found in
 - Women who have twins
 - Women who have preeclampsia/eclampsia
 - Older multiparous women
 - Not clear if race is an independent risk factor for PPCM
 - Clear that African American women are more likely to die of PPCM than Caucasian women when it does occur
 - Generally, one-third of these patients have complete resolution in the year following delivery.
 - One-third are left with residual cardiac dysfunction.
 - One-third have progressive cardiac decompensation.
 - Mortality rate is between 9% and 56%.
 - Highest in patient subset with persistent cardiomegaly beyond 6 months
 - May be due to end-stage heart failure, arrhythmia, or thromboembolism
 - Pathologic findings include
 - Four-chamber enlargement with normal coronary arteries and valves
 - Light microscopic findings include myocardial hypertrophy and fibrosis with scattered mononuclear infiltrates.
 - Clinical signs include symptoms of ventricular failure with possible associated arrhythmias and/or pulmonary emboli.
 - Treatment
 - Bed rest
 - Sodium restriction
 - Diuresis
 - Preload/afterload reduction with a calcium channel blocker and hydralazine while pregnant and an angiotensin-converting enzyme inhibitor postpartum.
 - With ejection fraction <35%, consider anticoagulation with low-molecular-weight heparin while pregnant, and warfarin postpartum.
 - Antidysrhythmics should be utilized in a manner similar to what would be done for any patient with an idiopathic cardiomyopathy.
 - Evidence that peripartum cardiomyopathy may recur or worsen with subsequent pregnancies.

Hypertrophic Cardiomyopathy

- During pregnancy, course of hypertrophic cardiomyopathy (HCM) variable:
 - While the normal increase of blood volume is beneficial, the decrease in systemic vascular resistance and the increase in heart rate may be detrimental.
 - Complications are not common but include
 - Congestive heart failure
 - Chest pain
 - Supraventricular tachycardias, ventricular tachycardia, and sudden death
 - Can occur at any point in pregnancy or labor as a result of stress, pain, and increased circulating catecholamines
 - Immediate postpartum period can increase risk due to blood loss and decrease in systemic vascular resistance
 - Atrial fibrillation and supraventricular tachycardias are a common feature of this cardiac anomaly.
 - Cardioselective β -blockers and verapamil are usually administered.
 - Tocolytics, sympathomimetic agents, and digoxin should be avoided in these patients, as they may increase the risk of arrhythmia.
 - Peripartum period should include cardiac monitoring and use of forceps or vacuum extractor to minimize pushing.
 - Regional anesthesia should be done incrementally.
 - With agents that minimize the risk of a sudden drop in preload

Ischemic Heart Disease in Pregnancy

- Myocardial infarction (MI) in pregnancy is uncommon.
 - Incidence estimated to be between 1 in 10,000 and 1 in 35,700
 - Does appear to be increasing
- Risk factors include
 - Advancing age
 - Preeclampsia
 - Multiparity
 - Chronic hypertension
 - Diabetes
- MI associated with pregnancy occurs at any time during gestation.
 - 38% occurred antepartum
 - 21% intrapartum
 - 41% in the first 6 weeks postpartum
 - Maternal mortality rate ranges from 7% to 35%.
 - Disproportionate number of deaths occurring among the antenatal cases
 - A large portion of pregnancy-associated MI not due to atherosclerotic heart disease but to coronary artery *in situ* thrombus formation, dissection, or spasm.
- Diagnosis of ischemic heart disease in pregnancy
 - Requires considering it as part of the differential diagnosis
 - Even in absence of traditional risk factors
 - Creatine phosphokinase (CPK) and creatine kinase-MB (CK-MB) can be mildly elevated following a cesarean delivery.
 - Troponin is a more specific marker of cardiac disease in the peripartum period.

- Stress testing can be safely carried out in pregnancy, including nuclear imaging.
 - Diagnostic coronary angiography is performed on pregnant women for the same indications as for nonpregnant patients.
- Treatment of coronary artery disease is largely unchanged in pregnancy.
 - None of the medications commonly used to treat ischemic heart disease have been shown to cause adverse effects in the fetus.
 - Broad experience with low-dose aspirin, nitrates, β -blockers, and heparins in pregnancy
 - Paucity of data regarding use of clopidogrel and glycoprotein IIb/IIIa inhibitors limit their use in pregnancy.
 - Coronary angiography, angioplasty and stenting, and thrombolysis have been and can be carried out safely throughout pregnancy.
 - Management of laboring patients with ischemic heart disease is the same as for other cardiac patients and has strong parallels with the management of the cardiac patient undergoing general surgery.

Cardiac Arrhythmias in Pregnancy

- Arrhythmias appear to be more common than in the non-pregnant population.
 - Hormonal changes, stress, and anxiety are contributing factors.
 - Most arrhythmias are not serious unless associated with organic heart disease.
- **Atrial fibrillation** occurring in pregnancy is usually associated with an underlying disease such as mitral stenosis, peripartum cardiomyopathy, hypertensive heart disease, thyroid disease, or atrial septal defects.
 - With acute atrial fibrillation and hemodynamic changes
 - Direct current cardioversion
 - Cardioversion appears to have no adverse effects on fetus
 - Most require medical management with rate-controlling or rhythm-restoring antidysrhythmics.
 - β -Adrenergic blockers—metoprolol
 - Calcium channel blockers—diltiazem or verapamil
 - Agents such as procainamide or digoxin
 - All safe during pregnancy
 - Amiodarone is not a first-line agent for hemodynamically stable atrial fibrillation.
 - Possible effects on the fetal thyroid
 - Use in pregnancy not absolutely contraindicated.
 - Anticoagulation for atrial fibrillation has same indications as in nonpregnant patients.
 - Must use heparin (usually in the form of subcutaneous low-molecular-weight heparin).
 - Warfarin is associated with adverse fetal effects throughout gestation.
- **Supraventricular tachycardia (SVT):** SVTs during pregnancy can occur with or without organic heart disease.
 - Four percent of women with SVT report that the condition was first identified during pregnancy.
 - Up to 22% state pregnancy exacerbated the condition.
 - Absent underlying cardiac disease, not usually associated with increased morbidity

- With underlying structural cardiac disease or cardiomyopathy, SVT can lead to heart failure and death.
- Treatment protocols for supraventricular tachycardia remain unchanged in pregnancy and include carotid sinus massage, adenosine, calcium channel blockers, β -blockers, and direct current cardioversion.
- **Ventricular arrhythmias:** During pregnancy, these may be associated with cocaine use, peripartum or any other form of cardiomyopathy, ischemic heart disease, and digitalis toxicity.
- Antiarrhythmic agents for which we have the most pregnancy data are lidocaine, β -blockers, and procainamide,
 - Amiodarone is associated with increased risk of fetal thyroid disease.
 - Should not be considered a first-line agent
 - Implantable defibrillators can and should be used when indicated in pregnancy.
- **Bradycardia:** Bradyarrhythmias during pregnancy are rare.
 - May result from
 - Lyme disease
 - Hypothyroidism
 - Myocarditis
 - Drug-induced congenital or acquired heart blocks
 - Permanent pacemakers are indicated for hemodynamically significant bradycardia.
 - With pre-existing pacemakers
 - May need to increase baseline rate to mimic normal physiologic changes of pregnancy
- **Antiarrhythmic Drugs:**
 - Table 7 classifies the commonly used antiarrhythmic agents on the basis of what is known about their safety in pregnancy.
 - Treatment should never be withheld from a pregnant woman based on theoretic fears of fetal harm.

Cardiac Surgery during Pregnancy

- Nonurgent cardiac surgery should take place during second trimester.
- Deferring until after first trimester avoids period of organogenesis and risk of miscarriage.
- Third-trimester surgery carries risk of precipitating preterm labor.
 - Surgery that is important to a patient's short-term well-being and survival should be done at any point.
- Coronary artery bypass grafts, valvuloplasties, valvular replacements, and aortic root replacements have all been done in pregnancy with good outcomes for both mother and baby.
- When medical management can ameliorate the disease process, surgery may be postponed.
 - Until at least 4 to 6 weeks postpartum
 - Decisions should be based on the best plan of action for the mother's safety rather than a cultural discomfort related to performing surgery in pregnancy.
- Special intraoperative considerations in pregnant patients include:
 - Fetal monitoring during and after surgery
 - Maintenance of high flow and systemic mean arterial pressure (during cardiopulmonary bypass)

- Uterine displacement devices if patient in supine position for median sternotomy
- Pregnant women fare well with open-heart procedures; fetal mortality rate can be high.
 - Better results seen in closed-heart procedures.
 - Postoperatively, fetal monitoring should be continued and maternal analgesia maintained to avoid precipitating labor from accelerated postoperative pain.

Pregnancy after Prosthetic Valve Surgery

- Mechanical heart valve prostheses pose significant risk during pregnancy.
 - Secondary to coagulation status
- Fewer maternal and fetal complications occur with bioprosthetic valves.
 - Need for reoperation on these valves for degenerative changes means not commonly used in reproductive women
- Typically low-molecular-weight heparin (LMWH)
 - Anticoagulant agent of choice during pregnancy
 - Molecular weight prevents placental crossover.
 - Not teratogenic
 - Anticoagulant of choice in pregnancy except for mechanical heart valves
 - Unclear whether LMWH provides same level of protection against mechanical valve thrombosis as warfarin.
 - Warfarin and its derivatives are associated with increased risk of CNS anomalies and warfarin embryopathy.
 - Risk may be worth taking to prevent the catastrophic consequences of valve thrombosis.
 - Can use LMWH during the period of organogenesis; switch to warfarin for the majority of the pregnancy and then switch back to LMWH close to term to avoid both fetal and maternal bleeding associated with delivery.
 - Conversely, can use LMWH with frequent anti-Xa levels.

Cardiac Transplant Patients

- Increasing number and survival of heart transplant recipients
 - Increasing numbers of women recipients have become pregnant.
 - Pregnancy experience with solid tissue transplants has a 25% risk of maternal complications.
 - 44% to 50% of these complications are hypertension.
 - 29% risk of miscarriage
 - 41% risk of prematurity
 - 22% risk of rejection
 - 13% risk of worsening renal function
 - Women who have undergone cardiac transplantation are encouraged to wait 2 years after transplantation before becoming pregnant.
 - Drugs used to prevent rejection should be continued during pregnancy.
 - Evidence of their safety is accumulating.
- Peripartum management should be dictated by the quality of LV function

Cardiopulmonary Resuscitation in Pregnancy

- Cardiopulmonary resuscitation (CPR) in pregnancy poses unique problems.
 - Third trimester and particularly near term, the gravid uterus impairs venous return.
 - During CPR, the uterus should be displaced (i.e., left uterine tilt).
 - If defibrillation is required, the left breast needs to be displaced because of marked enlargement during pregnancy.
 - Unlikely but theoretical possibility of electrical arcing between a defibrillator and fetal monitoring devices.
 - Devices should be removed prior to defibrillation.
 - Otherwise, ACLS protocols, including medications and the use of the defibrillator, should be followed as done in non-pregnant woman.
 - Data about the risk and benefits of an emergency cesarean delivery in the context of maternal resuscitation are very limited.
 - If fetus has reached more than about 24 weeks gestation
 - Emergency cesarean should be considered a part of the resuscitative efforts.
 - Evacuation of the gravid uterus may improve efficacy of chest compressions and improve the outcome for both mother and baby.
 - Present recommendations are
 - Consideration of cesarean delivery in pregnant women more than 24 weeks gestation
 - In cardiac arrest and failed to respond to 5 minutes of aggressive and appropriate resuscitative efforts
 - Major causes of maternal cardiac arrest are:
 - Trauma
 - Cardiac arrest
 - Embolism
 - Other causes are:
 - Sepsis
 - Magnesium overdose
 - Complications of eclampsia
 - Result of an unanticipated difficult intubation
- General treatment of the pregnant patient in cardiac arrest is no different than any other patient, including drug dosages and defibrillation settings.
 - Chest compressions and ventilations should be performed with the recommended sequence.
 - Slight left tilt of the pregnant patient during CPR enhances venous return after 24 weeks of gestation.
 - Because of the reduced pulmonary reserve, pregnant women do not tolerate hypoxia well.
 - IV fluid should be running wide open on pressure bags, and blood products should be considered if hemorrhage is suspected.
 - Once the age of the fetus is determined, a decision can be made whether to proceed with a perimortem cesarean section.
 - Fetus can tolerate hypoxia longer than normal, but the decision to proceed with a cesarean delivery should be made within 4 minutes.
 - Management of the airway in the obstetric patient may be especially challenging.
 - Main mechanisms for airway problems are inadequate ventilation, esophageal intubation, and difficult intubation.
 - Unanticipated difficult airway may require alternative airway management attempts including the laryngeal mask airway or the Combitube.
 - If cricothyrotomy becomes necessary, this maneuver should be initiated in a timely fashion to minimize the chance of maternal hypoxic brain damage.

CHAPTER 63 ■ HEMORRHAGIC AND LIVER DISORDERS OF PREGNANCY

MAJOR PROBLEMS

- Maternal mortality
 - Defined as deaths occurring during pregnancy or within 6 weeks postpartum
 - Cause of death identified as complications related to pregnancy, delivery, or the puerperium (ICD-9 codes 630–676)
 - Decreased significantly over the past century
 - From 850 deaths in 1900 to 7.5 deaths per 100,000 in 1982
 - Rate has remained stable between 1982 and 1996
- Hemorrhage and hypertensive disorders the major contributors to maternal death rates
 - Hemorrhagic disorders can become life threatening quickly

HEMORRHAGIC CONCERNS

- Significant bleeding in pregnancy can be quantified by total amount
 - Postpartum hemorrhage is established when:

- Greater than 500 mL for vaginal deliveries
- More than 1 L for cesarean deliveries
- Clinical symptoms and signs with respect to the blood loss are considered in the management

PLACENTAL COMPLICATIONS

Placental Abruption

- Placental abruption (abruptio placentae):
 - Condition in which placenta separates from implantation site of uterus prior to delivery of fetus
 - Area of hemorrhage along the decidua basalis expands as the bleeding progresses
 - Hematoma may be concealed or present clinically with vaginal bleeding
 - Underlying mechanism may be related to:
 - Vascular damage caused by pre-eclampsia
 - Trauma
 - Cocaine/alcohol use
 - Chorioamnionitis
 - Risk factors for abruption include:
 - Maternal or paternal (second-hand) smoking
 - Multiparity
 - Prior cesarean delivery
 - African American ethnicity
 - Incidence ranges between 0.4% and 0.8%
 - A 15% recurrence rate for a subsequent pregnancy
 - A 20% recurrence rate for two previous episodes
- Classic clinical manifestations include:
 - Vaginal bleeding
 - Abdominal pain/uterine irritability
 - Fetal heart rate abnormalities or fetal distress
 - None or all of these symptoms may be present
 - Ultrasound has limited usefulness as it reveals a retroplacental blood clot in only 15% of cases, thus giving a high false-negative rate
- Treatment:
 - Fluid resuscitation
 - Adequate oxygenation
 - Close fetal monitoring
 - Critical to anticipate additional postpartum complications, such as uterine atony, to limit further hemorrhage

Placenta Previa

- Occurs with improper implantation of the placenta such that it overlies the internal os of the cervix during the third trimester
- Incidence of placenta previa approximately 0.5%
- Risk factors include:
 - Prior placenta previa
 - History of cesarean delivery
 - History of suction curettage
 - Maternal age older than 35 years
 - African American or nonwhite ethnicity
 - Cigarette smoking
- Clinical symptoms include:
 - Painless vaginal bleeding beginning in the second or third trimester

- Ultrasound then performed to confirm or rule out the diagnosis
- Management expectant unless maternal bleeding or fetal heart rate abnormalities/fetal distress necessitates imminent delivery via cesarean section
- If the patient is stable—meaning no bleeding—and the fetal surveillance is reassuring, the patient is closely monitored on pelvic rest
 - Nothing per vagina, no vaginal examination, no intercourse
 - Until fetal lung maturity or 37 weeks' gestation, then cesarean delivery is performed
- Risks of placenta previa include other placental implantation abnormalities:
 - Placenta accreta
 - Placenta increta
 - Placenta percreta
- Physician must be aware of these risks at the time of delivery and be prepared for a possible cesarean hysterectomy (hysterectomy performed at the time of the cesarean delivery) if necessary

HEMOLYSIS, ELEVATED LIVER ENZYMES, AND LOW PLATELETS (HELLP) SYNDROME AND DISSEMINATED INTRAVASCULAR COAGULATION (DIC)

- HELLP thought to be a distinct variant, rather than a progression, of the pre-eclampsia/eclampsia continuum
- Incidence is rare: 310 per 100,000 pre-eclamptic patients
- Associations with genetic mutations of the Fas gene and regulation of the immune system
- Risk factors have been shown to include:
 - African Americans
 - History of prior pregnancy with HELLP
- Recurrence rate has been reported as 14%
- A disease with significant morbidity and mortality, both maternal and perinatal
 - Maternal death 1.1%
- Significant maternal morbidity included:
 - DIC (21%)
 - Placental abruption (16%)
 - Acute renal failure (7.7%)
 - Pulmonary edema (6%)
 - Rare occurrences of subcapsular liver hematoma and retinal detachment
 - Case reports of hepatic rupture have been documented
- Fetal outcome typically related to the necessity to proceed with preterm delivery
- Neonatal outcomes include risk of intensive care requirements, mechanical ventilation, sepsis, and intraventricular hemorrhage
- Clinical features and laboratory evaluation of HELLP not firmly defined
 - Generally, findings reflect disease process on the vascular supply of the maternal liver
 - Hemolysis can be noted by an abnormal peripheral smear, elevated serum bilirubin, low serum haptoglobin levels, elevated lactate dehydrogenase (LDH) of subtypes LDH1/LDH2, or a fall in the hemoglobin

- Elevated liver enzymes, generally aspartate transaminases (AST), alanine transferase (ALT) and/or bilirubin present
- However, no strict definition of the degree of elevation
- Also great variability in establishing the criteria for low platelets
 - Varying from 150,000 to <50,000 cells/ μ L
 - Patients with HELLP have altered vascular reactivity
 - Methods of prediction of HELLP by Doppler ultrasound have been examined, revealing a decrease in dual hepatic blood supply preceding the onset of HELLP
- Objective parameters for DIC include:
 - Prolonged prothrombin time (PT) and activated partial thromboplastin time (aPTT)
 - Elevated fibrinogen degradation products
 - Elevated D-dimers
 - As fibrinogen is increased in a normal pregnancy, the value in DIC may decrease to “normal” (nonpregnant) values, so it is not used as an objective parameter
- Treatment of HELLP includes:
 - Supportive care in a facility suited for such high-level care
 - Prompt delivery of the fetus is indicated if the patient is beyond 34 gestational weeks or sooner if disease has progressed to multiorgan dysfunction, DIC, liver infarction or hemorrhage, renal failure, suspected placental abruption, or a nonreassuring fetal status
 - More controversy regarding the recommendations if the pregnancy is <34 weeks gestation and there are only mild to moderate laboratory abnormalities
 - Expectant management and corticosteroids for fetal lung maturity are given with delivery after completion of the course of steroids
 - Significant debate over use of steroids for *treatment* of the laboratory abnormalities of HELLP
 - Benefit of plasma exchange therapy has been shown to improve treatment outcome
 - Heparin therapy is associated with further bleeding complications
 - Transfusion of both packed red cells and component therapy as indicated
 - Fluid replacement and oxygenation are critical

LIVER CONCERNS

Physiologic Changes Associated with Pregnancy

- Pregnancy-related hormones and fetal enzymes significantly affect the maternal liver
- Changes in liver profile reveal:
 - Decreased serum albumin secondary to the dilutional effect of a 50% increase in maternal plasma volume
 - Increased serum alkaline phosphatase due to placental/fetal production
 - Markers of liver injury—aspartate aminotransferase, alanine aminotransferase, and lactate dehydrogenase—will not change in normal pregnancy
 - Bilirubin and γ -glutamyl transpeptidase are both significantly lowered
- One main hormone causing alterations in hepatic physiology is estrogen

- Produces increase in hepatic rough endoplasmic reticulum
 - Increases the production of proteins
- Approximate 12 times increase in estradiol through pregnancy related to multiple factors:
 - Changes in the binding hormones
 - Changes in metabolism and production
- Stimulates approximate six times increase in production of sex hormone-binding globulin
- Estrogen also has an inverse relationship with bile salt production and bile flow
 - Change in both composition of the bile and in the rate of cholesterol and phospholipid production
 - Produce an increased lithogenicity
- Progesterone mainly affects an increase of smooth endoplasmic reticulum and an increase in cytochrome P-450
- Also notable smooth muscle relaxation of the gallbladder and biliary ductal system
- Can produce slow wave dysrhythmia in the gastrointestinal tract

Hyperemesis Gravidarum (HG)

- HG a condition characterized by serious and persistent vomiting that limits fluid intake and adequate nutrition
- Clinical manifestations include:
 - Weight loss >5% of prepregnancy weight
 - Weakness
 - Dehydration
 - Ketosis
 - Muscle wasting
- HG occurs in approximately 0.3% to 2.0% of pregnancies
- Seems to affect a diverse population with multiple risk factors
 - Associated with various hormone levels including:
 - Human chorionic gonadotropin
 - Estrogen
 - Prolactin
 - Thyroxine
 - Androgens
 - Cortisol
 - Maternal prostaglandins
 - Other factors identified include:
 - Prior history of HG with previous pregnancies
 - Female fetal gender
 - Maternal age
 - Maternal weight
 - Smoking
 - *Helicobacter pylori* may or may not have a role
 - Chronic medical conditions contribute to risk:
 - History of gastritis
 - Allergies
 - Gallbladder disease
- Complete differential diagnosis includes multiple systems:
 - Obstetric and gynecologic conditions: molar pregnancy, degenerating uterine leiomyoma, or ovarian torsion
 - Gastrointestinal causes: gastroenteritis, gastroparesis, achalasia, biliary tract disease, hepatitis, intestinal obstruction, peptic ulcer disease, pancreatitis, and appendicitis
 - Urinary tract conditions: pyelonephritis, uremia, and kidney stones

- Metabolic diseases: hyperthyroidism, diabetic ketoacidosis, porphyria, and Addison disease
- Neurologic disorders, drug reactions, and psychiatric conditions are other considerations
- HG may or may not be protective against adverse outcomes
 - Relationship between HG and low birth weight that is mostly attributed to poor maternal weight gain
 - Additionally worsened maternal morbidity and mortality are also noted
 - Wernicke encephalopathy
 - Central pontine myelinolysis
 - Severe liver injury
 - Splenic avulsion
 - Pneumomediastinum following esophageal rupture
 - Acute kidney injury
- Treatment for HG is primarily supportive:
 - Antiemetics
 - Fluid therapy
 - Electrolyte replacement
 - Natural remedies: pyridoxine (vitamin B₆) and ginger shown to be effective
 - Behavior modification with avoidance of strong odors/scents and adjustment of diet may be tried
 - If these measures are inadequate, hospitalization and treatment with steroids and parenteral nutrition may be necessary

Intrahepatic Cholestasis of Pregnancy (ICP)

- ICP the most frequent of the pregnancy-related liver diseases
 - Occurs in approximately 1% of pregnancies
 - Characterized by:
 - Progressive pruritus of cholestasis
 - Elevated fasting bile salts $>10 \mu\text{mol/L}$:
 - Chenodeoxycholic acid
 - Deoxycholic acid
 - Cholic acid
 - Elevated amino transferases
 - Clinical manifestations:
 - Begin in the late second or third trimester
 - Most often will resolve spontaneously within 2 to 3 weeks postpartum
 - Direct cause is unknown, a strong familial component recognized
 - ICP affects specific populations at different rates:
 - Occurs in $<0.2\%$ of pregnancies in women of North American and Central/Western European descent
 - Scandinavian and Baltic populations show a rate of 1% to 2%
 - Chilean and Bolivian populations have shown rates of 5% to 15%
 - Severe form of ICP with bile acid levels $>40 \mu\text{mol/L}$
 - In the Swedish population is associated with a frame shift mutation in the gene coding for the adenosine triphosphate (ATP) binding cassette transporter
 - Specifically the ABCB4_5 gene variant (formerly known as multidrug resistance gene 3 [MDR3])
 - Mutations in the bile salt export pump (BSEP) can also predispose to ICP
 - Other possible causes relate to “leaky gut” theories

- Based on the increased absorption of bacterial endotoxins and the enterohepatic circulation of cholestatic metabolites of sex hormones and bile salts
- Also an association with low maternal serum estrogen
- Fetal complication rates:
 - Directly related to maternal serum bile acids
 - Levels $>40 \mu\text{mol/L}$ associated with:
 - Preterm delivery
 - Fetal asphyxial events
 - Meconium staining
 - Case reports of neonatal respiratory distress syndrome and fetal death are noted
 - Maternal morbidity and mortality are low
- Treatment:
 - Supportive measures for pruritus with antihistamine is inadequate
 - Has limited effectiveness and fails to address the bile acid elevation and fetal concerns
 - Cholestyramine, S-adenosylmethionine, and dexamethasone were the treatments of choice
 - Newer work advocates use of ursodeoxycholic acid (UDCA), a tertiary bile acid
 - Initial use of UDCA was with bear bile in traditional Chinese medicine for the treatment of liver disease
 - UDCA effective in reducing bile acids and bilirubin
 - Fetal risks are decreased, but not eliminated
 - Careful fetal monitoring and delivery at fetal lung maturity should be considered
 - Ondansetron being evaluated as a treatment for pruritus
 - No data are noted on fetal benefits of that antiemetic

Acute Fatty Liver Disease of Pregnancy (AFLP)

- AFLP a rare but potentially fatal disease that occurs in the third trimester
 - Mean gestational ages vary between 34.5 and 37 weeks
 - Incidence documented as between 1 in 6,659 births to 1 in 15,900 births
 - Characterized by:
 - Significant malaise
 - Nausea/vomiting
 - Anorexia
 - Abdominal pain
 - Jaundice
 - Clinical signs include:
 - Hypertension
 - Jaundice
 - Elevated serum transaminases
 - Coagulopathies
 - Thrombocytopenia
 - Hypoglycemia
 - High index of suspicion should be maintained if signs and symptoms are noted
 - Imaging studies are often performed but have limited usefulness:
 - Ultrasound may show nonspecific changes
 - Computed tomography has a high false-negative rate
 - Liver biopsy is the gold standard in confirming the diagnosis

- Rarely necessary and carries significant maternal risk in setting of DIC
- Disease has significant risks with respect to morbidity and mortality
 - Older work reported maternal and perinatal mortality rates as high as 75% and 85%, respectively
 - While maternal mortality rate has fallen significantly, fetal mortality remains as high as 66%.
 - Maternal morbidity includes:
 - Coagulopathies (specifically DIC)
 - Hepatic encephalopathy
 - Respiratory compromise (pulmonary edema or respiratory arrest)
 - Renal insufficiency

- There is an associated genetic component with mitochondrial trifunctional protein mutations
- Treatment is supportive:
 - Management in an intensive care unit
 - Delivery is recommended as efficiently as possible
 - Hypoglycemia should be treated with dextrose-containing solutions
 - Elevated ammonia levels can be decreased with neomycin
 - Blood transfusions and replacement of clotting factors should be considered as appropriate
 - AFLP generally resolves within 2 to 3 days postpartum
 - Cases of fulminant hepatic failure requiring liver transplantation have been reported

CHAPTER 64 ■ ACUTE ABDOMEN AND TRAUMA DURING PREGNANCY

IMMEDIATE CONCERNS

- About 1 in 500 (0.2%) of pregnant women require surgery for nonobstetric conditions.
 - Appendectomy, cholecystectomy, and adnexal procedures constitute most common surgeries during pregnancy.
 - Pregnancy outcomes after surgery are often good.
 - But fetal loss rates can be as high as 2% to 20%, depending on condition.
- Trauma an additional important cause for surgical intervention during pregnancy.
 - Incidence of trauma is approximately 8%, or 1 in 12 pregnancies.
 - Leading cause of nonobstetric maternal death
 - Fetal losses can be significant.
 - Always consider the possibility of pregnancy in any female between 12 and 44 years of age presenting with abdominal pain or trauma.
- Evaluation
 - First task is to ensure that airway, breathing, and circulation (ABCs) are adequate.
 - Adequate maternal oxygenation and uteroplacental perfusion are the means by which the fetus is also resuscitated.
 - Achieve hemodynamic stability in the mother before evaluation and treatment of pregnancy issues.
 - Physiologic adaptations of pregnancy affect the clinician's ability to address the ABCs (Table 64.1).
 - Once assured that the patient is hemodynamically stable, attention is turned to detailed secondary assessment.
 - Centered on evaluation of specific injuries or organ systems and pregnancy
 - Focused patient history is central to the evaluation of abdominal pain or trauma during pregnancy.

- Abdominal symptoms can be nonspecific during pregnancy.
 - Clarify the location, intensity, and quality of pain, including associated symptoms and aggravating or alleviating factors.
 - Obstetric symptoms, such as contractions, cramps, bleeding, or fluid leakage, should be noted.

TABLE 64.1

KEY POINTS IN THE ABCS OF THE RESUSCITATION OF PREGNANT WOMEN

Airway	Weight gain Breast enlargement Short time to establish airway before desaturation Edema of airway Difficulty in positioning neck Delayed gastric emptying—aspersion risk
Breathing	Elevated diaphragm Decreased fetal heart rate—rapid desaturation Respiratory alkalosis Limited chest wall expansion Limited accessory muscle use Normal large and small airway function
Circulation	Aortocaval compression at >20 weeks gravid Increased cardiac output Increased resting heart rate Decreased peripheral vascular resistance Decreased systolic and diastolic blood pressure Large shunt due to placental blood flow Hypercoagulable state

- In trauma, important details of the incident should be elicited, including vehicle speed, position seated in the vehicle, use of restraints, airbag deployment, and injuries to the head, abdomen, or extremities.
- Understanding normal physical changes and common complaints associated with pregnancy will help the clinician determine which symptoms are benign and pregnancy-related versus pathologic.
 - Many patients report nausea and vomiting in early pregnancy, but not typical in the later two trimesters.
 - Pyrosis due to acid reflux is reported by many gravidas, but is often easily relieved with antacids.
 - Constipation is a common complaint, due to the increased transit time of the gastrointestinal tract.
 - Transient discomfort or intermittent contractions are not rare, but persistent, rhythmic, or severe abdominal pain merits evaluation.
 - In all trimesters, right lower quadrant pain may signal appendicitis.
 - Colicky right upper quadrant pain is suggestive of cholelithiasis, and the symptom profile for biliary tract disease in pregnant women is similar to that of their nonpregnant counterparts.
- In the third trimester, it is important to evaluate and exclude the possibility of obstetric complications such as:
 - Preterm labor (PTL)
 - Premature rupture of membranes
 - Placental abruption
 - Intrauterine infection
- Basic obstetric (OB) triage evaluation includes external fetal heart rate monitoring, assessment of contractions, palpation of the uterine fundus, speculum examination for pooling, Nitrazine and fern tests, and digital cervical examination.
- Suggested approach to the initial evaluation of the pregnant patient with surgical diseases or trauma is shown in Table 64.2.

DIAGNOSTIC STUDIES

Laboratory Values

- During pregnancy, results can be misinterpreted or confusing unless pregnancy-specific norms are considered.
- Physiologic changes of pregnancy, including increased blood and plasma volumes, hormone production, and altered metabolic clearance, cause changes in the plasma concentration of many analytes.
- Selected laboratory values are displayed in Table 64.3.

OB Tests of Interest

- **Fetal fibronectin (fFN):** fFN is a protein produced by fetal membranes involved in adhesion of the placenta and membranes to maternal tissues.
 - Between 24 to 34 weeks, fFN is not normally detectable in cervicovaginal secretions
 - Presence of fFN may indicate a disruption of the membranes and decidua.
 - Due to inflammation or other causes

TABLE 64.2

KEY STEPS IN THE APPROACH TO THE PREGNANT PATIENT WITH SURGICAL DISEASES OR TRAUMA

1. Consider pregnancy in any woman of reproductive age presenting after trauma or with abdominal complaints—check urine or serum HCG
2. Perform a primary assessment of airway/breathing/circulation (ABCs)
 - a. Use a 15-degree left lateral tilt
 - b. IV hydration with isotonic crystalloid solution
 - c. Supplemental oxygen as necessary
3. Primary assessment of maternal status should be done prior to evaluation and treatment of fetal issues—should be focused and brief
4. Perform a secondary assessment once patient is hemodynamically stable
 - a. Investigate specific injuries or organ systems
 - b. Evaluate pregnancy viability and gestational age
 - c. Assess for pregnancy complications such as preterm labor (PTL), intrauterine infection, placental abruption, or fetomaternal hemorrhage
 - d. Perform cardiotocography for patients over 24 weeks' gestation
5. Do not withhold necessary diagnostic procedures
 - a. Consider using modalities that do not use ionizing radiation when possible
 - b. Limit ionizing radiation exposure to less than a total dose of 5 rad, as doses less than this amount are not associated with fetal loss or anomalies
6. Obstetric consult for all cases of severe abdominal pain or injury in pregnant patients
 - a. Determine if intervention for fetal indications is appropriate
 - b. Manage pregnancy complications as necessary
 - c. Develop contingency plans for route and timing of delivery where appropriate
 - d. Consider neonatal, anesthesiology consultations
 - e. Ensure equipment and staff available to effect emergency delivery if indicated

HCG, human chorionic gonadotropin; IV, intravenous.

- In symptomatic patient, a negative test is associated with >95% likelihood of not delivering within 14 days.
- Useful in the management of patients with preterm contractions, not uncommon in the setting of surgical diseases complicating pregnancy
- **Amniocentesis:** In selected cases, evaluation important to exclude intrauterine infection as a cause of abdominal pain
 - Abnormal findings in amniotic fluid suggestive of bacterial infection include:
 - Bacteria seen on Gram stain and/or positive culture
 - Low glucose, typically <15 mg/dL
 - High white cell count
 - Inflammatory markers such as high granulocyte colony-stimulating factor (G-CSF), tumor necrosis factor- α (TNF- α), and interleukin-1 (IL-1) and IL-6 are strongly suggestive of amnionitis
 - There is a risk of preterm contractions, premature rupture of the membranes, or fetal loss due to the procedure
 - Thus should be done on a selective basis
 - Data can be extremely useful when the clinical picture is unclear.

TABLE 64.3**NORMAL LABORATORY VALUES DURING PREGNANCY**

WBC	Increased	5,000–15,000 cells/mm ³
Hemoglobin	Decreased	10.5–13.5 g/dL
Hematocrit	Decreased	30.5%–39%
Platelet	Decreased	150–380 × 10 ³ cells/μL
Fibrinogen	Increased	265–615 mg/dL
D-dimer	Frequently positive	—
HCO ₃ [−]	Mild acidosis	19–25 mEq/L
BUN	Decreased	3–4 mg/dL
Creatinine	Decreased	0.4–0.7 mg/dL
Albumin	Decreased	2.7–3.7 g/dL
AST, ALT	Unchanged	12–38 U/L
Bilirubin	Unchanged	0.2–0.6 mg/dL
Alkaline phosphatase	Increased	60–140 IU/L

ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; HCO₃[−], bicarbonate; WBC, white blood cell count.

From Lockitch G. The effect of normal pregnancy on common biochemistry and hematology tests. In: Barron WM, Lindheimer MD, eds. *Medical Disorders during Pregnancy*. 3rd ed. St. Louis, MO: Mosby; 2000.

Diagnostic Imaging Studies

- Medically necessary diagnostic tests should not be withheld solely on the basis of pregnancy.
- Consider the potential advantages/disadvantages when selecting a particular testing method.
- Ultrasonography uses sound waves (no ionizing radiation).
 - No known adverse fetal outcomes associated with use of prenatal diagnostic ultrasound under current clinical guidelines for energy exposure.
- Magnetic resonance imaging (MRI) makes use of the altered energy state of protons to enhance imaging.
 - Chief clinical uses have been to evaluate placental abnormalities and characterize fetal central nervous system (CNS) malformations
 - May also be a valuable tool for assessing for intra-abdominal pathology
 - To date, MRI has been used safely during pregnancy.
- X-ray studies and computed tomography (CT) involve ionizing radiation and need to be used judiciously in gravid women.

Obstetric Ultrasound

- Serves to confirm fetal viability
- Offers opportunity to assess fetal size, anatomy, amniotic fluid volume, and placental location
- Basic study can be completed quickly at the bedside and can be done at the time of sonographic evaluation for other indications, such as right upper quadrant ultrasound.

Sonography for Trauma

- Focused assessment sonography for trauma (FAST)-US:
 - Done to detect intra-abdominal bleeding after trauma

- Similar sensitivity and specificity among pregnant and non-pregnant patients
 - In 127 pregnant trauma patients, FAST examination identified intraperitoneal fluid in 5 of 6 patients and was negative in 117 of 120 patients without intra-abdominal injury.
 - False-positive scans had serous fluid.
 - In reproductive-age women with blunt abdominal trauma, free fluid in the cul de sac has been associated with a higher injury rate compared to no free fluid in both pregnant and nonpregnant women.
- Of limited value in the diagnosis of placental abruption after trauma.
 - May miss up to 50% to 58% of cases
 - Echotexture may be very similar to that of placental tissue, so identification of retroplacental bleeding is not always possible.
- Graded compression ultrasonography is the initial test of choice in assessment of appendicitis during pregnancy.
 - Imaging focused on the self-reported area of maximal pain
- Overall accuracy of this technique in diagnosing appendicitis is 86%.
 - May be limited in the setting of a retrocecal appendix or perforated appendicitis
 - Color Doppler sonography can be used as an adjunct for improving the sensitivity of the test.
 - In a series of 42 women with suspected appendicitis during pregnancy, ultrasound was found to be 100% sensitive, 96% specific, and 98% accurate in diagnosing appendicitis.
- Diagnosis of cholelithiasis during pregnancy similar to that in nonpregnant
 - Visualization of stones in gallbladder reported to be as high as 95% using sonography
 - Detection of gallstones in a patient with right upper quadrant pain is suggestive of acute cholelithiasis, other features should be considered
 - Gallbladder wall edema or thickening >4 to 5 mm
 - Murphy sign can also be elicited
 - As patient experiences pain from pressing the transducer over gallbladder

Computed Tomography

- May be considered for abdominal evaluation if initial examination or other studies are equivocal
- Most common indication for CT is blunt abdominal trauma after motor vehicle crash
- Other indications include appendicitis and renal colic.
- Helical CT has good success in detecting injuries after trauma during pregnancy.
 - Abnormal placental enhancement and when uterine rupture occurred, nonuterine injuries, and both uterine and other maternal injuries
 - Estimated radiation exposure was 8.7 to 17.5 mGy, depending on technique.
 - Limited data regarding the accuracy of CT for the diagnosis of appendicitis during pregnancy, one series of seven patients correctly identified all cases
 - Depending on the protocol, pelvic CT can deliver a dose of radiation to the fetus as high as 2 to 5 rad.
 - Threshold for teratogenesis may not be reached with this level.
 - But relative risk of childhood cancer may be increased.

- Odds of dying of childhood cancer increase from a baseline of 1 in 2,000 to approximately 2 in 2,000 after exposure of 5 rads.
- Potential risks and benefits of CT during pregnancy should be discussed with patients.
- CT contrast safe to use in pregnancy and is administered as usual.

Magnetic Resonance Imaging

- MRI used as a tool to identify the cause of abdominal pain during pregnancy
- MRI was able to correctly identify the appendix in 10 of 12 cases where sonography was uninformative.
- 29 pregnant women were evaluated with MRI for abdominal or pelvic pain, and correct prospective diagnoses were made in all but one patient.
- MRI compares favorably with sonography—the overall sensitivity was 100%, specificity 93.5%, and accuracy 94% for detecting appendicitis.
- Gadolinium contrast is not recommended for use in pregnancy.
 - Crosses the placenta and enters the fetal circulation
 - Enters the amniotic fluid, where it is swallowed by the fetus and absorbed
 - A pregnancy category C drug
 - Animal studies have revealed adverse effects, but no controlled studies have been performed in humans.

SPECIFIC MANAGEMENT

Specific Conditions: Trauma

- Complicates 1 in 12 pregnancies
 - Two-thirds of trauma cases in pregnant women are due to motor vehicle crashes.
 - Other common causes are falls, burns, and penetrating wounds.
 - Blunt abdominal trauma is the most frequent mechanism of injury.
 - 1% to 20% of gravidas experience domestic abuse.
 - Up to 60% of women affected report two or more assaults during pregnancy.
 - At one center, nearly 3% of all trauma patients were pregnant.
 - 11% of these pregnancies diagnosed during trauma evaluation.
 - Severe trauma requiring admission to intensive care unit infrequent—3 in 1,000 pregnancies
 - Maternal death due to trauma is estimated to be 1.9 per 100,000 live births.
 - Representing the leading cause of nonobstetric maternal death
 - Estimated that 1,300 to 3,900 pregnancies lost due to maternal trauma yearly
 - Mild maternal injuries carry a 1% to 5% fetal loss rate.
 - Life-threatening trauma is associated with loss rates up to 40% to 50%.
 - Population-based data indicate that motor vehicle crashes account for 82% of fetal deaths after trauma.
 - Highest rate of fetal death due to trauma seen in patients 15 to 19 years of age
 - Fetal death was associated with:
 - Ejection from vehicle
 - Motorcycle crash
 - Pedestrian collision
 - Maternal death
 - Maternal tachycardia
 - Abnormal fetal heart rate (FHR)
 - Lack of restraints
 - An injury severity score (ISS) >9
 - Preterm labor was associated with:
 - Gestational age over 35 weeks
 - Assault
 - Pedestrian collisions
 - Up to 20% of injured pregnant patients test positive for drugs or alcohol, and one in three do not report using seat belts.
 - Worst outcomes take place among those who deliver during their hospital stay for trauma.
 - Odds ratios (OR) are strikingly high for maternal death (OR 69).
 - Fetal death (OR 4.7)
 - Uterine rupture (OR 43)
 - Abruptio (OR 9.2)
 - Even minor maternal injury places fetuses at risk.
 - Other complications that can contribute to fetal morbidity and mortality include:
 - Abruptio placentae
 - Preterm labor
 - Fetomaternal hemorrhage
 - The diagnosis of abruptio is based on signs and symptoms.
 - One of the best indicators of placental abruptio is cardiotocography.
 - In patients with a normal study, the risk of abruptio after trauma is approximately 1% to 5%.
 - In patients with more than six contractions per hour or abnormal fetal heart rate patterns, the risk of abruptio can be 20% or higher.
 - All women over 24 weeks' gestation should undergo an initial evaluation with cardiotocographic monitoring for 4 to 6 hours after trauma.
 - Four to six hours of observation is sufficient for patients who have experienced minor trauma and are hemodynamically stable, with a negative primary evaluation, FAST-US, and reassuring cardiotocography.
 - Extended period of observation for 24 hours or more is indicated for women with six or more contractions per hour, nonreassuring FHR patterns, vaginal bleeding, uterine pain or tenderness, premature rupture of membrane (PROM), or serious maternal injury.
 - Consideration for prolonged monitoring is advised if laboratory data are abnormal, such as decreased fibrinogen or a positive Kleihauer-Betke (KB) test, as patients with these characteristics are more likely to experience abruptio or other complications.
 - Pregnant women occasionally present with other types of injuries due to trauma to the head, pelvis, or chest.
 - Pelvic fractures, especially those involving the acetabulum, are associated with high maternal and fetal mortality rates.
 - Penetrating injury is less common during pregnancy than other forms of trauma.

- Severity of maternal abdominal or vascular injuries may be less than that of nongravid women, but rate of placental injury and fetal loss tends to be high.
- Management is similar to that of nonpregnant persons.
 - With careful and prompt evaluation of the placenta and fetus

Specific Conditions: Appendicitis

- Acute appendicitis complicates approximately 1 in 1,500 pregnancies.
- Occurs in all trimesters, the second trimester is most typical.
- More than 80% of patients with appendicitis report right lower quadrant pain, irrespective of the trimester.
 - Difficult to diagnose during pregnancy because signs and symptoms can be easily confused with physiologic changes of pregnancy.
 - Nausea and vomiting are common during pregnancy, but not typically associated with pain.
 - Constipation and bowel irregularity, frequent bothersome symptoms of gestation, can be difficult to interpret.
 - Mild leukocytosis is a normal laboratory finding in pregnant women, rendering it of limited value in making the diagnosis of appendicitis.
 - White blood cell (WBC) count ranges from 5,000 to 15,000 cells/mm³ in the first two trimesters and can be as high as 20,000 cells/mm³ in labor.
 - Classic triad of obturator, psoas, and Rovsing sign are present in less than one in three pregnant patients.
 - Imaging plays an important role in the diagnosis of appendicitis during pregnancy.
- Complications may be increased when appendicitis occurs during pregnancy.
 - Delay in diagnosis and treatment over 24 hours associated with perforation in 14% to 43% of cases, and up to 69% in the third trimester.
 - Fetal loss rates as high as 33% and preterm delivery rates of 14% reported in women undergoing appendectomy
- When strongly suspected, surgery performed as per usual clinical indications
 - An incision over the point of maximal tenderness is most often recommended.
 - Laparoscopy may be considered as an alternative in patients under 24 weeks' gestation.

Specific Conditions: Gallstones

- Cholelithiasis is common among pregnant women.
 - Seen in 3% to 4% of OB ultrasounds
 - Symptomatic gallstones occur less frequently, in approximately 1 in 1,000 cases
 - Half or more of patients experience recurrent bouts of biliary colic.
 - Traditional management consists of intravenous hydration, nothing orally or a low-fat diet, analgesics, and antibiotics.
 - Cholecystectomy required in 1 to 6 per 10,000 pregnancies.
 - Typical indications for surgery include:
 - Acute cholecystitis (38%)

- Gallstone pancreatitis (28%)
- Common bile duct stone (20%)
- Refractory pain (18%)
- Laparoscopy has been used successfully during pregnancy.
- Traditional management emphasized deferring surgery for symptomatic cholelithiasis until after delivery.
 - More recent data suggest that relapse of symptoms seen in 38%.
 - Labor induction due to refractory symptoms results in preterm delivery in some cases.

Specific Conditions: Adnexal Surgery

- True incidence of adnexal masses during pregnancy unclear
 - Estimated to be approximately 1 in 200
 - Simple ovarian cysts compose the vast majority of cases.
 - Adnexal surgery is necessary in 1 in 1,300 pregnancies.
 - Typically due to masses >6 to 8 cm, complex masses, and ovarian torsion
 - Malignancy is uncommon, seen in <10% of cases
 - Care should be taken to avoid removal of the corpus luteum in the first trimester prior to 10 weeks' gestation, as this can result in disruption of the ongoing pregnancy unless progesterone supplementation is provided.

FETAL ASSESSMENT

Risk of Fetal Loss and Recommended Fetal Assessment

- Total fetal loss rate is low, at 2.5%.
 - Birth defects after first trimester surgeries occurred in 3.9%.
 - The miscarriage rate was 5.8%, likely not increased above background rates, but not proven due to lack of controls for comparison.
 - Premature labor after nonobstetric surgery was seen in 3.5%.
 - The overall rate of preterm birth was 8.2%.
 - The highest risk for preterm birth and fetal loss was seen with appendectomy.
 - Preterm delivery rate was 4.6%.
 - Losses occurred in 10.9% of cases.
- No consensus on optimal fetal monitoring in the perioperative period
 - During first trimester, no specific fetal evaluation is necessary.
 - Documentation of a live intrauterine pregnancy prior to surgery is prudent in those patients who present with abdominal complaints, primarily to exclude the possibility of ectopic pregnancy or nonviable gestation.
 - From 14 to 24 weeks, assessment of fetal heart tones is advised preoperatively and postoperatively.
 - Perioperative assessment of contractions may be considered after 20 to 24 weeks.
 - At 24 weeks or beyond, cardiotocography should be performed before and after completion of surgery.

PRETERM LABOR AND TOCOLYSIS

- In one series of 77 patients undergoing nonobstetric surgery
 - Preterm labor was seen in 26% of patients in the second trimester.
 - 82% of those in the third trimester.
 - Most common after appendicitis and adnexal surgery
 - Actual preterm birth was seen in 16%.
 - Only in 5%, however, was a clear link to the surgical procedure established.
- Tocolytic medications are given to reduce uterine contractions in many cases, because it is difficult to predict accurately which women will go on to deliver prematurely.
 - Most commonly used tocolytic agents include nifedipine, magnesium sulfate, and indomethacin.
 - Selection drug based on gestational age, maternal health conditions, and possible side effects
 - Tocolytic drugs prolong pregnancy for only 2 to 7 days; their chief utility is to allow for administration of steroids to improve fetal lung maturity.
 - Clinical assessment includes physical examination with palpation of the fundus, cervical examination, and cardiotocography.
 - Adjunctive tests to aid in predicting preterm birth include cervical length measurement, fetal fibronectin testing, and possibly amniocentesis.
 - Tocolysis should be undertaken with caution in the surgical patient, and obstetric consultation is recommended in the event of preterm contractions after surgery.

Corticosteroids for Fetal Lung Maturity Enhancement

- All pregnant women 24 and 34 weeks of gestation at risk of preterm delivery within 7 days:
 - Should be given a single course of corticosteroids for fetal lung maturity enhancement
 - Betamethasone, 12 mg intramuscularly every 24 hours for two doses, *or*
 - Dexamethasone, 6 mg intramuscularly every 12 hours for four doses
 - Corticosteroids for fetal lung maturity enhancement reduce the incidence and severity of respiratory distress syndrome in preterm infants.
 - Betamethasone has been shown to decrease neonatal mortality.
 - Intraventricular hemorrhage and necrotizing enterocolitis are decreased with steroid use.

Venous Thromboembolism (VTE) Prevention

- Pregnancy is a prothrombotic state
 - Risk of VTE increased among women who undergo cesarean delivery as compared with vaginal birth.
 - In the gravid trauma patient, pneumatic compression is reasonable and low-molecular-weight heparin (LMWH) prophylaxis can be considered.

- With additional risk factors for thromboembolism beyond pregnancy itself, pharmacologic methods should be combined with use of mechanical approaches

PERIOPERATIVE MANAGEMENT

Anesthesia

- Regional or local anesthetics thought to be safer than general anesthesia
 - For abdominal surgery, has advantage of minimal fetal local anesthetic drug exposure
 - Less likely to be associated with airway complications
 - Local anesthetics are not known to be teratogenic when used in this clinical setting
- Risk of aspiration from gastroesophageal (GE) reflux and delayed gastric emptying
 - Customary to administer a nonparticulate antacid or H₂ blocker
 - And medication to improve GE sphincter tone preoperatively
 - For general anesthesia, preoxygenation and rapid-sequence intubation typical
 - Avoid hyperventilation, as uterine blood flow is impaired.
 - Inhalational agents decrease uterine tone and effectively inhibit labor during surgery
 - Agents for general anesthesia, including a single dose of benzodiazepines, nitrous oxide, and inhalational agents, not shown to be teratogenic
 - Fetal loss, low birth weight, and perinatal mortality increase after nonobstetric surgery appear not to be influenced by the choice of anesthetic
 - Guidelines for laparoscopic surgery during pregnancy are displayed in Table 64.4.

TABLE 64.4

SOCIETY FOR AMERICAN GASTROINTESTINAL ENDOSCOPIC SURGEONS GUIDELINES FOR LAPAROSCOPIC SURGERY DURING PREGNANCY (2000)

1. Preoperative obstetric consultation
2. If possible, defer operation until second trimester, when fetal risk is lowest
3. Use pneumatic compression devices whenever possible, as pneumoperitoneum enhances lower extremity venous stasis and pregnancy induced a hypercoagulable state
4. Monitor fetal and uterine status, and use maternal end-tidal CO₂ and/or arterial blood gas (ABG)
5. Protect uterus with a lead shield if intraoperative cholangiography is possible. Use fluoroscopy selectively.
6. Attain abdominal access using an open technique, as the gravid uterus is enlarged
7. Shift the uterus off the inferior vena cava by using dependent positioning/lateral tilt
8. Minimize pneumoperitoneum pressures (8–12 mm Hg) and do not exceed 15 mm Hg

From Lu E, Curet M, El-Sayed Y, et al. Medical versus surgical management of biliary tract disease in pregnancy. *Am J Surg.* 2004;188:755–759, with permission.

Delivery Considerations

- Optimal maternal and infant outcome depends on planning for contingencies.
- Action items that might impact care when managing pregnant trauma or surgery patients are:
 - Admit the mother to a facility able to provide appropriate specialty care, including neonatology and neonatal intensive care unit (NICU) care.
 - Provide level I trauma center care for any gravid trauma patient whenever possible.
 - Ensure immediate availability of equipment for emergency delivery.
 - This includes all items for infant resuscitation, such as warmer bed, oxygen, endotracheal tubes, suction, other supplies, and emergency medications.
 - Plan for adequate staff to address obstetric issues, including fetal monitoring and/or emergency delivery.
 - Plan for adequate nursing care for perioperative needs on labor and delivery ward.
 - Ensure that clear instructions designate which providers or specialty services are responsible for various aspects of patient care.
 - Display contact information for the various providers prominently in patient medical record, in case emergency evaluation and treatment is necessary.
 - Encourage impeccable communication among specialists.
 - Obtain consultations early, and document recommendations or treatment plans.
 - Clearly indicate plans for fetal assessment and whether or not intervention is planned for indications, such as emergent cesarean in the event of nonreassuring fetal heart rate patterns.
 - Delivery timing and route may be individualized.
 - In general, delivery at full term (≥ 37 weeks) is the goal.
 - Cesarean reserved for usual clinical indications, with the notable exception of the perimortem patient (Table 64.5)
 - Typical trauma care team for a gravid patient includes:
 - Emergency room physician
 - Emergency room nurse

- Trauma surgeon
- Obstetrician
- OB nurse
- Anesthesiology
- Pediatrician available
- NICU or nursery nurse available
- Operating room team on standby

Perimortem Cesarean

- Intact survival of a fetus is most likely when cesarean delivery is accomplished within 5 minutes of cardiac arrest.
- In 38 cases of perimortem cesarean, there were 34 surviving infants.
 - Time of delivery was available for 25 cases.
 - 12 of 25 (48%) were delivered within 5 minutes, and 9 of these 12 infants had no neurologic deficits on follow-up.
 - Of 20 perimortem cesareans with resuscitable causes, 13 mothers were revived and discharged from the hospital in good condition.

Maternal Brain Death

- Rarely maternal brain death is identified in a pregnant woman while somatic support has been maintained and the fetus remains alive.
- Determination must be made as to whether to deliver the fetus immediately, to initiate supportive care to allow further fetal maturation, or to allow the fetus to die as the mother is removed from mechanical ventilation.
- Immediate delivery when gestational age is consistent with neonatal survival is preferred.
- It is possible to support the mother and previable fetus until fetal maturation allows for neonatal survival.
- Somatic support can be provided for extended periods with no apparent neonatal or pediatric sequelae.

Ethical Decision Making

- According to the American College of Obstetricians and Gynecologists (ACOG) Ethical Guidelines, “Every reasonable effort should be made to protect the fetus, but the pregnant woman’s autonomy should be respected. . . . Intervention against the wishes of a pregnant woman is rarely if ever acceptable.”
- In a patient who is incapacitated, state laws vary with respect to who may serve as a surrogate decision maker.
 - Designees should base their decisions on the values and wishes of the patient, which may or may not have previously been stated in writing.
 - If there is no consensus about who should be designated, the advice of an ethics committee should be considered.

TABLE 64.5

INDICATIONS FOR EMERGENT CESAREAN

Emergent cesarean may be warranted in the following circumstances:

- Fetal heart tones are present (there is a living fetus)
- The fetus is at a viable gestational age (≥ 23 to 24 weeks)
- Adequate equipment and personnel are available to perform cesarean
- Adequate equipment and personnel are available for neonatal resuscitation
- Lack of response to maternal cardiopulmonary resuscitation (CPR) within 4 minutes (discussed in text)
- Persistent nonreassuring fetal heart rate (FHR) pattern is present—examples include fetal bradycardia, prolonged decelerations, or repetitive late decelerations
- Deteriorating maternal condition—cardiovascular instability
- Direct uterine or fetal injury

DOMESTIC VIOLENCE AWARENESS

- Women who experience physical violence are at higher risk for pregnancy loss and low-birth-weight infants

- Among 949 women surveyed, low birth weight was increased in those reporting verbal abuse (7.6% vs. 5.1%).
- Neonatal deaths more common among those with physical abuse (1.5% vs. 0.2%).
- 94 women who declined interview had higher rates of low-birth-weight infants (12.8%), preterm birth (5.3% vs. 1.2%), abruption (7.4% vs. 2.2%), and NICU admission (7.4% vs. 2.2%) than those reporting no abuse.

- Battered women are commonly reported to seek medical services at eight times the rate of other women, but they are rarely identified or referred for services.
- Should a patient indicate that domestic violence is a concern, assistance is available from the National Domestic Violence Hotline, 1-800-799-SAFE. This 24-hour, toll-free hotline provides information and referrals from anywhere in the United States.

CHAPTER 65 ■ FETAL MONITORING CONCERNS

IMMEDIATE CONCERNS

- Immediate issues to be evaluated when caring for a pregnant woman include:
 - Viability of the fetus
 - Gestational age of the fetus
 - Assessment of the fetal condition
- Determination of fetal viability is the first priority in the initial assessment
 - Diagnosis of fetal demise eliminates it as a confounding factor in decisions regarding maternal treatment.
 - Confirmation of a live fetus indicates a need to avoid teratogenic agents and optimize oxygen delivery to the placenta.
- Estimation of gestational age is an important factor to establish early.
 - If pregnancy is near term and nonobstetric surgical treatment is indicated, delivery of the fetus prior to such treatment may be warranted.
 - Earliest gestational age at which neonatal survival may occur is around 23 weeks.
 - Survival without significant morbidity becomes more likely at later gestational ages.
- Fetal assessment is dependent on the current gestational age.
 - Early gestational ages, assessment includes only documentation of fetal cardiac activity
 - Later gestational ages, the goal of fetal assessment and monitoring is:
 - Determination of adequacy of fetal oxygenation
 - Alerting the physician to potential hypoxia and/or fetal compromise

FETAL OXYGENATION

- The intervillous space is where maternal blood bathes the fetal chorionic villi and where fetal-maternal and maternal-fetal exchange occurs.
 - Characterized by low pressure, but a pressure differential exists and ensures adequate circulation

- Placenta a low-resistance organ, and, accordingly, the pressure differential across the intervillous space is small
- The vascular resistance of the maternal arteries governs the rate of flow into and across the intervillous space.
- During uterine contractions venous pressure increases and causes cessation of flow into the intervillous space.
- Placenta serves as main organ of gas and nutrient exchange for the fetus
 - Oxygen extracted at the fetal-maternal interface serves fetus and placenta
 - Highly metabolic organ uses as much, and possibly more, of the total oxygen and nutrients as the fetus to maintain its own growth and metabolism
- Oxygen consumption remains constant over a wide range of changes in oxygen delivery and decreases only when extraction is maximal and delivery is further reduced.
 - 50% reduction in uterine blood flow is compensated by an increase in umbilical blood flow and an increase in oxygen extraction to maintain oxygen delivery with no change in fetal oxygen consumption
 - Compensatory mechanism adequate only with short-term reductions in uterine blood flow
 - Critical point exists below which oxygen uptake becomes dependent on oxygen delivery
 - Long-term reductions result in decreased consumption secondary to the decrease in delivery.
 - Chronic decrease in oxygen consumption leads to decreases in both fetal growth and fetal activity in an effort to conserve oxygen for cellular homeostasis
 - Where fetal oxygen consumption is decreased, maternal administration of oxygen will increase fetal oxygen consumption to near-normal range.
 - Placenta carries oxygenated blood to the fetus via the umbilical vein.
 - Deoxygenated blood is carried back to the placenta via the two umbilical arteries.
- Human fetal umbilical venous PO₂ is around 30 mm Hg.
 - Adequate oxygen delivered to fetal tissues
 - Facilitated by the high fetal cardiac output, relative to its body size, and the affinity of fetal hemoglobin for oxygen

- Transfer of carbon dioxide across the placenta is limited by the diffusion capacity.
 - Placenta is highly permeable to carbon dioxide.
 - Alterations in maternal PCO_2 content can lead to disturbances in the fetal PCO_2 content.
 - If maternal PCO_2 is abnormally elevated, fetal transfer is hindered and will result in elevations of fetal PCO_2 and fetal acidosis.
- Glucose is a major energy source for the fetus.
 - Primarily obtains glucose from maternal blood
 - Supplemented by its own glycogenolysis
 - Fetal glucose deprivation causes fetal hypoglycemia, which results in an increase in the maternal–fetal glucose gradient and thus increased glucose transport across the placenta.
 - Glucose transport is limited by the availability of transport proteins in the placenta as well as maternal blood glucose levels.
 - This is facilitated transport, different from simple diffusion
 - Severe glucose deprivation and the resultant decrease in placental uptake may result in fetal growth abnormalities.
 - Chronic glucose deprivation will decrease glucose utilization and increase glycogenolysis and gluconeogenesis by the breakdown of fetal protein.
 - Net protein loss results in fetal growth disturbances and ultimately may lead to growth restriction.
 - Transport of waste includes lactate
 - With a drop in oxygen supply and a change to anaerobic metabolism, the fetus begins to produce large amounts of lactate.
 - In this situation, the placenta becomes a major source of lactate clearance from the fetal circulation.
 - The placenta, in response to decreased glucose supply, will decrease its consumption of glucose and increase its consumption of lactate to account for the glucose deficit.

FETAL MONITORING

- Electronic fetal monitoring, introduced in the 1960s, has become ubiquitous in labor and delivery units in economically developed countries.
 - Typically used at any gestational age at which *ex utero* survival is possible
 - Requires very little except for an experienced interpreter
 - Results in continuous tracing of the fetal heart rate (FHR), coupled with a tracing of uterine activity
 - Regulation of the fetal heart rate is governed by a complex interplay of the sympathetic and parasympathetic nervous systems.
 - Fetal heart rate variability results from the constant push-pull of these two systems.
 - FHR tracing reactivity is defined by the presence of FHR accelerations.
 - Transient increases in baseline fetal heart rate due to fetal movement
 - Absence of FHR variability for periods of more than 1 hour, especially in the presence of FHR decelerations, is associated with fetal acidemia.
 - Decelerations occur when the FHR falls below the baseline heart rate and are classified according to their location in relation to uterine contractions and their appearance.
 - Different types of decelerations caused by different mechanisms
 - **Early Decelerations:** Begin at the onset of uterine contractions and appear to mirror the contraction (Fig. 65.1)
 - Caused by pressure on the fetal head, resulting in alteration in cerebral blood flow and stimulation of the vagal center

FIGURE 65.1. Early decelerations mirror the contraction and are not associated with fetal compromise.

FIGURE 65.2. Variable decelerations occur at various times in relation to the contraction and are a result of transient umbilical cord compression.

- Generally are not associated with other ominous findings and are not associated with fetal hypoxia, acidosis, or low Apgar scores
- **Variable Decelerations:** Caused by intermittent umbilical cord compression
 - Occur most often during uterine contractions, but are seen at variable times in relation to uterine contractions and even in absence of contractions (Fig. 65.2)
 - Physiologic basis for decelerations results in either a chemoreceptor or a baroreceptor response due to:
 - Fetal hypertension and stimulation of the baroreceptors
 - Fall in fetal PO_2 , leading to chemoreceptor activation and stimulation of vagal activity
 - Repetitive moderate or severe variable decelerations may indicate fetal compromise (Table 65.1)
- **Late Decelerations:** Occur late in relation to the uterine contraction. Their onset begins after contraction begins, and they resolve after contraction resolution (Fig. 65.3)
 - Occur as a result of decreased uteroplacental oxygen delivery to the fetus
 - Intermittent hypoxia, sometimes associated with fetal acidemia, results in fetal hypertension, leading to chemoreceptor and baroreceptor response
 - In the presence of fetal acidemia, response may also be mediated by direct myocardial depression
- Many clinical causes of late decelerations:
 - Maternal hypotension
 - Decreased uterine blood flow
- Persistence of late decelerations, especially without fetal variability, is an ominous sign of fetal compromise.
- Other fetal heart rate patterns seen in presence of fetal central nervous system (CNS) dysfunction
- Normal fetus may have episodes of decreased heart rate variability of 30 to 40 minutes due to sleep
 - In CNS dysfunction, may see persistently diminished variability or sinusoidal pattern
 - Patterns resemble a sine wave, with a frequency of 3 to 5 cycles per minute and an absence of fetal heart rate variability
 - Severe fetal anemia another potential cause of sinusoidal fetal heart rate tracing
 - Unstable, or wandering, baseline heart rates also may be seen

TABLE 65.1

CLASSIFICATION OF VARIABLE DECELERATIONS

Classification	Nadir	Duration
Mild variable	100 bpm	<30 seconds
Moderate variable	60 bpm	<60 seconds
Severe variable	<60 bpm or drop of >60 bpm from baseline	60 seconds

ANTENATAL TESTING

- Certain situations indicate periodic assessments of fetal well-being in antepartum period
 - Several methods require only electronic fetal monitoring
 - Some involve use of ultrasound

FIGURE 65.3. Late decelerations occur late in relation to the contraction and may be a sign of fetal compromise.

- Primary indication for most aspects of fetal surveillance is the need to evaluate a potentially viable fetus where there is a concern for:
 - Fetal hypoxia
 - Death
 - To assess likelihood of stillbirth during subsequent week
- The goal of fetal surveillance is to identify early fetal hypoxia and prevent perinatal asphyxia
- Most tests of fetal well-being lack specificity and have a low positive-predictive value
 - Used because of their high negative-predictive value

Nonstress Test

- Nonstress testing involves fetal heart rate monitoring for a period of 20 to 40 minutes
 - Underlying premise for this test relates to the fact that a nonacidotic, neurologically intact fetus will have fetal heart rate accelerations in response to fetal movement.
 - Presence within a 20-minute window of two fetal heart rate accelerations lasting at least 15 seconds, peaking at least 15 beats per minute above the baseline, characterizes a reactive nonstress test and is reassuring
 - Absence of these accelerations requires further testing or delivery, depending on the gestational age
 - Less than 32 weeks gestational age may not have reactive nonstress tests despite the absence of compromise
- Nonstress test is simple to perform and generally is required on admission for initial evaluation of fetal well-being.
- A reactive test is highly reassuring, with a false-negative rate of 1.9/1,000.

Contraction Stress Test

- Can be used as a follow-up test to a nonreactive nonstress test or used alone for fetal evaluation
 - Requires at least three spontaneous or elicited contractions during a 10-minute window
 - Evaluates the fetal heart response to these contractions
 - Contraindicated in significantly preterm gestations and those in whom labor is contraindicated
 - Underlying premise involves idea that fetal oxygenation will transiently worsen in presence of uterine contractions
 - In compromised fetus, this will result in late decelerations
 - Interpreted based on the presence or absence of late decelerations
 - Positive contraction stress test is one in which late decelerations occur with at least 50% of contractions and generally indicates that delivery is warranted
 - Negative test result with no late decelerations is highly reassuring, with a false-negative rate of only 0.3/1,000.

Biophysical Profile

- Consists of a nonstress test and an ultrasound evaluation of several parameters
 - Performed as a follow-up test to a nonreactive, nonstress test
 - Can be used as a form of surveillance on its own
- Attempts to evaluate the fetus in terms of acute and chronic compromise
 - Nonstress test is one of the parameters used for evaluation.

TABLE 65.2**COMPONENTS AND SCORING OF THE BIOPHYSICAL PROFILE**

Parameter	Score (= 2) ^a	Score (= 0) ^a
Nonstress test	Reactive with more than 2 accelerations in 20-minute time period	Nonreactive
Fetal breathing	At least one episode of fetal breathing for >30 sec	<30 sec of breathing
Fetal tone	At least one episode of active extension and flexion	No flexion/extension
Gross movement	Three or more limb or body movements in 30 min	Less than three movements in 30 min
Amniotic fluid	Single vertical pocket >2 cm	Largest fluid pocket <2 cm

^aScore is 2 or 0 for each parameter.

- Ultrasound examination seeks to evaluate the amount of amniotic fluid, fetal tone, gross body movements, and fetal breathing movements (Table 65.2).
- Final score derived from these various assessments
- Intervention based on both score and gestational age
- No contraindications to its use
- Entire evaluation takes <1 hour to complete
- High correlation with low scores and fetal compromise
- Best predictor of perinatal mortality appears to be the absence of fetal tone
- Normal biophysical profile score of 8 or 10 is very reassuring—the false-negative rate is 0.8/1,000.

Doppler Velocimetry

- Accomplished with the use of color Doppler during an ultrasound examination
- Umbilical artery most widely interrogated vessel for fetal surveillance
- Normal fetuses, the umbilical artery has a high diastolic velocity due to low placental resistance
 - With placental injury or pathology, the umbilical artery resistance may be increased.
 - As resistance rises, diastolic flow decreases.
 - With high levels of resistance, diastolic flow may cease or become reversed.
 - Reversed end diastolic flow in the umbilical artery is associated with significant perinatal morbidity and mortality.
- Doppler interrogation of the middle cerebral artery also has been shown to be of benefit in certain situations.
 - Setting of significant fetal anemia, the blood is thinner and the cardiac ejection fraction increases.
 - Results in an increase in the velocity of blood through the middle cerebral artery
 - Periodic middle cerebral artery interrogation is replacing the assessment of amniotic fluid for monitoring fetuses at risk of anemia

ADJUNCTS TO INTRAPARTUM FETAL HEART RATE MONITORING

Fetal Scalp Sampling

- To delineate fetuses with decelerations and acidemia from those with normal pH, fetal scalp sampling may be performed.
- Accomplished by taking a blood sample from the fetal scalp
- Normal fetal scalp pH is 7.25 to 7.35.
 - Values below 7.20 considered acidotic
 - Can be performed only in the presence of labor with ruptured membranes
 - Invaluable tool in the assessment of fetal acidosis
- Evaluated fetal scalp stimulation and its relation to fetal pH
 - Fetal heart rate acceleration in response to digital stimulation of the scalp reliably have a pH >7.20.
 - Of fetuses without accelerations, 50% have a normal pH, whereas the remaining 50% are noted to be acidotic.
 - Digital stimulation of the fetal scalp can be performed when the membranes are intact, requiring a cervix that is dilated.

ST Segment Analysis

- One of newest advancements is the ability to combine standard fetal heart rate assessment with an automated analysis of the fetal electrocardiogram, ST waveform analysis.
- Fetal ST segment analysis is based on the observation that fetal hypoxia results in characteristic changes in the ST segment as well as the T wave on the fetal electrocardiogram.
 - There is a reduction in neonates born with metabolic acidosis when using ST segment analysis.

CHAPTER 66 ■ THE OBESE SURGICAL PATIENT

- In the economically developed world, the incidence of obesity is rising at epidemic proportions.
 - University medical centers report 25% of routine surgical patients are obese.
 - At least 10% of all patients are morbidly obese (MO).
 - Estimates that incidence rate of morbidly obese patients requiring nonsurgical intensive care treatment approaches 14 cases per 1,000 intensive care unit (ICU) admissions annually
 - Bariatric surgical procedures in the United States increased from 37,000 cases in 2000 up to 200,000 in 2006.
 - The critically ill morbidly obese surgical patient presents the critical care team with many unique problems.
 - Eightfold higher mortality rate after blunt trauma than nonobese patients presenting with the same diagnosis
 - Significant increases in length of ICU stay, mortality, and duration of mechanical ventilation
 - Pathophysiologic consequences of obesity involve all major organ systems
 - Diabetes mellitus and hyperlipidemia contribute to chronic morbidity in the obese.
 - Main concerns for the intensivist, anesthesiologist, and surgeon have been the same for over three decades: the derangements of the cardiopulmonary system

CARDIOVASCULAR (CV) CONSIDERATIONS IN THE MO

- CV disease reported in:
 - 37% of adults with a body mass index (BMI) >30 kg/m²
 - 21% with a BMI of 25 to 30 kg/m²
 - 10% in those with a BMI <25 kg/m²
 - *Obesity*—a BMI ≥ 30 kg/m²—an independent risk factor for the development of hypertension.
 - Framingham Heart Study suggests that 65% of the risk for hypertension in women and 78% of the risk in men related to obesity.
 - Mortality rates were reported to be 3.9 times greater in the overweight group versus the normal weight group participating in the Framingham study.
 - Chances of myocardial infarction, heart failure, stroke, and kidney disease are all greater as a patient's blood pressure increases.
 - Many obese individuals also suffer from metabolic syndrome.
 - With strong association as precursor in development of diabetes, cardiovascular disease, and increased mortality rates from cardiovascular disorders
 - Also a 5% increased risk of heart failure for men and 7% for women associated with each unit of increase in body mass.

Preoperative Considerations

Pathophysiology

- In MO patients
 - Blood volume, cardiac output, systemic and pulmonary artery pressures, and left and right ventricular pressures all elevated.
 - Manifest clinically as arterial hypertension
 - With advancing age, may note ischemic heart disease and right-left heart failure.
 - Incidence of severe pre-existing CV disease in MO patients scheduled for elective bariatric surgery reported to be as great as 20%.
 - The complex interaction of hypertension, ischemic heart disease, and pulmonary hypertension contribute to development of global cardiac dysfunction and exacerbates congestive heart failure.
 - Clinical situation is referred to as *obesity cardiomyopathy*.

Arterial Hypertension

- Pathogenesis of obesity-related hypertension complex
 - A continuous relationship between BMI and systolic/diastolic blood pressures
 - Blood pressure is normally regulated by a series of feedback loops:
 - Baroreceptors
 - Vasoactive hormones
 - Renin, angiotensin, aldosterone
 - Catecholamines
 - Derangement in any of these feedback loops may lead to hypertension.
 - Many factors act together to promote vasoconstriction, sodium retention, and volume overload in obesity (Table 66.1).
 - Changes cause glomerular injury, ultimately leading to glomerulosclerosis.
 - Prolonged obesity may lead to a gradual loss of nephron function that worsens with time and exacerbates hypertension.
 - Hypertension contributes to a pressure overload of the heart and expansion of extracellular and blood volume combining to create a volume overload.
 - Other variables that may also lead to hypertension in obese patients by stimulating sympathetic activity and vasoconstriction include:
 - Leptin
 - Free fatty acids
 - Insulin
 - Obesity-induced insulin resistance and endothelial dysfunction may act as amplifiers of the vasoconstrictor response.
 - Obstructive sleep apnea (OSA) is more prevalent in obese patients.

TABLE 66.1**FACTORS THAT ACT TOGETHER TO PROMOTE VASOCONSTRICTION, SODIUM RETENTION, AND VOLUME OVERLOAD IN THE OBESE PATIENT**

- Elevated glomerular filtration rate, an elevated renal blood flow, and exhibiting delayed urinary sodium excretion in response to the saline load^a
- Increased renal sympathetic nervous activity, which directly promotes tubular reabsorption of sodium at the proximal and distal tubules^b
- The renin–angiotensin–aldosterone system is activated, which contributes to sodium retention and an increase in extracellular volume, despite an elevated blood pressure^c
- Natriuretic peptide levels are low, both at basal levels and also in response to salt loading^d
- Hyperinsulinemia directly promotes the tubular absorption of sodium.^e *Compensatory mechanisms in the obese for overcoming increased sodium reabsorption include renal vasodilation, an increased glomerular filtration rate, and a higher blood pressure.*

^dDessi-Fulgheri P, Sarzani R, Tamburrini P, et al. Plasma atrial natriuretic peptide and natriuretic peptide receptor gene expression in adipose tissue of normotensive and hypertensive obese patients. *J Hypertens.* 1997;15:1695–1699.

^eEndre T, Mattiasson I, Berglund G, et al. Insulin and renal sodium retention in hypertension-prone men. *Hypertension.* 1994;23:313–319.

- Leads to periods of apnea and hypoxia, triggering a chemoreceptor response, which causes sympathetic activation

Ischemic Heart Disease (IHD)

- Obesity a recognized risk factor for IHD
- Risk proportional to duration of obesity and distribution of fat
- Habitually overweight individual less likely to be at risk than individuals who exhibit continuous weight gain
- Central distribution of fat more at risk than individuals with a peripheral distribution
- Hypertension, diabetes, hypercholesterolemia, and increased levels of low-density lipoproteins (LDLs) further increase the risk of coronary stenosis.
- Nevertheless, more than 40% of obese patients with angina do not have significant coronary artery disease.
- Angina would then be attributable to the oxygen supply/demand imbalance due to cardiac hypertrophy and other factors.
- In MO, myocardial oxygen consumption is higher than in normal-weight adults.
 - Ventricular cavity dimension is enlarged due to a chronically augmented preload.
 - Enhanced sympathetic activity and subsequent arterial hypertension and/or increased heart rate promote higher wall tension and ventricular systolic stress.

- In addition, the ventricular wall is commonly hypertrophic.
- With chronic hypoxemia (pickwickian syndrome, obesity hypoventilation syndrome, and obstructive sleep apnea syndrome) secondary polycythemia and, subsequently, elevated blood viscosity develop.
- Due to the higher blood viscosity, contractility is augmented, which consequently increases myocardial oxygen requirements.

Cardiac Failure

- Risk of heart failure of 5% for men and 7% for women per each unit of increase in body mass
- Linear relationship between body weight and cardiac weight gain attributed to concentric and eccentric hypertrophy
 - Secondary to pressure overload, due to arterial hypertension and possibly increased blood viscosity
- Circulating blood volume, plasma volume, and cardiac output increase proportionately with rising weight.
- With a fat mass of 50 kg, blood flow to this fat mass accounts for an extra cardiac output of 1.5 to 2.0 L/minute.
 - Resulting in both ventricular enlargement and an increase in stroke volume
- Hypertrophy contributes to a reduction in cardiac compliance and left ventricular diastolic function, which leads to increased left ventricular end-diastolic pressure and possible pulmonary edema.
- Decrease in midwall fiber shortening and a decrease in ejection fraction may become evident in developing obesity cardiomyopathy.
- Right ventricle can also exhibit hypertrophy secondary to pulmonary hypertension due to obstructive sleep apnea and subsequent chronic hypoxemia and hypercapnia.

Preoperative Evaluation and Optimization for Surgery**Arterial Hypertension**

- Urgent and emergent surgeries should be evaluated on a case-by-case basis, and aggressive control of blood pressure in the perioperative period is vital.
- Acute hypertensive episodes and hypertensive emergencies approached as in the nonobese
 - Meticulous and adequate monitoring
 - Careful drug titration required due to the particular hemodynamic lability of this population
 - Pharmacokinetics and dynamics might be altered
- Measurement of blood pressure may be difficult, even to the point of deciding where to make the measurement.
 - Obese individuals—especially women—tend to have a conical shape of the upper arm, termed *gynoid obesity*.
 - Accurate measurement of blood pressure is difficult
 - Alternative is to place the cuff around the forearm for more predictable cuff pressures
 - Increasing arm circumference associated with miscalculation of blood pressure if standard-length cuffs used
- Appropriate-sized cuff that encompasses at least 80% of the arm should be used
- If these maneuvers fail to result in adequate and reliable measurements, invasive blood pressure monitoring should be considered.

Ischemic Heart Disease and Cardiac Failure

- No specific cardiac risk index has been proposed for obese patients.
- Preoperative cardiac assessment of obese patients follows same sequence as for lean patients
 - Careful appraisal of arterial hypertension and its consequences
 - Focus on assessing both cardiac function and the presence and severity of ischemic heart disease
 - Evaluation of cardiac function by clinical signs can be extremely difficult in the obese so objective evaluation of ejection fraction and cardiac function by echocardiography and/or left ventriculography usually necessary
 - The American College of Cardiology/American Heart Association (ACC/AHA) recommendation for preoperative noninvasive evaluation of LV function includes patients with:
 - Current or poorly controlled heart failure
 - History of heart failure
 - Dyspnea of unknown origin—an extremely frequent finding in this population
 - Evaluation for ischemic heart disease requires stress testing
 - No consensus on which type of stress test is optimal
 - Whether or not patients can exercise sufficiently to obtain 85% of predicted maximal heart rate
 - If they cannot, then a pharmacologic stress test is better indicated (e.g., stress echocardiography after dobutamine or atropine administration [DSE] or a dipyridamole thallium nuclear imaging study [DTS])
 - Positive stress test results will require coronary angiography
 - If cardiac catheterization is indicated, patient weight has to be taken into account due to some tables weight limits as low as 300 lb (136.4 kg)
 - Cardiac catheterization is considered safe in these patients
 - 55% of the time, cardiac catheterization results in negative findings
 - When positive, medical management, interventional cardiology therapy, or even cardiac bypass surgery may be indicated
 - When ischemic heart disease identified and severity quantified, three therapeutic options are available prior to elective noncardiac surgery:
 - Revascularization by surgery (coronary artery bypass graft [CABG])
 - Revascularization by percutaneous coronary intervention (PCI)
 - Optimized medical management (typically with β -blockers or α_2 -agonists)
- No irrefutable evidence that indications for preoperative cardiac revascularization are any different for obese patients than for nonobese patients

Coronary Artery Bypass Grafting

- Still a controversial topic
- Moderately and morbidly obese patients have a higher rate of deep sternal wound infection, renal failure, prolonged postoperative hospital stay, and operative mortality after CABG.
- Guided by the patient's cardiac condition:
 - Unstable angina
 - Left main coronary artery disease

- Three-vessel disease
- Decreased left ventricle (LV) function
- Left anterior descending artery disease
- And by added risk of the coronary intervention and the potential consequences of delaying the noncardiac surgery for recovery after the cardiac intervention
- When indicated, patients undergoing coronary revascularization prior to major-risk noncardiac surgery do better postoperatively
 - Comparing this population of preoperatively revascularized patients with those medically managed suggests that the latter patient group had a mortality rate two times higher than the former.

Percutaneous Coronary Intervention

- Evidence suggests that patients who underwent angioplasty prior to elective noncardiac surgery had better outcomes.
- Strongly suggested that elective noncardiac surgery should be delayed for 4 to 6 weeks after PCI with stenting to allow for complete endothelialization of stent and completion of aggressive GP IIb/IIIa inhibitor antiplatelet therapy
- Drug-eluting stents may obviate the need for such prolonged systemic anticoagulation, thus allowing patients to undergo noncardiac surgery sooner.
- Complication rate of PCI in obese patients not reported different from that of nonobese individuals

Medical Management

- Perioperative use of β -blockers efficacious in reducing perioperative morbidity and mortality
- ACC/AHA guidelines recommend initiating β -blockers as early as possible prior to high-risk surgery and titrating the patient's heart rate to 60 bpm.
- Perioperative β -blocker use is recommended for patients with one or more Revised Cardiac Index risk factors despite a negative stress test and for patients with two minor risk factors, even with a good functional status and/or a negative noninvasive stress test.
- Prophylactic role may decrease intraoperative ischemia
- General consensus appears to be that if β -blockers are indicated perioperatively, they should be given not only intraoperatively but, more appropriately, they should be initiated during the preoperative period and—except in the presence of significant contraindications—should be continued through the postoperative period.
- Pharmacokinetics of β -blockers are affected by obesity, and there exists significant pharmacodynamic variability.
 - Dosage of β -blockers should be initiated based on lean body mass and then titrated until the desired clinical effect is achieved.

Intraoperative Considerations

Mechanics

- Surgical beds available that accommodate patients weighing as much as 500 kg
 - These patients require tremendous preparation on behalf of the operative staff
 - Even with appropriate beds, at high risk for falling during sudden motion

- Extremely dangerous to the patient and the supporting staff alike
 - Institution of a lift team
 - Availability of both “bean” bags and bed extensions in order to keep the folds of pannus stable are of the utmost importance to the surgical team
 - Finally, institutional investments in lifting equipment such as ceiling-mounted lifts and beds that oscillate and/or transform into chairs may be necessary to fully deploy the necessary mechanical advantage to care for the obese patient.

Rhabdomyolysis

- Rhabdomyolysis often described in obese patients
 - Generally follows prolonged operations
 - Presents as dark urine, representing muscle necrosis from groups on the flanks or buttock
 - Also termed *pressure-induced myoglobinuria*
 - More commonly noted among patients with diabetes mellitus
 - Generally attributed to lying on a hard surface
 - Frequently associated with an exaggerated lithotomy position in the operating room (OR)
 - Treatment:
 - Initiate aggressive hydration
 - Monitor creatine phosphokinase (CPK)
 - If CPK exceeds 5,000 IU/L, staff must initiate diuresis with mannitol and alkalize the urine with sodium bicarbonate
 - Acute renal failure may develop, but recovery is generally expected

Anesthetic Technique

- No unquestionable evidence that one or another anesthetic technique is best for MO
 - Total intravenous anesthesia (TIVA) and inhalational, regional, and combined general/epidural or general/spinal anesthetics have been used safely
- Selecting one technique over another will depend on:
 - Patient’s clinical status
 - Type of surgery the patient requires
 - Expertise of the senior anesthesiologist
 - Availability of institutional resources
 - Patient’s verbal and/or written requests and consent
- The most frequent and prominent risks of MO patient undergoing surgery listed are in Table 66.2.

TABLE 66.2

MOST FREQUENT AND PROMINENT RISKS OF THE MORBIDLY OBESE PATIENT UNDERGOING SURGERY

- Pulmonary aspiration of gastric contents
- Difficult mask ventilation and tracheal intubation
- Rapid development of hypoxemia after apnea
- Pulmonary atelectasis
- Hemodynamic instability
- Decreased ability to deal with the physiologic responses to stressful situations (i.e., hyperglycemia, hypertension, cardiac failure, arrhythmias, and myocardial ischemia)
- Delayed recovery
- Postoperative respiratory dysfunction
- Deep venous thrombosis

- Basic anesthetic goals should be:
 - Hemodynamically smooth and rapid induction
 - Rapid access and securing of the airway
 - Prominent attention paid to hemodynamic stability
 - A high level of analgesia to avoid increments in catecholamine activity
 - Rapid recovery and early ambulation

Postoperative Considerations

Pathophysiologic Principles for a Rational Therapeutic Approach

- Obesity has been likened to “exercise,” that is, a *constant* state of “exercise”
 - MO patient’s cardiovascular system continuously overdemanded, even at rest, mainly because of chronic intravascular volume overload, blood hyperviscosity, and sympathetic hyperactivity.
 - These are components of a “dysfunctional compensating mechanism”
 - Tries to satisfy the increased metabolic rate imposed by the excessive adipose tissue
 - Additional increase in CO promoted by any perioperative stress may markedly increase LV filling pressure, often exceeding threshold for pulmonary edema
 - Obstructive sleep apnea syndrome (OSAS) and obesity hypoventilation syndrome (OHS) may affect the right heart cavities.
 - Heart of MO patient may have less tolerance to any kind of cardiovascular stress:
 - Hypovolemia
 - Hypervolemia
 - Hypertension
 - Hypotension
 - At a higher risk of organ failure

Importance of Coupled Cardiorespiratory Function

- Ventilation/perfusion (V/Q) mismatch is a prominent mechanism that can trigger respiratory and subsequent cardiac dysfunction in MO surgical patient.
- In mechanically ventilated MO patients, airway pressure may be elevated.
- MO associated with volume and pressure overload
 - Volume load conditions may fluctuate according to patient positioning
 - Changing position from the “physiologically ideal” reverse Trendelenburg to the supine position can significantly increase venous blood return to the heart
 - Resultant augmentation of cardiac output, pulmonary capillary wedge pressure, and mean pulmonary artery pressure potentially increases the risk of acute heart failure.
 - Maneuver will increase airway pressure as well due to the increased weight of the chest
 - Compression of inferior vena cava (IVC) may reduce venous return to the heart
 - Thus a possible mechanism of hypotension
 - Can be avoided by lateral tilting OR table or ICU bed with a wedge under the patient
 - Similar to that during caesarean section to reduce the pressure of the gravid uterus on IVC

- Reverse Trendelenburg position significantly improves cardiac and respiratory performance
- Should be maintained during the entire perioperative period unless there is a particular contraindication

Drug Dosing

- Distribution, metabolism, protein binding, and clearance of many drugs are altered by the physiologic changes associated with obesity.
- Additionally patient's underlying disease may substantially influence the pharmacokinetic properties of drugs
- Net pharmacologic alteration in a patient is often uncertain, especially in the MO
 - Nevertheless, for a number of drugs used in the ICU, toxicity may occur if the patients are dosed based on their actual, rather than ideal or adjusted, body weight:
 - Digoxin
 - Aminophylline
 - Aminoglycosides
 - Cyclosporine
- For drug dosing, base drug calculations on ideal body weight (IBW) and adjust doses through meticulous monitoring

RESPIRATORY CONSIDERATIONS IN THE MORBIDLY OBESE

- Higher morbidity and mortality of hospitalized obese patients may be related to the increased pulmonary complications such as:
 - Atelectasis
 - Aspiration
 - Ventilatory failure
 - Pulmonary embolism
- There are significant physiologic changes associated with obesity:
 - Reduced lung volumes
 - Increased work of breathing
 - Alterations in control of breathing and gas exchange
- Factors involved include, but not limited to:
 - BMI
 - Patient's age
 - Duration of obesity
 - Fat distribution (central or peripheral)
 - Strong association of certain disorders such as OSAS, OHS, and pickwickian syndrome
- Obesity itself has a major detrimental impact on the respiratory system

Preoperative Considerations

Respiratory Disorders

- **Obstructive Sleep Apnea Syndrome:** MO the most common and major risk factor for OSAS
 - Prevalence in general U.S. population is 2% to 4%
 - Increases to 40% to 78% in MO
 - 80% to 90% of U.S. sleep apnea sufferers are undiagnosed
 - Detection of OSAS among obese surgical patients is vital for several reasons:

- Obese patients more sensitive to depressant effects of hypnotics and opioids
- Perioperative administration may lead to life-threatening respiratory complications in face of preexisting OSAS
- OSAS associated with difficult laryngoscopy and mask ventilation
- Obese patients have diminished expiratory reserve volume (ERV) with, consequently, reduced oxygen stores
 - Promotes faster development of desaturation after apnea
- If OSAS is present, these effects become exaggerated
- **Obesity Hypoventilation Syndrome:** Some obese patients suffer from a disorder characterized by chronic daytime hypoventilation
 - Individuals typically extremely obese, with a BMI >40 kg/m²
 - Likelihood of OHS increases as the BMI increases
 - OHS is associated with chronic daytime hypoxemia and hypercapnia
 - PaO₂ <65 mm Hg
 - Essential to find out if the obese patient suffers from chronic daytime hypoxemia
 - This is a better predictor of pulmonary hypertension and cor pulmonale than the presence and/or severity of OSAS
- **Pickwickian Syndrome:** Patients suffering from OHS who additionally have signs and symptoms of cor pulmonale are termed *pickwickian*—from the Charles Dickens novel, *The Pickwick Papers*
 - They have an increased perioperative morbidity and mortality
- **Respiratory Insufficiency:** Obesity per se not a common cause for chronic respiratory insufficiency
 - Significant respiratory dysfunction more common when chronic obstructive pulmonary disease (COPD) and obesity coexist
 - When respiratory insufficiency is present, impairment of gas exchange greater than expected from a simple summation of the alterations caused by each pathophysiologic process

Simple Obesity

- Obese patients with minimal or no coexisting pulmonary conditions classified as “simple” obesity patients
 - Pathophysiology of simple obesity consists of:
 - Alterations in daytime gas exchange and pulmonary function
 - May result from compression and restriction of the chest wall and diaphragm by excess adipose tissue
 - ERV and functional residual capacity (FRC) are particularly affected, being reduced to 60% and 80% of normal, respectively
 - If ERV decreases below the alveolar closing volume:
 - Airway closure occurs during normal tidal breathing
 - Dependent alveoli are relatively or completely underventilated
 - Consequently, V/Q mismatch, pulmonary shunt, and daytime hypoxemia results
 - May see, in formerly obese patients after massive weight loss, a marked improvement in the PaO₂ and alveolar-arterial oxygen gradient; improvement directly proportional to increase in ERV
 - Other mechanisms may further impair respiratory function
 - Sleep apnea in the obese is usually obstructive, secondary to airway narrowing from abundant peripharyngeal

adipose tissue, and an abnormal decrease of upper airway muscle tone during rapid eye movement (REM) sleep

- Hypopneic and apneic events lead to arousal from REM sleep, oxyhemoglobin desaturation, and sympathetic nervous system activation in response to hypoxemia
- May explain the strong association between OSA and systemic hypertension
- The precise pathophysiologic mechanism of OHS unclear
 - Of most importance is that vital capacity, reduced to 90% of normal in simple obesity, decreases to 60% of normal in OHS
 - Reflects profound and important decrement in lung volumes in OHS, as compared with simple obesity patients
 - One may see:
 - Marked increase in distal airway resistance
 - More profound abnormality in V/Q matching
 - More significant impact on the PaO_2
 - Larger A–a gradient in patients with OHS
 - Supine positioning further reduces lung volume and, as a result, increases the magnitude of all these alterations
 - Diaphragmatic function is also affected due to overstretching and cephalad displacement, resulting from increased intra-abdominal pressure
 - All of these factors combined may lead to chronic respiratory muscle fatigue and the chronic hypoventilation characteristic of OHS

Venous Thromboembolism

- Perioperative venous thromboembolism (VTE) occurs in 0.2% to 2.4% of bariatric patients receiving thromboprophylaxis
- American College of Chest Physicians Consensus Statement, obese patients in the ICU will generally fall into high or highest risk categories
 - Left untreated, risk of deep venous thrombosis (DVT) ranges from 20% to 80%
 - Risk of clinical pulmonary embolus (PE) ranges from 2% to 10%
 - Fatal PE occurs in 0.4% to 5% of patients
- The obese population in surgical ICU requires thromboprophylaxis
 - Best regimen is not clear
 - Multiple variables are worthy of mention in regard to this matter:
 - Venous stasis ulcers are more common in the obese, and in turn, are associated with DVT
 - Prophylactic inferior vena cava filters can be considered, but may also be technically difficult in the heaviest patients
 - Sequential compression devices (SCDs) generally recognized as useful adjunct but may be limited by patient size
 - Adequacy of pedal pumps not clear
 - Unfractionated or low-molecular-weight heparins both viable options
 - Precise dosing regimens and duration of dosage have emerged largely from uncontrolled trials
 - Reports in the bariatric literature that 40 mg of enoxaparin every 12 hours may provide better thromboprophylaxis than 30 mg every 12 hours

Evaluation and Optimization for Surgery

- In simple obesity, preoperative assessment of respiratory function similar to that indicated in lean and healthy patients
- More extensive pulmonary function tests and preoperative treatment may be necessary for the obese patient who smokes or has pulmonary symptoms
- Elements of the history and physical examination can be more important than preoperative testing
 - Obese patients who habitually snore and report daytime somnolence and/or have suffered breath interruptions during sleep should be evaluated with polysomnography, the definitive diagnostic test for OSAS
 - MO and symptoms of OSA are not, per se, indications for preoperative pulmonary function testing and room air arterial blood gas (ABG) analyses
 - Have failed to demonstrate predictive values and/or lead to optimization of postoperative management or outcomes of bariatric surgery patients, and are not routinely indicated
 - Room air pulse oximetry in both the upright and supine positions may be a useful, noninvasive method for screening patients for daytime hypoxemia
 - Supine room air $\text{SpO}_2 < 96\%$ may merit further investigation.
 - An elevated hematocrit may also be a clue of chronic hypoxemia
 - If clinical evidence of OHS present, ABG analyses indicated because:
 - Chronic daytime hypoxemia— $\text{PaO}_2 < 65$ mm Hg
 - Sustained hypercapnia— $\text{PaCO}_2 > 45$ mm Hg
 - The morbidly obese patient without significant obstructive pulmonary disease is diagnostic for this syndrome
 - Must differentiate whether MO coexists with either OHS or COPD
 - Combinations often result in chronic daytime hypoxemia and increase the chances for pulmonary hypertension, right ventricular hypertrophy, and/or right ventricular failure
 - Assessment of these pickwickian patients may require extensive testing to guide preoperative medical optimization and postoperative management as their morbidity and mortality rate is increased.
 - Unclear if appropriate to delay bariatric surgery for aggressive optimization of airway status and oxygenation with continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP) therapy
 - Two to 3 weeks may be necessary not only to maximize medical benefits
 - Three weeks of nightly CPAP treatment prior to bariatric surgery improved left ventricular ejection fraction and afterload in obese patients with coexisting heart failure.
 - Eight weeks of preoperative nasal CPAP therapy may be required to treat hypertension secondary to OSA.

Intraoperative Considerations

Airway Management

- In some circles it is still debatable whether MO should be considered a risk factor for difficult airway management.
- Neither absolute obesity nor BMI is associated with problematic intubation in MO

- Only a large neck circumference and a Mallampati score of 3 or more were significantly correlated with a high probability of problematic intubation.
- Preoperative airway assessments similar in both morbidly obese and lean patients
- Whether or not morbid obesity is considered a risk factor for intubation, issues related specifically to the patient's BMI that impact airway management include:
 - Preoxygenation
 - Positioning
 - Immediate availability to adequate resources, both technical and human
 - Technical: special laryngoscopes, blades, tracheal tubes, oro- and nasopharyngeal cannulae, intubating laryngeal airway [ILA], laryngeal mask airway (LMA) Fastrach, Combitube
 - Human: personnel sufficient in both number and expertise
- In perioperative setting, one never knows when an emergent tracheal intubation or reintubation may be necessary or when an unpredicted difficult mask ventilation and difficult tracheal intubation combination may appear.
- Latter is a common situation in MO patients suffering from OSAS or OHS
- Presence of any of these urgent/emergent events will likely result in a life-threatening, although preventable/treatable, respiratory misadventure.
- American Society of Anesthesiologists algorithm for difficult airway management and indications for conscious tracheal intubation should be considered for both obese and lean patients.
- If conscious intubation is indicated, remember that most episodes of gastroesophageal reflux, and the greatest potential for pulmonary aspiration of gastric contents, occur from and during "bucking" on an endotracheal tube.
 - Appropriate preparation of the patient is crucial.
- Meticulous patient explanation, a low infusion rate of remifentanyl (0.05 $\mu\text{g/kg}$ IBW/minute) to avoid loss of response to verbally required active ventilation, and/or local anesthesia—such as bilateral blockade of the internal branch of the glossopharyngeal nerve—are most effective and safest induction alternative.
- Prudent to treat morbidly obese patients with prophylactic measures against gastric aspiration, such as cimetidine, ranitidine, Bicitra, and/or metoclopramide
 - Timing of administration of these agents is of great significance

Preoxygenation and Position

- Hypoxemia during induction of general anesthesia in obese individuals is a concern for anesthesiologist and/or intensivist
 - Patients may experience rapid arterial oxygen desaturation after apnea
 - Compared with supine-positioned, preoxygenation in the 25- to 30-degree head-up position with 100% oxygen for 3 minutes achieves higher oxygen tensions—more time and better oxygenation for intubation and airway control
 - Preoxygenation in the 30-degree reverse Trendelenburg position provides a longer, safer apnea period than the 30-degree semi-Fowler and supine positions
 - Recommended as the optimal position for induction of general anesthesia in obese patients

- The head-up position results in an unloading of the intra-abdominal contents from the diaphragm
- Pulmonary compliance and FRC increase, and oxygenation returns toward baseline values, as compared to same patients who were placed supine
- Prior to induction of general anesthesia in any setting—OR, ICU, or in hospital ward—obese patient should be positioned with pillows under the shoulders
 - With the head and upper body elevated in a semirecumbent or reverse Trendelenburg position
 - "Ramped" position strongly recommended in MO, to improve pulmonary function, oxygenation, cardiovascular function, conditions for mask ventilation, laryngoscopic view, and tracheal intubation
 - Extremely obese patients should not lie completely flat
 - Upper body constantly elevated at 25 to 30 degrees in perioperative period

Atelectasis

- In perioperative setting, reduction of chest wall and diaphragmatic muscle tone following the induction of general anesthesia and skeletal muscle relaxation impairs oxygenation.
- In simple obesity, net effect may reduce ERV and FRC to <50% of preinduction values
- Reduction of ERV and FRC increases exponentially with increasing BMI
 - The combination of these factors predisposes MO patient to suffer atelectasis during anesthesia and surgery and in the postoperative period.

Mechanical Ventilation: Invasive Positive Pressure Ventilation

- Initial tidal volume based on ideal body weight rather than actual body weight
- Adjustments made according to airway pressures and appropriate respiratory monitoring
- Lung-protective strategy of smaller tidal volumes (6 to 8 mL/kg IBW) and adequate positive end-expiratory pressure (PEEP)/CPAP to prevent airway closure and shear trauma important
- Technique may result in decreased cardiac output, fluid loading will correct the problem
- To improve ventilator–patient synchrony and reduce airway pressure, patient's spontaneous respiratory effort should be maintained and assisted with pressure support ventilation

Tracheal Extubation and Intrahospital Transfer

- MO associated with prolonged mechanical ventilation, extended weaning periods, and longer ICU and hospital lengths of stay
- Strategies suggested for facilitating the weaning process include:
 - Positioning of the patient in a 45-degree reverse Trendelenburg position to optimize lung mechanics, increase tidal volume, and reduce respiratory rate
 - BiPAP postextubation
 - If hemodynamic stability achieved, trachea should be extubated with patient's upper body elevated between 30 and 45 degrees

- Transfer from OR while in a semirecumbent or tilted reverse Trendelenburg position
- Recovering patient should be kept in a head-up position in order to minimize intrapulmonary shunting
- On days 1 and 2 postoperatively, a change from the semirecumbent to the supine position may result in significant decreases in PaO_2
- Obese patients should convalesce in the semirecumbent position while receiving supplemental oxygen if possible
- Intrahospital transfer of a morbidly obese patient is best and most safely accomplished if the patient remains in his or her own hospital bed

Ideal FiO_2 (Supplemental Oxygen)

- One uses the highest concentration of oxygen necessary to maintain life
 - But high oxygen concentrations have often been associated with atelectasis formation and recurrence
 - Using as low an oxygen concentration as possible has been recommended
 - Supplemental oxygen carries clear benefits for patients, especially the MO
 - Evidence suggests that an FiO_2 of 0.8:
 - Ensures appropriate oxygenation without increasing the risk of absorptive atelectasis
 - Reduces the incidence of postoperative nausea and vomiting (PONV) in patients with an increased risk of gastric aspiration
 - Improves the host's defense mechanisms against infection
 - Improvement seen in wound site and in respiratory system
 - Not proven in MO surgical patients, but possible benefit should not be ignored
 - Ideal FiO_2 should, then, result from a balance between a supplemental quantity of oxygen that is sufficient enough to avoid hypoxemia, reduce postoperative infections, and reduce PONV, but not so high as to facilitate the development and maintenance of atelectasis
 - Our recommendation is:
 - Deliver 100% oxygen before induction of anesthesia to retard the development of hypoxemia after apnea
 - Once tracheal intubation is confirmed, reduce FiO_2 to 0.8, if possible, according to respiratory monitoring

Monitoring

- FRC is reduced in the morbidly obese patient
 - If it drops below closing capacity dependent airways will collapse, promoting deterioration of gas exchange due to:
 - V/Q mismatch
 - An increase in the shunt fraction
 - An increase in the alveolar–arterial oxygen gradient
 - The more obese the patient, the greater the alveolar–arterial gas difference
 - MO patient will not be able to reach the same $\text{PaO}_2/\text{FiO}_2$ ratio as the normal-weight patient
 - MO leaves PaCO_2 values unaffected if the patient does not suffer from either OHS or pickwickian syndrome
 - ABG analysis increasingly important as it reflects the respiratory status more accurately than expiratory gas measurements

- MO, comorbidities, and the type of surgery should influence decision of which monitoring devices need be used
 - Routine noninvasive monitoring sufficient in simple cases
 - Presence of OSAS, OHS, pickwickian syndrome, daytime hypoxemia, and/or associated COPD should alert the anesthesiologist or intensivist to modify intra- and postoperative respiratory monitoring and narcotic use
 - Good practice demands obtaining SpO_2 or ABG analysis in the awake obese patient prior to any premedication for a reference
- Anesthesia and CMV will almost always have a negative impact on oxygenation and alveolar ventilation
 - Inadequate oxygen delivery may be reflected in increased, and sometimes unexplained, postoperative complications
 - Monitoring includes SpO_2 , respiratory rate, cardiac rhythm monitoring, and blood pressure measurement in the immediate postoperative period
 - With decreasing SpO_2 , ABG analysis and a chest x-ray may be useful
 - Sudden onset of respiratory distress, chest pain, and dyspnea may indicate cardiac event or PE
 - PE is major cause of mortality in 30-day postoperative period after bariatric surgery
- Increased risk of respiratory-related complications in postoperative period:
 - Can be as high as 3% for critical respiratory events in obese patients
 - Suggests importance of anesthetic and analgesic management on the speed and quality of recovery of CNS function
 - Combined thoracic epidural/general anesthesia techniques may be quite suitable in these major cases
 - Patients with confirmed or suspected OSAS, OHS, and pickwickian syndrome require more stringent observation
 - Postoperatively, this warrants prolonged surveillance in pulmonary acute care unit or admission to the ICU, especially for surgery lasting more than 4 hours and/or with critical comorbidities
 - Main reasons for ICU admission in MO patients are disturbances in pulmonary gas exchange
 - Preventable with prolonged one-on-one surveillance combined with meticulous medical care

Postoperative Considerations

Hypoxemia and Associated Postoperative Respiratory Disorders

- After major open abdominal surgery without postoperative oxygen supplementation, even normal patients experience hypoxemia ($\text{SpO}_2 < 90\%$)
- POD # 1 following open bariatric surgery, 75% of MO had $\text{PaO}_2 < 60$ mm Hg
 - Usually persisted and worsened in the following days
 - Explanation most frequently utilized is atelectasis
 - Pulmonary aspiration of oral or gastric secretions, pneumonia, acute lung injury, and acute respiratory distress syndrome should also be considered

- Tracheal tube displacement is mechanism of perioperative hypoxemia
 - Abdominal insufflation and OR table position to Trendelenburg position cause cephalad movement of the diaphragm, and can lead to migration of an initially correctly positioned endotracheal tube
 - In MO patients undergoing laparoscopy can result in right endobronchial intubation and intraoperative hypoxemia
 - Should be considered in intubated ICU patient because of frequent, necessary changes in patient's position

Atelectasis

- Atelectasis is a major cause of gas exchange impairment under anesthesia
 - Alterations in respiratory mechanics promote atelectasis, such as:
 - Decreased chest wall and lung compliance
 - Reduction in functional residual capacity
 - Conscious MO patients have alterations of their respiratory mechanics
 - They are particularly prone to intra- and postoperative atelectasis
 - During general anesthesia and in the immediate postoperative period MO likely to have significant impairment of pulmonary gas exchange and respiratory mechanics
 - Even before induction of anesthesia the MO had more atelectasis than nonobese patients
 - After tracheal decannulation, atelectasis increased in both groups
 - Significantly more severe in MO
 - Finally, 24 hours postoperatively, complete reexpansion of lung occurred in nonobese patients, while amount of atelectasis remained unchanged in MO
 - All possible measures to prevent/reduce severity and duration of atelectasis in this patient population are vital (Table 66.3)
 - Some use non-invasive positive pressure ventilation (NIPPV) routinely in postoperative care of MO patients after extubation
 - Others reluctant because of fear of anastomotic disruption
 - There are no data to support this concern
 - MO patients use some form of NIPPV—CPAP or BiPAP—chronically for treatment of OSA
 - Postoperatively these patients at risk for prolonged depressant effects of drugs administered during surgery
 - May promote airway collapse not only in MO patients with diagnosed OSAS
 - But also in previously undiagnosed MO patients
 - Airway collapse most frequent during REM sleep
 - Brief in initial postoperative period
 - Significantly longer on third to fifth postoperative nights
 - Risk increases even days after surgery
 - Means that SpO₂ monitoring and O₂ must be administered during this dangerous period
 - Prospective study of 1,067 bariatric patients evaluating risk of developing anastomotic leaks and pulmonary complications after gastric bypass
 - 420 had OSAS and 159 were dependent on CPAP
 - Were 15 major anastomotic leaks
 - Two occurred in CPAP-treated patients

TABLE 66.3

VITAL MEASURES TO PREVENT OR REDUCE THE SEVERITY AND DURATION OF ATELECTASIS IN THE OBESE PATIENT

- Place patients in the semirecumbent position and, if possible, out of bed in a chair as tolerated, as this maneuver may increase functional residual capacity.
- Provide effective analgesia, which will allow early and effective mobilization, cough, and excellent tolerance to physiotherapy.
- Institute aggressive incentive spirometry.
- During the first 3 postoperative days, deliver humidified supplemental oxygen, but avoid inspired fractions higher than 0.8. Supplemental humidified oxygen will not reduce atelectasis, but will facilitate respiratory secretion clearance, and will prevent hypoxemic episodes in efforts to improve the host's defenses against bacterial infections.
- During surgery or postoperatively in intubated patients, instituting positive end-expiratory pressure is probably effective in increasing functional residual capacity via recruitment of atelectatic regions of the lung. Applying vital capacity maneuvers (also known as recruitment maneuvers) may also reduce the incidence and/or severity of atelectasis while improving the quality and effective time of alveoli recruitment.^a
- Noninvasive positive pressure ventilation can be used to avoid intubation in selected patients.

^aData from Magnusson L, Spahn DR. New concepts of atelectasis during general anaesthesia. *Br J Anaesth.* 2003;91:61–72.

- No correlation between CPAP utilization and incidence of major anastomotic leakage demonstrated
- No episodes of pneumonia diagnosed in either group
- Conclude that CPAP is useful modality for treating hypoventilation after gastric bypass surgery without increasing the risk of developing postoperative anastomotic leaks
- BiPAP used prophylactically during first 24 hours postoperatively
 - Significantly reduces pulmonary dysfunction after gastropasty in morbidly obese patients
 - Accelerates reestablishment of preoperative pulmonary function

Pulmonary Aspiration

- Topic remains controversial
 - Still recommended taking precautions against acid aspiration
 - Massive pulmonary aspiration in MO patients a rare event in current anesthesia practice
 - Occurrence of unwitnessed microaspirations in the postoperative period difficult to assess because of diagnostic problems observed within this population
 - While massive aspiration uncommon, following cautionary list should be noted:
 - While in bed, patient must be adequately positioned in a semirecumbent or reverse Trendelenburg position at all times.
 - The care team must be ready for bag-valve-mask ventilation and tracheal intubation in a ramped position and have technical and adequate human resources.

- Drug dosing must be meticulously titrated to clinical response, based on IBW.

Radiographic Evaluation and Complications

- Radiographic evaluation of the obese patient is complicated
 - Made difficult by weight limitations of modern scanners
 - Patient's inability to cooperate with transfer
 - Tomographic tables now routinely handle patients weighing 400 lb (182 kg)
 - In absence of excellent radiographic capabilities, MO patients may require surgical exploration
 - Both patients and surgical team members must assume those additional risks

Venous, Arterial, and Nutritional Access

- When peripheral access is inadequate, the point of choice may be the internal jugular vein
 - Has fewer complications and requires fewer conversions to different locations
 - Arterial access generally recommended as noninvasive blood pressure cuffs can give inaccurate measurements in this patient population
 - Nutritional access in critically ill obese patients is imperative
 - Despite their weight, these patients can be relatively malnourished.
 - Obese patients preferentially mobilize protein instead of fats compared to lean patients.
 - If the patient requires reoperative interventions, a feeding gastrostomy or jejunostomy can be placed.
 - Percutaneous gastric access can be extremely difficult, especially in a patient following a gastric bypass procedure.

Analgesia

- **Overview:** Acute pain can result in reduced:
 - Tidal volume
 - Vital capacity
 - Functional residual capacity
 - Alveolar ventilation
 - These factors contribute to:
 - Atelectasis
 - V/Q mismatch
 - Hypoxemia
 - Hypercapnia
- Pain-related muscle splinting interferes with the patient's ability to:
 - Cough
 - Clear secretions
 - Efficiently participate in chest physiotherapy
- Efficacy of analgesia must be measured by the ability to cough and move without pain or discomfort, and not only by the absence of pain while in a resting state
 - All the potential consequences of poor pain control are of outstanding importance in the MO surgical patient.
 - Early mobilization without discomfort considered a major anesthetic target
 - DVT and PE are some of the most frequent causes of mortality during the first 30 postoperative days
 - Sufficient and safe postoperative pain control would result in a more effective and tolerable respiratory physiotherapy.
- **Analgesic Strategies (IV, Thoracic Epidural, Multimodal Approach):** Uncertainty remains as to the superiority of one pain treatment modality versus another
 - Open versus laparoscopic surgical techniques
 - Personal skills and experience may influence the patient's and anesthesiologist's choice of pain treatment
 - Postoperative epidural analgesia, using either local anesthetics or opioids
 - May be the route of choice for postoperative analgesia in MO patients as it:
 - Allows a more vigorous cough and chest physiotherapy
 - Better diaphragmatic function
 - More powerful leg exercise
 - Earlier ambulation and discharge from hospital
 - These advantages may lead to a more benign postoperative course
 - Other populations who had earlier walking, earlier feeding, had a lower incidence of pulmonary alveolar collapse, and fewer thromboembolic complications
 - Thoracic epidural analgesia (TEA) improved by adding opioids, possibly epinephrine, to epidural solution
 - TEA may be particularly beneficial in the pathophysiologic context of MO:
 - LV work conditions (both preload and afterload) may be improved by the sympathetic blockade
 - Reducing the chances for developing heart failure
 - Myocardial oxygen balance may be improved
 - Due to a decrease in oxygen demand and augmented myocardial perfusion induced by coronary vasodilatation, both secondary to sympathetic block
 - Reducing the risk of ischemia
 - Improved efficacy and safety have been shown when IV patient-controlled anesthesia management includes:
 - Adjunct analgesics such as nonsteroidal anti-inflammatory medications
 - Local anesthetic wound infiltration in a multimodal approach

CHAPTER 67 ■ THE GERIATRIC PATIENT

GENERAL

- In 2000 U.S. census, those 62 years of age and older represented 14.7% of the population
- Those 85 years of age and older numbered 4,239,587, or 1.5% of U.S. population
 - Increase of 1.2 million more than found within the similar population range 10 years earlier
- In 2000, life expectancy beyond the age of 65 years was:
 - Nearly 19 years for a woman
 - 16 years for a man
 - Predictions for those 85 years old were 7 and 6 years, respectively
- At dawn of the 20th century
 - Elderly population in United States was 4%, or 3.1 million people
 - Presently it is 35 million people
- Based on advances in public health and medications and techniques of acute medical care provided to those born in the 20 years after World War II, 70 million individuals will be in “elderly” subgroup by 2030
 - At that time, those 65 years and older will compose 26% of the population of Florida
- In 2005, spending by Medicare for those older than 65 years totaled \$342 billion
 - Representing 17.1% of the total of \$2 trillion spent nationwide for health care
 - Intensive care consumes 4% of national health care expenditures
 - During last 6 months of their lives, 11% of Medicare recipients spend 8 or more days in the intensive care unit (ICU)
 - Various studies documenting ICU occupancy by those older than 65 years old note that this ranges from one-quarter to one-half of the available beds

CARDIOVASCULAR (CV) DISEASE IN THE ELDERLY

- Approximately 35% of all deaths in the United States attributable to one of several manifestations of CV disease:
 - Coronary artery disease and other conditions that involve the myocardium
 - Hypertension
 - Arteriosclerosis of the central and peripheral arterial tree and cerebral vascular system
 - Three-fourths of these deaths are directly attributable to cardiac cause
 - Proportion is higher in more aged population
 - CV disease manifests itself as a complicating cofactor in the management of *any* older person’s serious illness

- Although only 6% of the U.S. population is 75 years of age or older
- Such individuals account for 30% of all myocardial infarctions and 60% of the infarction-related deaths

Acute Coronary Syndrome in the Elderly

- One of the underpinnings of any strategy is that of expeditious implementation
 - The more quickly the intervention is begun, the greater the mass of myocardial tissue preserved and the greater number of lives saved.
 - Rapid restoration of coronary blood flow is the major goal of treatment for STEMI (ST-segment elevation myocardial infarction)
 - Decrease in mortality of 25% with reperfusion therapy has been demonstrated
 - From identification of STEMI, recommended that the infusion of thrombolytics begin within 30 minutes, or that the dilating balloon be inflated within 90 minutes
 - Percutaneous coronary intervention (PCI) is the preferred mode of treatment for STEMI, as long as the time constraints are met.
 - PCI yields lower mortality in the elderly population than thrombolysis
 - More benefit found as age progressively advanced, although possibly at the risk of a slightly increased rate of major bleeding events
 - In the management of non-ST-segment elevation MI (N-STEMI)
 - Early invasive strategy with catheterization and revascularization (when warranted) significantly benefits those older than 65 years of age
 - Early invasive strategy led to a significant increase in in-hospital major bleeding (16.6% vs. 6.5%; $p = 0.009$) and blood transfusion (20.9% vs. 7.9%; $p = 0.002$) in the patients older than 75 years.

Cardiomyopathy

- Decompensated heart failure (HF) is frequently encountered in management of critically ill elderly
 - In the United States, 5 million persons suffer from heart failure
 - More than 50,000 new cases diagnosed yearly
 - Over 80% of the individuals with heart failure are older than 65 years of age
 - Symptomatic heart failure *by itself* carries a dismal prognosis, with a median survival of 1.7 years for men and 3.2 years for women

- Common causes for HF in the elderly include:
 - Coronary artery disease and hypertension
 - Diabetes mellitus
 - Valvular disease (especially aortic stenosis and mitral regurgitation)
 - Cardiomyopathies other than ischemic

Dysrhythmias

- Dysrhythmias are frequent in the elderly patient, including those who manifest no other overt cardiovascular abnormalities.
- For example, the so-called *lone atrial fibrillation*
 - With advancing age, sinus node and conduction system integrity deteriorate, with gradual replacement of cardiac pacemaker cells by collagen and elastic tissue
 - The occurrence of atrial fibrillation (AF) increases with age, carrying an increased risk of stroke and death in those older than 60 years, even in the absence of other cardiac abnormalities.
 - No clear survival advantage to either rate or rhythm control in AF
 - But rate control strategy did appear to manifest some advantages in the area of medication side effects
 - Choices for immediate rate control include β -blockers and calcium channel blockers
 - Amiodarone or digoxin may be used in those with heart failure in the absence of an accessory pathway
 - Digoxin is not recommended in such patients, as it may precipitate *profound* tachycardia via the accessory pathway, with heart rate nearing 300 bpm, leading to rapid cardiovascular collapse
 - In acute hemodynamic instability, recovery of sinus rhythm with biphasic DC cardioversion after sedation is appropriate
- No one-size-fits-all solution to the question of anticoagulation
 - Well demonstrated to reduce the incidence of stroke related to AF
 - Equally well demonstrated is the extent to which anticoagulation is *underused* in the elderly, presumably because of concern for bleeding risk in this accident- and fall-prone population, and inadequate awareness of the extent to which AF warrants anticoagulation to minimize the risk of AF-associated stroke.
 - For the long-term patient, anticoagulation is best accomplished by using vitamin K antagonists for those at highest risk of severe stroke (>75 years), and aspirin for those elderly (<65) with less stroke risk.
 - In the 65 to 75 age range, either will suffice.
 - Target international normalization ratio (INR) of 2.0 to 3.0 is recommended for those receiving vitamin K antagonists
 - Maintenance of long-term anticoagulant regimens have limited applicability to the patient who suffers a critical injury or illness, and rapid normalization of INR may be warranted.
 - Quickly reversible heparin may be a better choice.
 - AF that persists beyond 48 hours mandates anticoagulation for 2 weeks

- Complex ventricular dysrhythmias and ventricular tachycardia (VT) are difficult management problems.
 - Sudden cardiac death a product of untreated VT degenerating into ventricular fibrillation (VF), followed by asystole
 - Defibrillation for VF provides the optimal chance of survival if provided within 3 minutes
- With advancing age comes increase in conduction system disease, often mandating permanent pacemaker (PPM)
- In 1990, implantation rate for cardiac pacemakers was 329 devices per million patients
- In 2002, the rate had risen to 612 per million
- Mean age of implanted patients was 75.1 years

PULMONARY DISEASE

- Healthy elderly individuals said to have significantly lower PaO_2 for a given FiO_2 , compared to equally healthy younger counterparts
 - Traditional teaching has proposed the following formulae:
 - PaO_2 (mm Hg) = $104.2 - (0.27 \times \text{age})$
 - $\text{PaO}_2 = 100.1 - 0.325 \times \text{age}$ (years)
 - $\text{PaO}_2 = 109 - 0.43$ (age)
 - More recent studies have yielded varying results

NUTRITIONAL ISSUES

- Malnutrition/undernutrition a common companion of elderly individuals
 - Frequent complicating factor in efficient and successful management of elderly ICU patient
 - The natural decline in energy expenditure with age begins at about age 30
 - Accompanies age-related increase in body fat-to-protein ratio
 - In elderly nursing home patients incidence of undernutrition can approach 85%
 - Mortality considerably higher in malnourished elderly patient, compared to the nutritionally replete
- Undernutrition imposes considerable burden on marginally compensated geriatric patient
 - Conditions known as protein-energy malnutrition (PEM) and micronutrient deficiency complicate treatment of several conditions seen in ICU:
 - The contribution of gastrointestinal tract nonintegrity to multiorgan system failure
- Other common cardiovascular, pulmonary, and infectious issues
 - Wound healing is impeded by a poor nutritional state
 - Development of decubitus ulcers more common in malnourished elderly
 - Successful management is decidedly more difficult
 - PEM patients are at increased risk for serious complications while in hospital:
 - Slower recovery
 - Poorer functional status at discharge
 - Higher rates of mortality after discharge
- Obtaining patient's weight *immediately on admission* an obvious step in assessing nutritional condition

- Calculation of the Quetelet body-mass index (BMI) is helpful to standardize weight to height, providing a relatively standardized estimate of body fat:
 - BMI = weight (in kg) divided by height (in m²)
 - Department of Health and Human Services defines:
 - Normal BMI within the range of 18 to 24.9
 - BMIs <8 being underweight
 - Overweight range being 25 to 29.5
 - BMI >30 being obese
 - In the geriatric population:
 - BMI <20 is predictive of nearly 50% 1-year mortality
 - A stronger predictor of mortality than is diagnosis
 - In general, use of BMI in elderly is suspect, regardless of the height measurement used
 - There are few normal BMI data that specifically describe those older than 65 years
- Several easily measured laboratory parameters reflective of nutritional status on admission:
 - Albumin
 - A product of hepatic metabolism
 - Synthesized ultimately from ingested or infused nitrogenous precursors in the presence of adequate caloric support
 - Held that the serum albumin level is reflective of the nutritional state
 - Various factors influencing serum albumin levels make it only vaguely reflective of overall nutritional status
 - ROC (receiver operating characteristic) curve rating of 0.58 compared to the clinical subjective global assessment tool
 - Substantial decline in serum albumin concentration is accurately predictive of mortality and worse outcome among the elderly
 - Half-life of albumin is 18 to 19 days, making it less than optimal in monitoring metabolic and synthetic functions
 - Alternatives include prealbumin and retinol binding protein
 - Former has half-time of 2 days
 - Not affected by age but is elevated with steroid use
 - Latter has a half-time of 12 hours
 - Decreases slightly with age
 - Elevated in the setting of acute liver injury
- Critical illness induces substantial catabolism and resting energy expenditure (REE) rises during the first 2 weeks of this state
 - Mobilization of nitrogen stores a component of associated inflammatory response to physiologic insult
 - Total energy expenditure (TEE) may rise to 40 to 50 kcal/kg/day in critically ill, septic, or trauma patients
 - Repletion most difficult without correcting the underlying inciting process
 - Traditional guidance recommends 25 kcal/kg/day of nutritional support
 - With additional protein supply of 1.2 to 1.5 g/kg/day based on *usual* body weight
 - Obese individuals warrant feeding based on *ideal* (IBW), rather than usual, body weight:
 - **Men:** IBW (kg) = 50 + 2.3 kg per inch over 5 ft
 - **Women:** IBW (kg) = 45.5 + 2.3 kg per inch over 5 ft
 - Greater accuracy achieved using Harris-Benedict equations to determine REE as a guide to calculation of nutritional needs:
 - **Men:** REE = 66.5 + (13.75 × weight in kg) + (5.003 × height in cm) – (6.775 × age in years)
 - **Women:** REE = 655.1 + (9.563 × weight in kg) + (1.850 × height in cm) – (4.676 × age in years)
 - May be insufficient in the critically ill geriatric patient in the throes of the inflammatory response
 - Protein supplementation at a rate of 2 g/kg recommended for the most critically ill, catabolic patients
 - Enthusiastic overprovision of macronutrients in a misguided and vain attempt to thwart and correct inflammatory catabolism
 - Leads to a host of complications and considerable morbidity for which geriatric patient may be unable to compensate
 - Measurements of energy expenditure performed at frequent intervals are even more strongly advisable, since energy requirements fluctuate with time and medical condition
- Most studies show that enteral nutrition preferred because of:
 - Purported preservative effects on intestinal mucosal integrity
 - Cost issues
 - Risk exposure to the patient, both infectious and mechanical, associated with placement of flexible nasointestinal feeding tube versus central venous line (CVL) for parenteral nutrition
- Statement is the source of endless controversy

RENAL CONSIDERATIONS

- Deterioration of renal function in a critically ill patient has a dramatic impact on survival.
 - Acute renal failure (ARF) carries mortality of nearly 30% in general ICU population
 - Decline of renal function of lesser severity impacts mortality significantly and more so in geriatric population
 - Chance for at least partial renal functional recovery after critical illness-related ARF is >90% among those alive a year after illness
- A gradual deterioration of renal function, beginning at age 30 years
 - When sixth decade reached deterioration *generally* continues with a very wide bell curve of distribution
 - Decrease in glomerular filtration rate (GFR) of 30% to 40% by age 80
 - Individualize each assessment of GFR by using the Cockcroft-Gault formula to generate more accurate estimate of function based on weight, age, and serum creatinine (S_{cr}):
 - Creatinine clearance = [(140 – age) (weight in kg)] / (72 × S_{cr}) (arithmetic result × 0.85 = clearance for female patients)
 - Formula provides a snapshot of function at a given time
 - Most useful if calculated on ICU arrival and daily thereafter
 - S_{cr} may be increased by excessive muscle breakdown due to rhabdomyolysis, critical illness, or medications
 - Other laboratory surrogates of GFR are:
 - Measurement of cystatin C
 - MDRD (modification of diet in renal disease) equations

- If GFR remains uncertain, urine collection for measurement of creatinine clearance can be done with fair accuracy using at least an 8-hour urine collection period
- 24-hour collection is preferred in critically ill patients
- Sodium excretion and reabsorption declines in efficiency, with those older than 60 years requiring considerably more time to achieve homeostasis in the face of sodium overload or deprivation
- Rectification of acid-base perturbations similarly deficient
- Management of deteriorating renal function requires accurate diagnosis of the inciting cause, while addressing complicating or resultant metabolic derangements and preventing further insult:
 - Acute kidney injury occurs in as many as 67% of ICU admissions as identified by RIFLE (risk, injury, failure, loss, end-stage) criteria
 - Initial evaluation must include:
 - Performance of a physical examination that may reveal an occluded urinary catheter causing an enlarged bladder
 - Hypovolemia, both absolute, as in severe dehydration, and relative, as in sepsis, must be aggressively corrected with appropriate fluid and blood products.
 - Invasive monitoring is warranted in this population of patients with compromised reserve.
 - Dosage adjustment of potentially nephrotoxic medications is mandatory.
 - Loop diuretics, mannitol, and natriuretic peptides have largely been demonstrated to be of no use in preventing incipient acute renal failure.
 - Role of N-acetylcysteine and bicarbonate to minimize deleterious effect of radiocontrast medium on renal function in critically ill individuals remains controversial.
 - Should generally be used in any elderly patient receiving contrast
- Arterial blood gas analysis a convenient tool
 - Quickly performed
 - Allows frequent measurement of hemoglobin, base deficit, and lactate
 - Latter two values are powerful indicators of resuscitation status and, when elevated, predict increased mortality in the elderly population
 - In elderly trauma patients mortality is decreased from 54% to 34% ($p < 0.003$) by:
 - Institution of a protocol of trauma team activation
 - Early noninvasive and subsequently invasive monitoring for resuscitation of all patients older than age 70 years with an injury severity score (ISS) > 15 , even with nonworrisome initial vital signs and fairly minor injuries
- Certain patterns of injury are found in geriatric patients.
 - Traumatic brain injury (TBI) afflicts the elderly with extraordinary severity.
 - High mortality leaves fewer survivors, most of whom suffer debilitating sequelae.
 - In 2003, there were 90,000 emergency department visits involving TBI in those older than 65 years, of whom 38.4% died.
 - Some series document mortality rates for severe TBI in those older than 55 years of age as high as 80%.
 - Initial neurologic examination of an elder with significant intracranial injury may be deceptively normal.
 - Cornerstone of TBI treatment is:
 - Maintenance of cerebral oxygenation by ensuring adequate oxygen content and cerebral perfusion pressure (CPP)
 - Guided by data derived via invasive intracranial monitoring devices that are inserted based on specific indications
 - CPP of 70 mm Hg is considered the standard but has not been rigorously tested specifically in the elderly as it affects outcome
 - Cerebral autoregulation in the elderly is subject to the same influences as those that affect the younger individual
 - Abundance of comorbidities, such as untreated hypertension, may have acclimated the cerebral vasculature to a new baseline, making invasive cerebral monitoring even more critical in ensuring adequate perfusion for the aging brain
 - Cervical spine injury common in geriatric trauma patient
 - Plain radiographs may be unrevealing of fracture or difficult to interpret because of age-related bony changes obscuring acute pathology
 - Fracture of upper cervical spine more common in elderly than in younger individuals
 - More likely to be unstable
 - Helical computed tomography (CT) is superior to plain radiographs to identify cervical spine injury in this population
 - One must be mindful of the greater likelihood that cervical injuries in elderly often occur in arthritis-prone superior vertebrae—notoriously difficult to depict on plain films—and consider CT evaluation of virtually all geriatric trauma patients in whom even subtle symptoms, history, or mechanism of injury suggest cervical injury, regardless of the initial examination findings or protocol-based decision-assisting algorithm that suggest the safety of less aggressive investigation.

ASSESSMENT AND MANAGEMENT OF TRAUMATIC INJURIES

- In 55 to 64 age group, unintentional injury the sixth leading cause of death in 2003
 - In those older than 65 years, nearly 35,000 deaths were attributed to trauma
 - Most serious injuries caused by falls
 - Occurrence rising dramatically as age advances into 60s and beyond
 - From a standing or even sitting position, imparting an apparently trivial amount of kinetic energy to frail tissue may result in fatal injury, disproportionately accounting for half the trauma-related deaths when compared to those of younger people.
 - Most remaining significant traumatic injuries to elderly involve motor vehicles, either as vehicle occupants or as pedestrians
 - Small but persistent incidence of injury and death from penetrating trauma in elderly, $< 1\%$ in those older than 75 years
- Sequential measurement of routine hematology tests, even in stable patient, may show unsuspected hemorrhage.

- Traumatic rib fractures impose substantial morbidity.
 - Those older than 45 years of age with more than four fractures are particularly affected.
 - In patients traditionally defined as *elderly*—those older than 64 years—rib fractures profoundly affected morbidity and mortality.
 - Longer length of stay in the ICU
 - More frequent pneumonia
 - Overall mortality rate of 22% versus 10% ($p < 0.001$) in those less seriously affected
 - Rates of mortality and pneumonia both increased with each additional rib fracture
 - Epidural analgesia would appear to be the ideal technique to alleviate the pain associated with rib fractures to optimize pulmonary status and is successful in nongeriatric adults.
- Management of abdominal trauma follows pathways similar to those for younger patients.
 - Findings on physical examination indicating serious abdominal pathology can be subtle.
 - Especially when complicated by distracting orthopedic or mild head injury
 - Liberal use of CT scanning is strongly recommended if mechanism of injury, external abdominal findings such as a seat belt mark, or laboratory evidence of hypoperfusion (elevated base deficit or serum lactate) suggest visceral injury.
 - Nonoperative management of certain radiologically well-characterized injuries of solid organs—namely the spleen, the liver, and the pancreas—in the hemodynamically stable elderly patient is becoming increasingly accepted as evidence of the success this approach accumulates.
- Serious orthopedic injuries frequently befall older victims of polytrauma
 - Decrease in bone mineral density (BMD) with age older than about 30 years heightens the risk of fracture in general.
 - Observed in varying degrees in both genders and all ethnicities
 - But particularly severe in postmenopausal white women
 - Pelvic fracture in the aged is associated with a greater likelihood of significant blood volume transfusion and mortality ($p < 0.005$)
 - Open pelvic fracture often has substantial associated bleeding, which is seldom treatable, with the exception of arterial bleeding, in any way other than with early stabilization, aggressive transfusion, and correction of coagulopathy
 - Arterial bleeding from lacerated pelvic vessels warrants embolization
 - More typical scenario, however, is that of diffuse venous oozing, which may render patient hemodynamically unstable.
 - Requiring large-volume transfusion of blood products as a temporizing measure until anatomic stabilization can be achieved
 - Hemodynamic consequences of large-volume transfusion and frequent septic complications can drive the mortality in both younger and older adults to nearly 80%.
 - Long-bone fractures warrant early immobilization and stabilization to minimize ongoing hemorrhage and generation of fat emboli.
 - Such fixation improves mortality significantly
 - Optimal timing of surgical stabilization of these quite morbid fractures is a complex issue to resolve when they occur in the larger setting of the patient with severe head, chest, or abdominal injuries.
 - Prolonged immobilization with such a fracture prior to stabilization:
 - Forgoes the profound respiratory benefits of early mobilization
 - Exposing the patient to extended intubation, pulmonary thromboembolus, and infection
- In 38,707 elderly trauma patients with a mean ISS of 11.7 ± 0.05 (SEM)
 - 10.3% died in hospital
 - 52.2% of the survivors went home
 - Percentage of patients returning home after serious traumatic injuries, many requiring prolonged intensive care, varied considerably with age:
 - 66.7% of those 65 to 74 years
 - 30.5% of those 85 years of age or older
- With aggressive rehabilitation, improvement in function and independence can continue for substantial periods of time after discharge, including in those who have suffered TBI

OUTCOME AFTER A CRITICAL ILLNESS IN THE GERIATRIC POPULATION

- Most people die after the age of 65 years
 - Life expectancy is greater at any given age now than it was even 15 years ago
 - Geriatric patients represent between 25% and 50% of all ICU admissions
 - In 2000, ICU costs represented 13.3% of hospital costs
 - 4.2% of health care expenditures
 - 0.56% of the U.S. gross domestic product
 - Family member's "do *everything* for Granddad" dictum is familiar
 - Often represents an unrealistic appraisal of the possible benefit from care
 - Complicated technology and meticulous attention to detail that characterize ICU not the basis for "magical"
 - Nonetheless, death can often skillfully be forestalled with polished and professional ICU care to such a degree that:
 - It may occur immediately after a deescalation of such care
 - Later on the general ward, in a step-down unit or rehabilitation facility
 - After returning home (either early or late) to a life with varying similarity to that prior to the original serious medical occurrence
 - Meaningful discussions with elderly patients and their families about the ICU *must* include accurate outcome data.

DRUG DOSING IN THE ELDERLY

- *Pharmacokinetics*, the study of the action of a drug in the body over a period of time, changes with age.

TABLE 67.1

AGE-RELATED CHANGES RELEVANT TO DRUG PHARMACOLOGY

Pharmacologic process	Physiologic change	Clinical significance
Absorption	Decreased absorptive surface Decreased splanchnic blood flow Increased gastric pH Altered gastrointestinal motility	Little change in absorption with age
Distribution	Decreased total body water Decreased lean body mass Increased body fat Decreased serum albumin Altered protein binding	Higher concentration of drugs that distribute in body fluids; increased distribution and often prolonged elimination half-life of fat-soluble drugs Increased free fraction in plasma of some highly protein-bound acidic drugs
Metabolism	Reduced hepatic mass Reduced hepatic blood flow Decreased phase I metabolism	Often decreased first-pass metabolism and decreased rate of biotransformation of some drugs
Elimination	Reduced renal plasma flow Reduced glomerular filtration rate Decreased tubular secretion function	Decreased renal elimination of drugs and metabolites; marked interindividual variation
Tissue sensitivity	Alterations in receptor number Alterations in receptor affinity Alterations in second-messenger function Alteration in cellular and nuclear responses	Patients are more sensitive or less sensitive to an agent

- Physiologic changes accompanying aging affect the pharmacologic processes of absorption, distribution, metabolism, and excretion (Table 67.1)
- Effects of these age-related changes are variable and difficult to predict
- Absorption of drugs, which occurs mainly by passive diffusion, changes little with advancing age.
- In elderly, relative increase in body fat and decrease in lean body mass alter drug distribution so that fat-soluble drugs are distributed more widely and water-soluble drugs less so (Table 67.2)
- Important pharmacokinetic change occurring in elderly is reduced renal drug elimination
 - Results from age-related decline in both GFR and tubular function
 - Drugs that depend on glomerular function (e.g., gentamicin) and/or on tubular secretion (e.g., penicillin) for elimination both exhibit reduced excretion in elderly

- Average creatinine clearance declines by 50% from age 25 to age 85 despite a serum creatinine level that remains unchanged at approximately 1.0 mg/dL
 - Two clinically relevant consequences:
 - Half-lives of renally excreted drugs are prolonged
 - Serum levels of these drugs are increased
- The biochemical and physiologic effects of drugs and their mechanisms of action—*pharmacodynamics*—and the effects of aging are not clearly known.
- Elderly seem to be more sensitive to the sedative effects of given blood levels of benzodiazepine drugs (e.g., diazepam).
 - But less sensitive to the effects of drugs mediated by β -adrenergic receptors (e.g., isoproterenol, propranolol)
 - An age-related decline in hormone receptor affinity or number (e.g., in β -adrenergic receptors) is suspected, but definitive data demonstrating such an alteration are sparse.
 - Other possible explanations offered are alterations in second-messenger function and alterations in cellular and nuclear responses.

TABLE 67.2

VOLUME OF DISTRIBUTION OF COMMONLY PRESCRIBED DRUGS

Increased volume	Decreased volume ^a
Acetaminophen	Cimetidine
Chlordiazepoxide	Digoxin
Diazepam	Ethanol
Oxazepam	Gentamicin
Prazosin	Meperidine
Salicylates	Phenytoin
Thiopental	Quinine
Tolbutamide	Theophylline

^aIf the volume of distribution is decreased, drug levels tend to be higher.

SPECIAL PROBLEMS OF THE ELDERLY

- Over one-half of all ICU admissions are patients older than 65 years of age
 - They account for almost 60% of all ICU days
 - Many of these older patients' final days before death are spent in the ICU
 - 40% of Medicare patients who die are admitted to an ICU during their terminal illnesses
 - Accounting for 25% of all Medicare expenditures
 - There is a 6-month post-ICU survival of 53% in 116 patients over 70 years of age who had required mechanical ventilation for more than 24 hours.
 - Compared to their younger counterparts, octogenarians have a higher ICU mortality rate (10% vs. 6%, $p < 0.01$)

and higher discharge rate to a subacute care facility (35% vs. 18%, $p < 0.01$).

- Those discharged to subacute care facility had a higher mortality rate compared to those discharged home (31% vs. 17%).
- Preadmission comorbidities and severity of illness independent predictors of discharge to subacute care facility:
 - Degenerative brain disease
 - Cerebrovascular disease
 - Chronic heart failure
 - Chronic pulmonary disease
 - Diabetes mellitus
- Malnutrition more commonly associated with care dependency

Neurologic Disorders

Delirium

- **Background and Risk Factors.** Delirium is an acute mental disorder common among elderly patients
 - 14% to 56% of the hospitalized elderly develop delirium
 - This increases 6-month mortality rate among these patients to 10% to 26%
 - Recognition difficult, only 25% of cases diagnosed using standard screening tools
 - Delirium-associated morbidity:
 - Complicates the hospitalization of 2.3 million older people annually
 - Adding 17.5 million inpatient days
 - \$4 billion to Medicare expenditures to cover:
 - Increased lengths of stay
 - Greater need for postdischarge institutionalization, rehabilitation, and home care
 - Older adults with multiple comorbidities, particularly preexisting cognitive deficits, are predisposed
 - Prevalence rate surpassing 50% during intensive care
- **Pathophysiology.** Specific mechanisms are not well understood
 - Can be viewed as a final pathway of various causes of acute brain dysfunction, including:
 - Direct brain injury from trauma
 - Cerebrovascular disease, or central nervous system (CNS) infection
 - Systemic disturbances such as hypoxemia, hypotension, renal failure, hepatic failure, sepsis, and endocrine dysfunction
 - Effects of toxic or pharmacologic agents such as anticholinergics, narcotics, and sedative hypnotics
 - Consequences of withdrawal of substances to which the brain has developed tolerance (e.g., alcohol or benzodiazepines)
 - Current theory proposes alteration of CNS neurotransmitter levels and metabolism by age, medication, or illness, particularly:
 - Acetylcholine and dopamine pathways
 - Serotonin
 - γ -aminobutyric acid
 - Histamine
 - Glutamine
 - Norepinephrine
- **Diagnosis.** Criteria defining delirium are detailed in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) of the American Psychiatric Association, specifically:
 - A disturbance of consciousness with impaired ability to focus, sustain, or shift attention
 - A change in cognitive function (in terms of memory, orientation, and language) or a perceptual disturbance that is not better explained by preexisting or evolving dementia
 - Disturbance development over a short period of time in hours or days, fluctuating through the day
 - History, physical examination, or laboratory data suggestive of the abnormalities caused by a general medical condition
 - Additional features include:
 - Alteration of sleep–awake cycle and psychomotor activities
 - Patterns of psychomotor symptoms are termed hyperactive and hypoactive
 - *Hyperactive* patients are agitated and combative, with loud, inappropriately boisterous outbursts and motor activity that can be harmful to self or a caregiver.
 - *Hypoactive* alternate between calm, appropriate behavior and a minimally interactive, withdrawn state, making this variant easy to overlook.
 - Delirium may erroneously be attributed to such conditions as dementia or depression (these three may coexist) or simply not be recognized, delaying diagnosis.
 - Delays may be explained by:
 - Fluctuating nature of signs and symptoms
 - Inadequate or insufficiently detailed scheduled neurologic and cognitive assessments of patients at risk for delirium
 - Avoidance of interactions with patients displaying altered mental status
 - Misperception of mental status changes “expected” in critically ill patients
 - Altered mental status in any patient suggests delirium
 - An organized approach to its investigation focusing on known risk factors is paramount to avoid overlooking the condition
 - Of particular interest are alterations of mental status temporally related to surgical procedure
 - Specifically delirium developing within the immediate (minutes to days) postoperative time
 - More indolent neurocognitive decline that may appear days to weeks to months later, termed *postoperative cognitive dysfunction* (POCD)
 - Uniqueness of these conditions lies in their association with the postoperative period
 - Emergence delirium, the transitory restlessness and disorientation often apparent in the postanesthesia care unit or an ICU that receives patients directly from the operating room, often resolves within a brief period of time.
 - More worrisome is interval delirium, appearing 2 to 7 days after operation
 - Patient manifesting disorientation and agitation and being at risk for suboptimal outcome by virtue of its appearance
 - Risk factors for postoperative delirium are additive to those menacing the nonoperated elderly patient, including:
 - Perioperative hypoxemia and hypotension

- Exposure to medications that are used in the operating room—anticholinergics such as atropine, volatile inhalational anesthetics, neuromuscular blocking agents, and potent opioids
- High-volume blood transfusion and rapid fluid shifts associated with surgery
- Procedures using cardiopulmonary bypass raise the possibility of microscopic atheromatous or air emboli as contributors
- Incidence of postoperative delirium ranges from 0% to 74%, varying with age group, type of surgery, variability of diagnostic criteria, and preoperative and postoperative cognitive status
- Most cardiac surgery patients suffer various concurrent confounding medical conditions that make the specific effects solely of cardiac surgery on subsequent mental status difficult to isolate
 - Attention to statistical and study control issues allows identification of a substantial incidence (53%) of coronary artery bypass graft (CABG) patients (average age, 60.9 years \pm 10.6 years) showing cognitive deterioration consistent with POCD at time of discharge, and 42% at 5 years
 - Age being a univariate predictor of decline
- Specific cause of POCD is obscure.
 - Suggested causes those noted above as well as more abstract considerations such as brain inflammation, genetic factors, cerebral edema, and blood–brain barrier dysfunction
- Symptomatic treatment uses both pharmacologic and non-pharmacologic strategies:
 - Use of repeated reorientation, cognitive stimulating activities, promotion of adequate sleep on a normal sleep–wake cycle, physical therapy and mobilization
 - Early removal of catheters and physical restraints
 - Provision of eyeglasses and hearing aids
 - Judicious use of medications particularly targeted at calming agitation
 - All neuroactive medications such as benzodiazepines, opioids, or those with anticholinergic effects that are not absolutely fundamental to the patient's treatment plan and improvement should be discontinued.
 - The butyrophenone haloperidol is often used in the management of delirium-induced agitation, having few active metabolites and minimal anticholinergic, sedative, and hypotensive effects.
 - Retrospective analysis suggested haloperidol use was independently associated with lower mortality in 989 critically ill patients.
 - For POCD, there is no management other than prevention.

Stroke

- **Incidence and Risk Factors.** Stroke is the third leading cause of death and the *leading cause of disability* in the elderly.
 - About 500,000 individuals in this age group suffer strokes annually in the United States.
 - Corresponding to one event every 45 seconds
 - Leads to one death every 3 minutes
 - Among those 55 years and older, the incidence of stroke doubles with each additional decade of life.
 - Despite a decline in the United States, Canada, and Western Europe through the later part of the 20th century to the present, attributable to improved management of modifiable risk factors
 - Hypertension is by far the most powerful
 - Aggressive blood pressure control reduces risk of stroke by 40%
 - Coronary atherosclerosis, left ventricular hypertrophy, and atrial fibrillation contribute to stroke risk
 - Diabetes mellitus may increase likelihood of stroke by a factor of 2 to 4
 - Tight glucose control significantly reduces this risk and may postpone such vascular complications as retinopathy and nephropathy.
 - Modifiable factors also include cigarette smoking, hyperlipidemia, and excessive alcohol consumption.
- **Location.** Approximately two-thirds of ischemic strokes occur in middle cerebral artery (MCA) distribution.
 - Findings include contralateral hemiplegia and hemianesthesia
 - Proximal MCA occlusion produces profound symptoms: homonymous hemianopsia or deviation of the head and eyes toward the side of the lesion
 - Involvement of dominant MCA distribution may cause aphasia, expressive or receptive
 - Dominant hemisphere MCA lesions may induce depression in the elderly.
 - Those in the nondominant hemisphere produce visuospatial deficits, unilateral neglect, and emotional lability that can mimic depression, sometimes delaying correct diagnosis.
 - Anterior cerebral artery (ACA) stroke is least common, accounting for about 2% of ischemic infarcts.
 - Most profoundly affects the contralateral leg and foot, generally with lesser impact on the arm and little involvement of the face.
 - Very proximal ACA occlusion, however, may affect the entire contralateral side
 - Abundant collateral flow in ACA territory yields various symptoms associated with anterior circulation stroke
 - May see frontal lobe features such as emotional lability, mood impairment, personality changes, and intellectual deficits
 - Aphasia uncommon
 - Stroke-related paraplegia and incontinence may leave the elderly victim wheelchair bound and unable to control critical body functions, greatly complicating rehabilitation and subsequent independent living.
 - Posterior cerebral artery (PCA) strokes manifest a diversity of findings due to the variability of anatomic origin
 - Partial or complete origin from the basilar artery or internal carotid arteries
 - Neurologic consequences of PCA stroke include:
 - Contralateral hemianesthesia and hemianopsia with sparing of central macular vision
 - Difficulty with reading and calculations
 - Hemiballismus from subthalamic involvement
 - With vertebrobasilar atherothrombotic disease, cerebellar dysfunction predominates
 - Common symptoms include vomiting, dizziness, ataxia, nystagmus, and double vision

- Vertigo can be profound, causing an already tenuously balanced elderly person to sustain a fatal fall
- Other symptoms include weakness of the face and the opposite side of the body, with dysarthria or dysphasia
- Facial numbness may occur
- Brainstem involvement may be revealed by altered mental status or quadriplegia
- Lacunar strokes—small occlusions of the penetrating and subcortical arteries—tend to occur in the basal ganglia, internal capsule, thalamus, or pons.
- Depending on specific sites of lesions, a wide variety of presentation may occur, including:
 - Pure motor or sensory findings
 - Symptoms that appear parkinsonian
 - A mixture of presenting abnormalities
- **Cause.** Strokes are either ischemic or hemorrhagic
 - Ischemic, about 85% of the total, involve occlusion of the cerebral vessel by embolus or thrombosis
 - Remaining 15% include hemorrhage into the brain parenchyma or its surrounding spaces
 - Rapid identification of the specific cause of the stroke is fundamental to its management, since modalities of treatment vary with cause
 - Embolic phenomena most often originate from the heart, commonly associated with atrial fibrillation
 - Atherosclerotic disease of the aortic arch is emerging as an increasingly important and recognized risk factor for recurrent stroke when the wall thickness exceeds 4 mm.
 - Atheroma-associated clot formation may produce neurologic syndromes known as *thrombotic stroke*
 - Subintimal vascular disease is the ultimate inciting event, inducing arterial narrowing with ulcerated plaque formation in areas of more turbulent flow, such as the carotid bifurcation, leading ultimately to symptoms ranging from a temporary deficit (i.e., a transient ischemic attack, or TIA) to complete arterial occlusion caused by clot formation
- **Time Course.** Stroke phases are termed acute, subacute, and chronic, each with its unique needs and goals of care. Time spans are generally said to be:
 - *Acute phase of stroke (admission to 48 hours):* Management of the acute phase involves, first and foremost, ensuring airway and hemodynamic stability
 - Thereafter, the goals of care are:
 - Identification of the stroke as ischemic or hemorrhagic
 - Initiation of thrombolytic therapy when indicated
 - Recognition and therapy of medical or neurologic complications
 - First goal is most easily achieved by obtaining a noncontrast-enhanced CT scan of the brain as quickly as possible when stroke is suspected.
 - Hemorrhage is usually obvious on this scan, although early in the course of ischemic stroke there may be no visible abnormality.
 - May reveal one of the many mimics of stroke: subarachnoid hemorrhage, subdural hematoma, neoplasm, or hydrocephalus
 - Contrast enhancement may improve yield if tumor or infection is likely.
 - If decided that ischemic stroke is present, the risks and benefits of thrombolytic therapy must be weighed:
 - Current recommendations for management include initiation of intravenous thrombolytic therapy with recombinant tissue plasminogen activator (rt-PA) within 180 minutes of onset of stroke, in the absence of contraindications
 - Intra-arterial thrombolysis an option for those with occlusion of MCA
 - Use of rt-PA appears to improve outcome from stroke at 3 months
- **Subacute and Chronic Phases:**
 - Acute events and aggressive treatment often stabilize within 48 hours
 - Close attention to complications or neurologic decompensation warranted
 - Early extubation advisable
 - Meticulous attention to the return of intact airway reflexes and sufficient recovery of mental status
 - Otherwise, tracheostomy for airway protection allows withdrawal of sedation, early mobilization, and more robust participation in physical and occupational therapy
 - Common companions of those with compromised mental status:
 - Pulmonary aspiration
 - Skin breakdown
 - Infections
 - Limitation of extremity range of movement
 - Ameliorated by aggressive rehabilitation efforts
 - Early nutritional support via feeding tube must be initiated early
 - General goals of rehabilitation include restoration of motor and sensory function and strengthening of intact functions to facilitate compensation for residual deficits.
 - Stroke recurrence rate of 30% within 10 years warrants continued attention to chronic medical conditions.
 - Framingham study data documents survival in stroke victims of 50% in 5 years
 - Preservation of functional gains, avoidance of complications, and aggressive management of contributing comorbid conditions may well forestall the decline that often follows a stroke in an elderly patient

Sleep Disorders

- **Background.** Insomnia afflicts nearly 50% of older adults
 - Genders are generally equally affected, but sleeplessness in men predominates after 85 years
 - Prevalence increases in the elderly with the number of coincident medical conditions
 - Common sleep complaints among the community-dwelling elderly are:
 - Difficulty in initiation of sleep
 - Nighttime and early morning awakening
 - Sequelae of insomnia include:
 - Physical and mental fatigue
 - Anxiety
 - Irritability
 - All of which worsen as bedtime approaches and personal worries reemerge without the protective diversion of normal daytime activities
 - Chronic dysfunctional sleep induces a state of endless fatigue, affecting memory and concentration

- Elderly are particularly affected, with steepened cognitive decline and risk of falls, with associated morbidity and mortality
 - Hospitalization amplifies the morbidity of sleep disturbances
 - ICU admission likely subverts any semblance of a normal sleep pattern
 - Sedation to facilitate mechanical ventilation subdues consciousness but disrupts normal variation in sleep stages, preventing rest
 - Circadian rhythms are disrupted, with dyssynchrony with anticipated light/dark time cycles and adequate daily morning exposure to sufficient bright light
 - Many elderly patients become disoriented at night, exhausted and confused by constant alarms, noises, dressing changes, unscheduled diagnostic procedures, and the impact of acute severe illness, producing delirium in nearly two-thirds of elderly ICU patients.
 - Dementia contributes to this phenomenon.
- **Identification and Management of Sleep Disorders.** Sleep–wake cycle is regulated by a complex neurochemical interaction subserved by the brainstem, hypothalamus, pons, and preoptic areas of brain.
 - Aberrations of sleep patterns produce dysfunctional sleep
 - Normal sleep architecture displays three segments:
 - Light sleep (stages one and two)
 - Deep (delta or slow wave) sleep (stages three and four)
 - The most restorative segment
 - Rapid eye movement, or REM, sleep (stages one and four)
 - In nonelderly adults, typical cycle time between REM and non-REM sleep is 90 to 120 minutes.
 - Advanced age alters sleep by shortening sleep latency and total sleep time, preserving REM sleep, decreasing the delta segment, and advancing the natural onset of sleepiness to an earlier time in the evening.
 - Nocturnal sleep fragmentation worsens
 - Daytime somnolence and frequent napping being commonplace, sometimes causing reversal of the sleep–wake cycle
 - Acute insomnia in the geriatric patient may be precipitated by a host of issues, including the critical illness itself.
 - Effective treatment obviously requires an accurate diagnosis.
 - All possible accommodations should be made to minimize interruption of the older patient's restful nighttime sleep periods.
 - Minimizing noise, procedures, and cycling of lights on and off
 - Daily exposure to bright sunlight through nearby windows is beneficial
 - Various medications are available but each may provoke delirium in elderly patients

SECTION XI ■ INFECTIOUS DISEASE

CHAPTER 68 ■ UNIVERSAL PRECAUTIONS: PROTECTING THE PRACTITIONER

PRECAUTIONS

- There are several types of precautions used in patient care settings that have been described
- Implementation of standard precautions (previously termed *universal*) does not negate the need for further specialized infection control precautions if necessary, such as droplet precautions for influenza, airborne isolation for pulmonary tuberculosis, or contact isolation for methicillin-resistant *Staphylococcus aureus* (MRSA)
- There are four types of precautions recommended in the Centers for Disease Control and Prevention (CDC) guidelines (Table 68.1):
 - Standard (previously termed *universal*)
 - Contact
 - Droplet
 - Airborne

Standard Precautions

- Those that are applied to anyone whom the practitioner comes into contact, regardless of diagnosis
- Include handwashing before and after contact with every patient, and between anatomic sites on same patients
- Additional precautions may be required to care for patients who do not have a diagnosis requiring other specific categories of isolation
 - Blood and body fluids (including secretions and excretions, excluding sweat)
 - Broken skin
 - Mucous membranes

TABLE 68.1

RECOMMENDED ISOLATION PRECAUTIONS FOR SELECTED PATHOGENS

Organism	Recommended precaution/isolation
Methicillin-resistant <i>Staphylococcus aureus</i>	Contact
Vancomycin-resistant enterococcus	Contact
<i>Clostridium difficile</i>	Contact
Multidrug-resistant Gram-negative infections	Consider contact
Varicella-zoster virus	Contact/airborne
Influenza	Droplet
Tuberculosis	Airborne
<i>Neisseria meningitidis</i>	Droplet

- Health care workers (HCWs) may also require use of
 - Gloves
 - Mask
 - Eye protection
 - Face shield
 - Gowning
- Other considerations include special handling of patient care equipment, including sharps and other instruments, and environmental control with correct disposal and cleaning of linen and other contaminated items

Handwashing

- Hands must be washed before and after every patient contact
- Even where there has been no visual contamination with blood, body fluids, secretions, excretions, and contaminated items
- Hands must be washed immediately after gloves are removed if they were worn
- Washing of hands should be done whenever indicated to avoid transfer of micro-organisms to other patients and the environment
 - As after contact with intravenous (IV) tubing or a monitor even when there has been no direct patient contact
- Plain, nonantimicrobial soap could be used for routine handwashing
 - Antimicrobial soap or a waterless antiseptic agent can be used for specific circumstances
- Alcohol-based hand sanitizers have been shown to be more convenient, faster, and more efficient than handwashing

Gloves

- Clean, nonsterile gloves are appropriate when contact with blood, body fluids, secretions, excretions, and contaminated items is expected.
- Clean gloves should be used if expected contact with broken skin or mucous membranes
